Satellites help confer a decisive advantage in terms of combat timing, battle space awareness, operating tempo, synchronization, maneuverability, and the application of

firepower. In Table 2 a summary of possible use of satellites for military forces is presented.

The growth of the presence of military forces worldwide for peace keeping and peace enforcement missions has increased the use of commercial satellites for military applications. Most of civilian fleets have been used, such as Intelsat, Eutelsat, Inmarsat, Globalstar, Iridium, and others (see Figure 5).

The satellite systems have become the typical demonstration of dual-use systems. Technically, as is frequently noted, there is no clear difference between civil and military satellite systems. Orbital imagers and communications satellites are prime examples of dual-use technologies. For example, communication satellites can carry either military or civilian traffic, and navigation satellites are used both by the military and civilian communities. From a service point of view, military communications satellites are including a bunch of applications (see Figure 6). This approach tends to maximize the availability of new services and the use of all the available space bandwidth capability.

Figure 5: Milsat transportable station operating with commercial satellite. (Courtesy of Telespazio, Italy.)

Figure 6: Milsat new service scenario.

Traditionally, military satellite systems have dedicated frequency bands and present better performance in terms of communications security, robustness, and availability performance.

Communications and Transmission Security

Military communication systems present the capability of providing secure, encrypted, and antijam-protected communications to prevent an external enemy from intercepting and interrupting vital communications in time of crisis. Encryption is based on private key schemes; the link protection is obtained with a number of techniques:

- direct sequence CDMA (code division multiple access);
- frequency-hopping CDMA;
- power control, forward correcting codes, and user bandwidth optimization; and
- antenna beam nulling antijam capability.

As introduced previously, antenna nulling capability is probably the most powerful technique to counteract one or multiple jammers and minimize the antenna gain in the directions of the jammer sources. This nulling capability is obtained via a phased array system capable of minimizing a number of jammers according to its freedom degree number (based on the number of elements of the phased array).

Navigation and Remote Sensing Satellites

In addition to communications, satellites are used for navigation and remote sensing. These applications are a fundamental complement to communications and they are typical dual-use services.

The best known navigation system is the GPS (briefly introduced previously), which supplies localization information with two different accuracies (the *n* code and the *p* code, reserved to military applications). The constellation is formed by 24 satellites orbiting at 20,000 km from

the Earth surface on four different orbits (six satellites per orbit), inclined 55° on the equatorial plane. Localization is obtained using at least four satellites for triangulation. Navigation systems integrated with communications (typically via satellites) are essential for security, safety, and rescue in the following scenarios:

- airborne navigation systems,
- personal computers and other portable devices,
- vehicle and asset tracking systems,
- secure timing and synchronization systems, and
- smart munitions.

Remote sensing satellites are low orbiting (typical sun synchronous) and are capable of collecting images of the Earth surface either via passive sensors (optical, infrared, panchromatic) or active microwave sensors (SAR, scatterometers, radar altimeters).

These satellites produce images at low, medium, and high resolution (from a few meters to some tenths of centimeters), which are essential for battlefield analysis, early warning applications, border control, international agreement monitoring, disaster forecast, mapping, etc. Figure 7 shows the newest SAR system announced for early 2006: Cosmo skymed and its three observation modes.

CONCLUSIONS

Security represents a very critical and real important issue from the different points of view, spanning from information protection to human life security. To achieve the needed level of security, telecommunication systems surely play a crucial role and the satellite component can increase the capability thanks to its features. In fact, we believe that only through a strong connection among all the components of the GII an adequate level of security can be provided. In this chapter, the main contributions that the satellite can provide to overall security have been highlighted along with the main limitations. The use of

Figure 7: Active remote sensing (SAR) image acquisition modes. (Courtesy of Telespazio, Italy.)

satellites for civilian telecommunications and for military purposes has been mainly addressed. Also the use for localization and navigation and for Earth observation has been briefly highlighted.

GLOSSARY

Broadcast A connection allowing information transfer from one to everybody.

Conditional access A procedure to allow only a restricted subset of users to access information.

Coverage Area The area on the Earth's surface over which the signal-to-noise ratio in both up- and down-link for a user located inside is greater than the required ratio.

Forward Link The link from the hub station to the user terminal.

Gateway The earth station of a satellite system that ensures connection to terrestrial networks.

Global Information Infrastructure The concept of a unique telecommunication infrastructure at planetary level to provide services everywhere to everyone.

Multicast A connection allowing information transfer from one to many.

Multiple Access A regulated exploitation of a common resource by different users distributed at different locations.

Omnidirectional The characteristic of an antenna capable of transmitting and receiving electromagnetic power to and from any direction with the same gain.

Reliability The capability for equipment and systems to provide service without interruption from failure.

Return Link The link from the user terminal to the hub station.

Unicast A connection allowing information transfer from one to one.

INTRODUCTION

“Broadband” Internet Access: Definition and Technologies

There is no generally accepted broadband definition. The U.S. Federal Communications Commission (FCC) defines “first-generation broadband” to mean “advanced telecommunications capability” and “advanced service” that differs from dial-up Internet access in several important ways (Powell et al., 2004):

- First, broadband Internet access provides high-speed connection with more than 200 Kb/s customer-to-provider (upstream) and provider-to-customer (downstream) transmission speeds.
- Second, unlike dial-up access, broadband provides always-on connections so that users can receive as well as send data without having to reconnect to the network.
- Third, broadband provides low latency.

Today, most broadband providers are offering services with download rates well in excess of 200 Kb/s and, given the asymmetric use of most residential subscribers, somewhat slower upload rates. Note that the International Telecommunication Union (ITU) uses the term broadband for “services with rates of more than 2,048 Kb/s” (ITU Internet Reports, 2003).

Broadband Internet access for residential users (i.e., subscribers or customers) is provided by a variety of “last mile” technologies. Depending on population density, geographic situation, or techno-political issues, one or several from the following technologies are used:

- **Cable technologies** give access to high-speed data services over coaxial cables that are part of community antenna television (CATV) operators’ hybrid fiber-coaxial (HFC) infrastructures. The so-called data-over-

cable (DOC) systems cover the whole CATV network area and offer typical download and upload speeds of up to 6 Mb/s and up to several hundred Kb/s, respectively (Dutta, 2001).

- **Copper technologies** provide for high-speed data services on the telephone operators’ twisted-pair cable infrastructures. There are multiple variants of these so-called digital subscriber line (DSL) technologies. The most common variant of DSL is asymmetric digital subscriber line (ADSL), which has approximately 5.5 km maximum cable length and download and upload speeds of up to 3 Mb/s and up to 768 Kb/s, respectively (Starr, 2003; Bascher et al., 2004).
- **Fiber technologies** ensure ultra-high-speed services on specially installed fiber optic cable infrastructures. Fiber-to-the-home (FTTH) installations deliver up to 500 Mb/s data services and up to 870 MHz high-definition television services via fiber cables that terminate at the subscriber homes. Fiber-to-the-curb (FTTC) facilities terminate in the vicinity of the homes.
- **Unlicensed wireless technologies** provide up to 3 Mb/s for non-line-of-sight applications in the 902–928 MHz band and up to 54 Mb/s wireless fidelity (Wi-Fi), that is, wireless LAN (WLAN) in the 2.4 GHz and 5 GHz industrial, scientific, and medical (ISM) bands. Wi-Fi using the Institute of Electrical and Electronics Engineers (IEEE) 802.11 series standards became very common for Internet access via commercial and noncommercial hotspots. Another unlicensed wireless technology in line-of-sight areas is the worldwide interoperability for microwave access (WiMax), based on IEEE 802.16 series standards with up to 75 Mb/s speeds and covering up to 20 km in distance.
- **Licensed wireless technologies** allow for Internet access with broadband mobile services that are also referred to as third-generation (3G) mobile services.

Table 1 Broadband Transmission Speeds and Number of Homes per Distribution Point

Cable Infrastructure, Technology	Downstream Rate	Upstream Rate	Maximum Distance	Homes per Distribution Point
Existing coaxial CATV cables with fiber backbone (HFC), shared cable (bus), DOC	45 Mb/s	1.5 Mb/s	Up to several 10 km	1,000–2,000
One existing twisted pair (star), ADSL	6 Mb/s	640 Kb/s	5.5 km	1,000–3,000
Two (existing) twisted pairs (star), HDSL	2 Mb/s	2 Mb/s	7 km	NA
One existing twisted pair for the last 100 to 300 m (star), VDSL	50 Mb/s	20 Mb/s	300 m	100
	25 Mb/s	5 Mb/s	1 km	100
	12 Mb/s	1.5 Mb/s	1.5 km	100
Existing power lines, PLC	27 Mb/s	18 Mb/s	NA	1,000
New fiber installation and existing twisted pair for the last up to 100 m, FTTC/VDSL	25–50 Mb/s	25–50 Mb/s	100 m	10–50
New fiber installation to the home, FTTH	155 Mb/s	155 Mb/s	10 km	10–200

The commercially available technologies are wideband CDMA (WCDMA) and Universal Mobile Telecommunications System (UMTS), which allow for maximum downstream data rates of up to 2 Mb/s. The upstream speeds are typically around 300 Kb/s and it should be noted that the experienced delays may be significant (more than 100 ms round-trip).

- **Power line communication** (power line Internet) uses existing electrical power lines for symmetric Internet access at up to 45 Mb/s (Abe (2004)). In the United States, it is called broadband over power lines (BPL); the Europeans use the term power line communication (PLC). The industrial “HomePlug” alliance was formed to standardize data networking via electrical wiring inside the premises (i.e., on the low voltage [230 V] level) at up to 14 Mb/s. HomePlug has now expanded its scope to include power line communication (Jones, 2004).

Currently, the most widely used technologies for broadband Internet access are ADSL and DOC. The ADSL connection generally transports voice and data services, and the DOC connection focuses on video and data services. Both ADSL ISPs and DOC ISPs are now moving towards “triple-play” service: delivering voice, data, and video. See Table 1 for comparisons of transmission speeds.

Broadband Market Situation

Broadband Internet access with upload data rates between 64 Kb/s and 800 Kb/s and download data rates between 128 Kb/s and 3 Mb/s has become affordable for many residential users. However, there are still many more private Internet-capable personal computers (PCs) connected to narrowband dial-up networks than to broadband networks (in 2003, only 14% of the U.S., 4% of the European, and 6.4% of the Swiss home PCs had a broadband connection). Nevertheless, there are around 100 million worldwide broadband subscribers today. The largest broadband markets are United States with 28 million, Europe with 23 million, Japan with 14 million, China with

12 million, and Korea with 11 million broadband subscribers (data from 2003; ITU Internet Reports, 2003).

DSL and DOC are by far the most important broadband technologies. The market share of the broadband technologies in a region or country is influenced by geographical, historical, and techno-political issues. DSL is the dominant broadband access technology in Asia and in most European countries; DOC is more widely used in the United States, Switzerland, the Netherlands, and Austria. See Figure 1.

In South Korea, cheap DSL access is available in 85% of the homes and unlimited broadband access costs \$25/month for 2 Mb/s and around \$34 a month for 8 Mb/s (flat rate). Japan uses mainly DSL but there are also FTTH systems (Saito et al., 2003).

In Germany, Deutsche Telekom, one of Europe’s largest DSL broadband operators, has prevented large-scale upgrades of cable networks. German DSL ISPs offer a variety of tariff models (volume-based, time/volume limit-based, and flat rate; Stuart & Bhalla, 2003).

The U.K. and Swiss DSL/DOC broadband market is already fairly competitive. In Switzerland, where CATV traditionally has a very high penetration and where DOC networks are not controlled by the telecom operators, roughly 40% of connections are DOC and 60% are DSL (OFCOM, 2003). The cost for the widely used 100 Kb/s upstream and 600 Kb/s downstream ADSL service is about \$35 per month (flat rate; Paltridge & Matsui, 2004).

Broadband Threats and Vulnerabilities

All Internet service subscribers should be aware of threats and vulnerabilities. Today, most people understand that their data traffic could be read or modified, that is, there is no guarantee of confidentiality and/or integrity of transmitted data (see Figure 2) because of various forms of wiretapping, sniffing, or traffic rerouting. Not everybody is aware of source or destination spoofing threats, which compromise the authenticity of the sender or receiver (see Figure 2). Such attacks (e.g., man-in-the-middle and

Figure 1: Broadband technology market share in various countries. Source: Powell et al., 2004.

phishing attacks) may result in identity theft and even financial loss. However, these attacks are similar in broadband and narrowband environments.

Computers from residential users with broadband connections are much more attractive for attackers than computers with narrowband connections because of the always-on connection and the high data rate. The always-on connection gives an attacker more opportunity to access a subscriber system and to test for vulnerabilities (see Figure 2). The high data rate makes broadband systems very attractive targets for the installation of all sorts of malicious mobile code. Most residential users are not aware of such threats and vulnerabilities. The exposure of their private data might be their own business. However, if their computer is hijacked by other people, this might also

severely affect other Internet users. Today, the millions of vulnerable (unpatched) residential broadband computers are a dangerous source for distributed denial of service (DDOS) attacks (Shannon & Moore, 2003) and for worm and spam distribution (i.e., mass mailings). A mass mailer program self-replicates by sending itself out via e-mail. Typically, the program obtains e-mail addresses by searching in files on the system or responding to messages found in the e-mail client inbox. Mass mailers may be used to send spam mails. It is said that spam network services, which can be bought on the Internet underground, account for more than a third of all junk e-mails.

Many penetrated residential broadband computers have become a place for attackers to hide data and to anonymously distribute data, for example, copyright

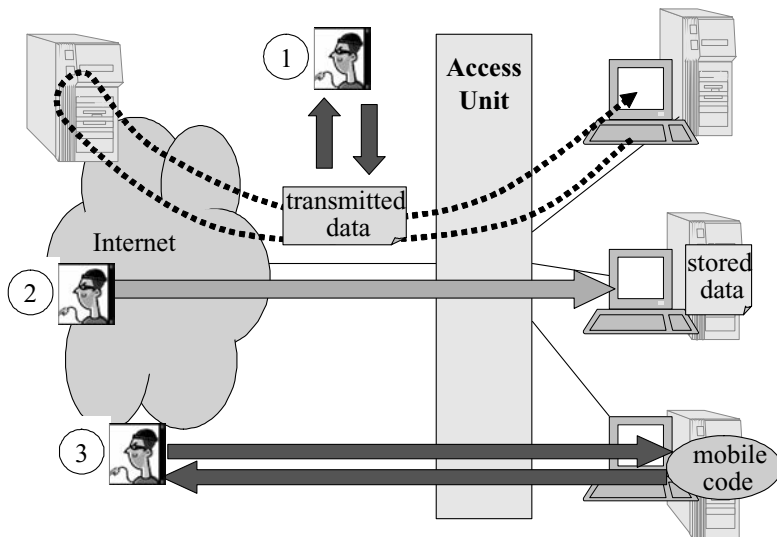

Figure 2: Basic threats and vulnerabilities: 1, attacking (read, modify) transmitted data; 2, accessing systems (scan for vulnerabilities), reading, modifying stored data; 3, using systems (install and execute programs).

protected material (Richmond (2004). (See also volume 3, part 1 of the *Handbook*.)

So-called blended threats exploit system vulnerabilities to distribute malicious mobile code, for example, viruses, worms, or Trojans (see Figure 2). The distribution takes place via e-mail and Web access as well as by programs that automatically scan for vulnerable computers and replicate themselves (worms). In 2003, blended threats accounted for 80% of attack activity. Examples of blended threats include Klez, Bugbear, SoBig, SQL Slammer, Nimda, and Code Red (McCarthy, 2003).

Some worms replicate themselves to designated IP network blocks of the compromised system's network or domain. If successful, the worm then uses the infected system as a platform from which to scan for new victims. The homogeneity and the high speed of the broadband network, the high number of vulnerable (unpatched) computers, and the high computing speed of target systems result in a dramatic rise of the speed of worm propagation. An unprotected PC can expect to become infected by a worm within minutes of being connected to an unprotected network. The actual survival time for a specific computer to be compromised will vary widely, depending on the filters applied by the ISP, the configuration of access units, and on the configuration of the subscriber's computer.

Once a system is compromised, there may be malicious code installed that allows the attacker to use the system remotely. A malicious code application that serves as an agent for another program or user is called a "bot" (short for robot). Many bots form a botnet, that is, an entire

network of infected systems. The bots of a botnet can be controlled by issuing commands through Internet Relay Channel (IRC) (see volume 1, part 1, of the *Handbook*). There may be thousands of listening bots of a botnet that will execute any command issued by the controller of the botnet. Bots for denial-of-service attacks are called "zombies" (see volume 3, part 1 of the *Handbook*).

Some malicious code is now being installed with commercial interest. In 2004, growing evidence showed that underground companies exist that specialize in identity theft and spam (see volume 2, part 2 of the *Handbook*). Their malicious code will install spyware, which tracks Internet browser usage. Even more dangerous is their keystroke-logging software, which can compromise user passwords, credit card numbers, and other confidential information.

BROADBAND NETWORK SECURITY ISSUES

Broadband Network Architecture

Overview

Following the data path from an end-user device (i.e., customer premise's Equipment [CPE], or computer) to an Internet server, the main components and subsystems of a broadband Internet access system are identified (see Figure 3).

The subscriber's access unit (AU) is typically called a "modem" or "router" in an ADSL system and a "cable modem" (CM) in a DOC system. It provides an Ethernet

Figure 3: Architecture and components of broadband access systems.

or universal serial bus (USB) interface to attach the local subscriber's computer or communication equipment. Modems are owned by the subscriber or leased from the ISP; the latter is typically the case in DOC offerings. The access unit may act as a bridge or as a router. The bridge provides for transparent connectivity to the CPE. The router will typically incorporate network address translation (NAT) functions and therefore block connection attempts from the outside to the CPE.

The access network section consists of a telecom provider's telephone network wires or a cable television provider's coaxial cables, which connect the access modems with some concentration and multiplexing devices. This central device is called "digital subscriber line access multiplexer" (DSLAM) in an ADSL system or "cable modem termination system" (CMTS) in a DOC system. One CMTS typically controls one DOC cell with up to 2,000 cable modems. One DSLAM typically serves about 3,000 ADSL modems.

The access provider backbone network guarantees the connection of all multiplexers with the ISP authentication and gateway systems. The ISP assigns IP addresses with its dynamic host configuration protocol (DHCP) server. The ISP also takes care of the Internet peering contracts.

Data-Over-Cable (DOC)

Most cable network systems are based on the data-over-cable service interface specification (DOCSIS, Cable Television Laboratories, 2004). DOCSIS specifies how to operate a DOC system with cable modems (CM) and cable modem termination systems (CMTS). It defines the interaction between CM and CMTS on one side and between the CM and CPE on the other side. DOCSIS 1.0 describes how to deliver high-speed "best effort" services simultaneously with (analog) video services. DOCSIS 1.1 adds quality of service, which enables Internet protocol (IP) telephony, and DOCSIS 2.0 allows for higher upstream capacity (up to 30 Mb/s in both directions). The next generation network architecture (NGNA) shall lead to even higher capacity by using various compression technologies in an all-digital cable network. With NGNA, top North American cable operators are exploring options to unify their IP and MPEG video infrastructure and aiming to lower equipment costs, make more efficient use of the HFC spectrum, and promote high-value digital services.

Asymmetric Digital Subscriber Line (ADSL)

ADSL is the most common variant of DSL (Dutta-Roy, 1999). An ADSL subscriber access unit communicates with the DSLAM equipment at the other end of the (twisted-pair) telephone line, creating three channels: a high-speed downstream channel, a medium-speed upstream channel, and plain old telephone service (POTS). The POTS channel is split off from the digital modem by splitters, guaranteeing uninterrupted access for voice services. ADSL end users must be within 5.5 km of the local (central office) exchange.

There are variants of DSL with further restrictions on the maximum distance from the serving central office. Symmetric DSL (SDSL) delivers up to 2 Mb/s over a single line, whereas high-speed DSL (HDSL) uses two or three lines. The asymmetric very high-speed DSL (VDSL)

supports downstream data rates of more than 50 Mb/s, but the subscribers must be within about 300 m from the local exchange switch. Rate-adaptive DSL (RADSL) extends the range from the central office (i.e., exchange switch) to up to 5.5 km but works with variable upstream speeds, depending on the quality and actual length of the telephone cable (TTC, 1998). Next-generation ADSL (ADSL2 and ADSL2+) are expected to offer higher bandwidth (12 Mb/s upstream and 25 Mb/s downstream), hence enabling service providers to offer triple play services (DSL Forum, 2003).

Basic Broadband Network Security Concerns

The basic security concerns in broadband networks (see Figure 4) are these:

1. Wiretapping and traffic rerouting to get access to transmitted data (passive [1a] and active wiretapping [1b]),
2. Direct access to subscriber systems to test for vulnerabilities,
3. Subscriber file and resource access to read and modify stored data, and to install and execute programs (mobile code),
4. Service parameter change to increase upload and download data rates.

Reading and/or changing another user's transmitted information by passive or active wiretapping has been heavily discussed in the context of DOC networks. Some authors claimed that passive wiretapping (see 1a in Figure 4) would be easy because of the broadcasting nature of the DOC downstream channel. There were also reports on successfully intercepting traffic via active wiretapping, that is, traffic rerouting or connection hijacking with address spoofing attacks (see 1b in Figure 4; Lindstrom, 2002). However, passive wiretapping is not really a problem as will be shown in following sections, and also the various proposed active wiretapping attacks are not possible any longer in appropriately configured broadband access systems (Cisco, 2002).

Today, the basic security concern should be about access to end users' systems (see 2 in Figure 4) and to end users' resources (see 3 in Figure 4). Access to another computer from within the same network or from the Internet is the basic aim of computer networking. However, there are a number of vulnerabilities that can be exploited if arbitrary packets can be sent to unpatched systems. Such attacks might lead to full control of the subscribers' system. The aim of such attacks could be the distribution and installation of malicious mobile code (e.g., worms) and the execution of distributed denial of service (DDOS) attacks. Massive DDOS attacks that are started from subscribers within broadband-attached systems have the potential to severely affect the network availability.

Most broadband ISPs see themselves as "data carriers" and do not offer special protection of transported data. Many ISPs are concerned about people using their service without permission or about users changing their service parameters to exceed their assigned service level (see 4 in Figure 4). This is known as "uncapping attacks" by which attackers try to overcome bandwidth limitations.

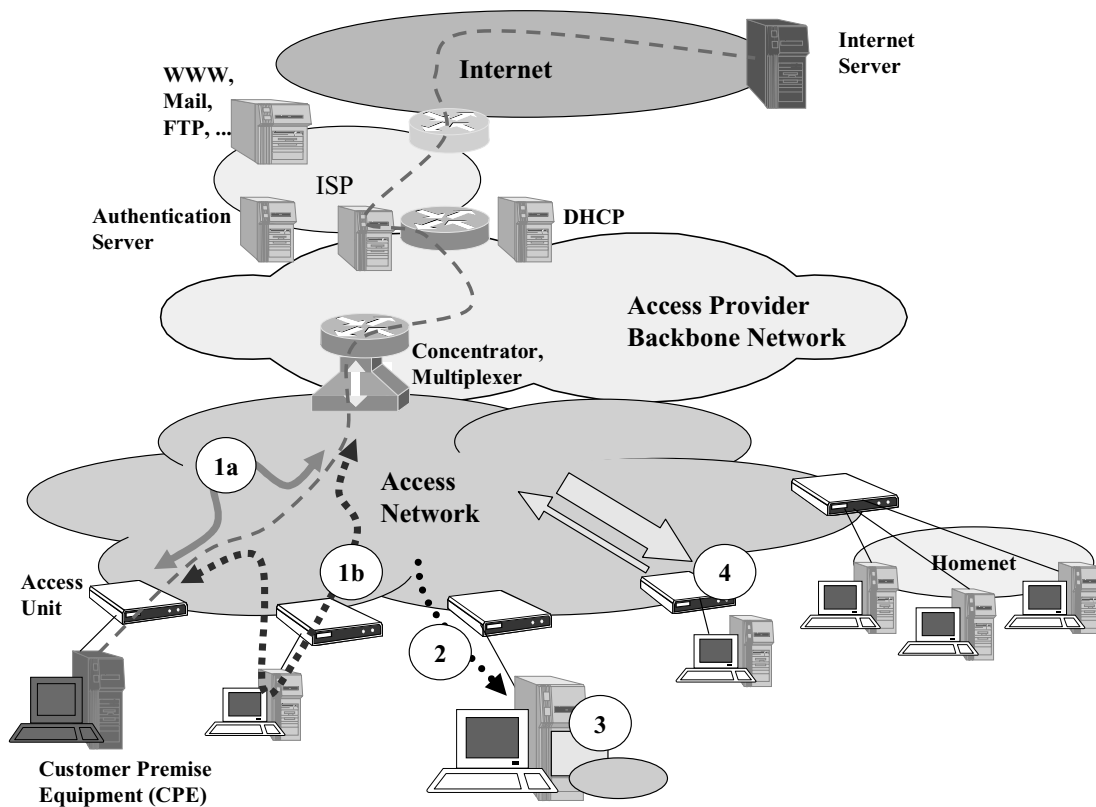

Figure 4: Security issues in broadband networks.

ISPs generally do not feel responsible for the security of their subscribers' systems. However, even just a few compromised user systems within an ISP's network may disable the correct function of the whole provider network. Performance may drop and hosts of the ISP's IP range may appear on spam-server blocking lists, which might lead to severe availability and reputation problems.

The following sections discuss the four basic types of attacks and outline differences with respect to DOC and ADSL networks. The focus is on Windows systems because they account for more than 95% of the home user systems (in August 2004; W3Schools, 2004).

Wiretapping

In ADSL systems, only data addressed to the connected subscriber is transmitted via the access cable from the DSLAM to the subscriber's site. Hence, there is no other subscribers' data on the cable that could be tapped at a specific subscriber's site.

In DOC systems, all data addressed to any of the subscribers in a given cell is sent in the 50–850 MHz frequency band from the CMTS to all subscribers. However, the cabling system, amplifiers, directional splitters, and couplers are designed such that upstream signals—sent in the 5–42 MHz frequency band toward the CMTS—do not reach all subscriber stations of the cell (see signals in Figure 5: transmitted signals from CM_b do not pass at CM_c, CM_d, and CM_e).

Because each cable modem is designed to receive/demodulate in the 50–850 MHz frequency band and

to send or modulate in the 5–42 MHz frequency band, consumer brand cable modems cannot demodulate upstream signals. Only the CMTS is equipped to demodulate the upstream frequencies. For example, CM_a cannot demodulate the upstream signals from CM_b. In conclusion, using standard equipment, it is physically impossible to receive and demodulate upstream signals. Hence, the ideas that it would be easy to tap any data of other people at the subscriber's site is a false assumption.

As mentioned, all downstream signals reach all stations of a cell, and the signals are demodulated by all cable modems. However, the data packets are only forwarded to the CPE if the destination address of the packets (DA) matches the address of the modem. To forward all packets, a modem would have to be put in a sort of "promiscuous mode." For example, packets with DA = c (see Figure 5) are not forwarded to the CPE at CM_f unless this modem was set in promiscuous mode. Broadcast packets (DA = all) are received by all modems and forwarded to all CPE.

The DOCSIS 1.1 standard supports a baseline privacy interface (BPI+) that provides bidirectional encryption (Cable Television Laboratories, 2004). BPI+ prevents unauthorized access to data transport services by the CMTS and thereby enforces encryption of the traffic flows. The CMTS controls distribution of keying material to client CMs using an authenticated client/server key management protocol. DOCSIS 1.1 currently employs the cipher block chaining (CBC) mode of the U.S. Data Encryption Standard (DES) to encrypt a DOCSIS MAC frame's packet data. DOCSIS 2.0 also supports the

Figure 5: Signal propagation in DOC networks.

advanced encryption standard (AES; Woundy, 2001; Thornhill, 2001). (See volume 2, part 3 of the *Handbook*.)

Today, for example, all access units of the largest Swiss DOC provider use at least 40-bit DES encryption. Hence, even if somebody could demodulate all signals and have its modem in promiscuous mode, it would still not be possible to read the transmitted data unless the attacker was able to decrypt the data.

Direct Access to Subscriber Systems

Access Unit (NAT) Effects

Some broadband systems use routers to connect the CPE; others use bridge-type access units. The routers were mainly deployed with the intention of address reuse on the client's side. For this reason, such routers commonly provide network address translation (NAT) functionality. NAT routers became a key element in improving security because NAT routers in their default configuration do not allow connections from any Internet station to the CPE (Shieh et al., 2000). It is therefore impossible to exploit local computers' vulnerabilities or to access local resources (such as Windows shares).

To get an estimate on the percentage of directly—and therefore potentially vulnerable—broadband subscriber PCs, the company cnlab Internet Research AG, Rapperswil, Switzerland, carried out tests in Switzerland and Germany. In Switzerland, every month about 100,000 broadband subscribers use performance test applets, which are provided by cnlab (Cnlab, n.d.). Based on the data collected from these tests, the distribution of NAT and non-NAT access could be determined. The analysis of the distribution of NAT and non-NAT over time

(see Figure 6) shows significant differences between ISPs. In February 2004, there were two Swiss providers with more than 40% of the CPEs directly reachable from the Internet (see Figure 6, providers Hi and Su). Among the five German DSL providers tested, there were between 37% and 45% directly reachable from the Internet.

The chart in Figure 6 indicates a general trend toward fewer CPEs being directly reachable from the Internet, that is, toward more NAT router and firewall installations.

The differences among the ISPs are mainly determined by the type of default installation and promotion of access system packages. Swiss provider Hi, for example, is a DOC provider with a default cable modem installation without NAT or firewall functionality. Provider Su ran several promotions with simple modems, that is, non-NAT ADSL access units.

Popup Messages

One of the obvious problems of direct access to always-on subscriber systems is Windows messenger service alerts popping up on the subscriber's computers (see Figure 7).

In their initial state, Microsoft Windows operating systems (98, ME, XP, 2000, NT) allowed anyone on the Internet to open Messenger windows on somebody else's screen. Unlike e-mail advertising, an individual that is online will instantly see the advertisement that pops up on the computer in front of all active windows, which forces the recipient to react to the ad. There are tools available for sending Windows Messenger service messages to ranges of IP addresses (Direct PopUp Advertiser, n.d.). Thanks to this instant message broadcasting to IP addresses, high-volume advertising across the Internet through instant pop-up windows is possible.

Figure 6: Percentage of subscribers of different ISPs with direct system access (evolution of the percentage of access units without NAT functionality).

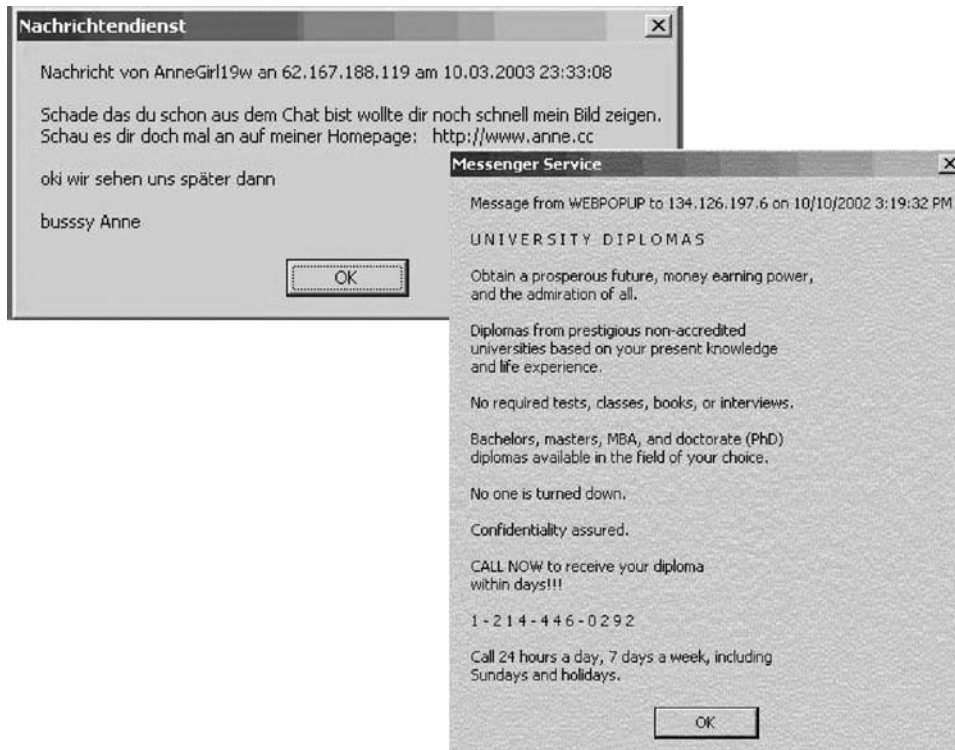

Figure 7: Pop-up windows sent to IP addresses.

Figure 8: Blaster worm and MS-SQL attacks in relation to the percentage of directly accessible subscriber systems in different ISP networks (measurements date from February 2004).

Worm Propagation

One of the major problems with directly reachable CPEs in broadband networks is worm propagation. Cnlab has installed Snort Intrusion Detection Systems (IDS) to monitor “malicious mobile code activities” in the networks of various ISPs. Figure 8 shows the frequency of Blaster and MS-SQL worm propagation attempts in relation to the percentage of directly reachable CPEs for four ISPs.

The results indicate the expected strong correlation between the percentage of NAT access devices and Blaster worm activities: the more directly accessible CPEs in an ISP network, the higher the number of Blaster attacks per hour.

The Blaster worm (also known as Lovsan) exploits the DCOM RPC vulnerability on Windows 2000 and Windows XP installations via TCP port 135. If the worm has penetrated a system (let’s say with IP address x.y.z.n), it tries to install itself on other systems in the same IP network by scanning other IP addresses in the x.y.z.n range. There is a 40% probability that the worm will increment the n part of the IP address by 1, in an attempt to find and exploit other computers based on the new IP address, until

it reaches 254. There is a 60% probability that the generated IP address is completely random (Symantex, 2003). Hence, there is a good chance that the worm will mainly distribute within the same network. This explains why the network of the ISP with the highest percentage of directly accessible systems (63%) shows the highest number of Blaster attacks per hour. Those ISPs with small numbers of directly accessible systems have significantly fewer Blaster attacks per hour.

The MS-SQL worm (also known as SQL Slammer) targets systems running Microsoft SQL Server 2000, as well as Microsoft Desktop Engine (MSDE) 2000. It sends 376 bytes to the SQL server resolution service port (UDP port 1434). Because there are not many systems running Microsoft SQL Server or MSDE components, and because the worm sends itself to randomly selected IP addresses, there are fewer systems affected within the ISP network than with the Blaster worm.

The number of IDS alerts depends on the time of day and the ISP. Generally, a clear correlation between typical activity periods of the subscribers and the number of worm attacks can be observed (see Figure 9). The

Figure 9: Number of Snort alerts per hour measured by time of day during eight days.

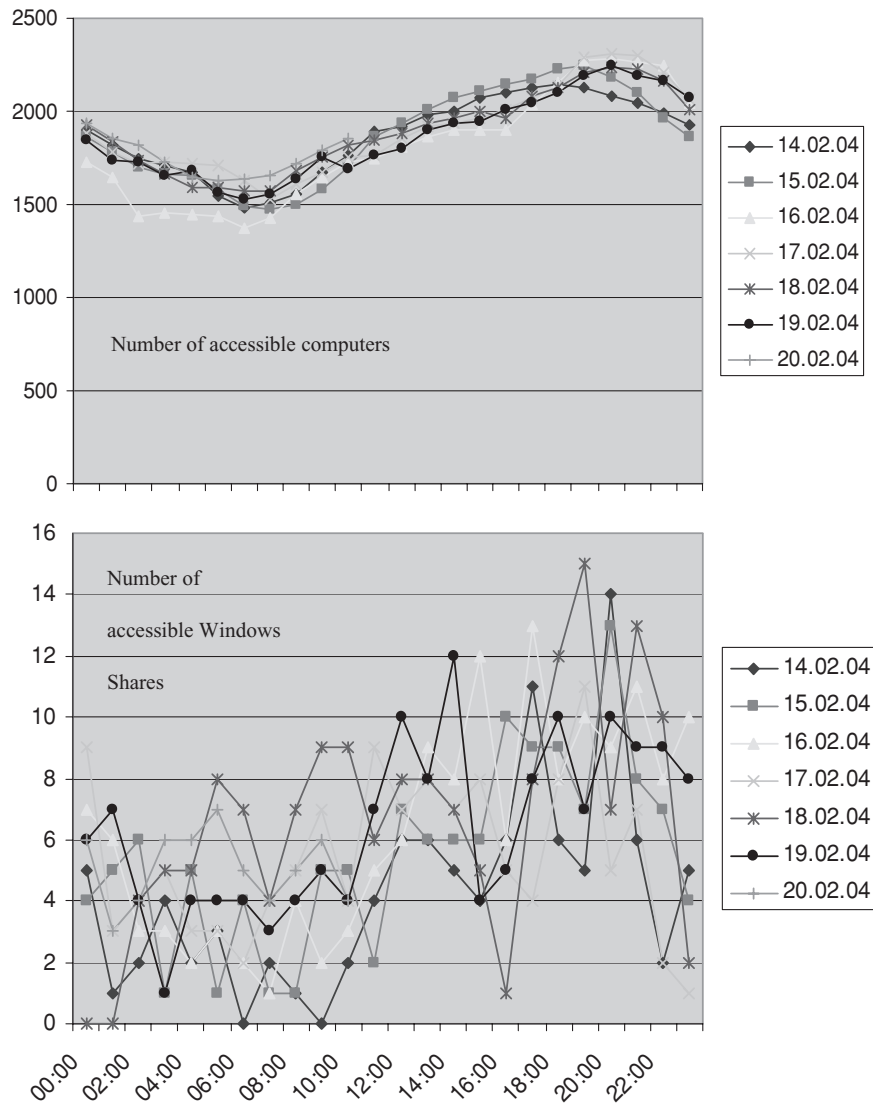

Figure 10: Number of accessible systems and Windows shares measured by time of day during seven days (of a total of 4,096 scanned addresses).

more active systems there are, the more attacks per hour there are.

Access to Subscriber Files and Resources
Open Windows Shares

The issue that has attracted the greatest attention in the public is access to subscriber files. Investigations in Switzerland show that in the first quarter of 2004, about 4% of the systems connected to broadband networks had accessible Windows shares that may or may not be password protected (see Figure 10).

Direct access from the Internet to a system with open Windows shares will give unauthorized access to the locally stored data files from anywhere in the Internet. Once Windows shares are activated, the computer is also exposed to other attacks because of the various opened services (e.g., NetBIOS name service at UDP port 137, NetBIOS datagram service at UDP port 138, NetBIOS session service at TCP port 139).

The number of accessible shares is clearly correlated with the typical activity periods of residential subscribers.

Installation of Mobile Code

The problem of open shares is not only relevant in connection with the exposure of private information. It can also be exploited for spreading malicious code. For example, the Biscuit worm, which attempts to copy itself to both the local host and reachable remote network shares, can propagate itself. Also, the Sobig worm attempts to copy itself to remote network shares. Finally, the Bugbear mass-mailing worm spreads via network shares. It has keystroke-logging and backdoor capabilities. This worm attempts to terminate the processes of various antivirus and firewall programs.

Having mass-mailing programs put on broadband subscribers' computers may create a problem or at least bad reputation for the ISP. Mass-mailing activity may result in the ISP's domain or some of ISP's IP addresses being published in spam databases. IP addresses of an ISP

might, for example, be published on the antispam service SenderBase, which reports on the top senders (i.e., spammers) based on data provided from more than 9,000 organizations (SenderBase, n.d.).

Changing Service Parameters

An ISP's major security concern is to protect its own offerings. Broadband ISPs typically have different service offerings on their access units (e.g., 100–600 Kb/s, 400–2000 Kb/s upload and download data rates).

In DOC networks, the upload and download data rates are controlled in the CM. The service is defined upon TFTP download of the configuration parameters to the CM at modem boot up. The subscriber is identified by the CM physical address (MAC address) and optionally by certificate exchange with the CMTS. The subscriber might be able to change his CM configuration because he has physical access to the device. Such a “theft of service” attempts are known as “uncapping attacks” (How to Uncap DOCSIS Compliant Cable Modems, n.d.).

In ADSL networks, the upload and download data rates are defined by “hardware configuration” at the DSLAM. The subscriber is identified by username and password, which are sent to the ISP authentication system. “Uncapping” in ADSL seems rather unrealistic because the speed-limiting parameters would have to be changed at the DSLAM. However, working on a given ADSL connection with other users' accounts is simple. Hence, a subscriber who booked for a specific account can use the username and password of somebody else. This might be attractive when the other subscriber has some special services that the attacker would not get on his own account.

HOW TO IMPROVE BROADBAND SECURITY

Measures and Responsibilities

There are multiple possible ways to improve the security of broadband Internet access and there is not a single point or party responsible for security. All involved parties—ISPs, equipment manufacturers, software vendors, and subscribers—should take measures to fight all sorts of attacks. Figure 11 illustrates the situation and lists measures to improve the security in the broadband access environment.

The software vendors and equipment manufacturers should provide default installations that avoid unintended exposure of personal files and resources. Here are some examples of favorable default configurations:

- On the computer: Windows share access with transmission control protocol/Internet protocol (TCP/IP) is not enabled; personal firewall is activated.
- Communication equipment: access device has NAT or firewall functionality, default access unit configuration is not “always-on,” that is, has inactivity timeout; access device cannot be configured via the Internet port.

Furthermore, software vendors and equipment manufacturers should provide simple, preferably automatic, reliable, and secure system patch and upgrade procedures. The introduction of Microsoft's Windows XP Service Pack 2 “Security Center” points in a good direction by adapting various default configurations and forcing the installation of personal firewall and antivirus software.

The subscribers (i.e., end users) should work with up-to-date antivirus software (see volume 3, part 2 of the

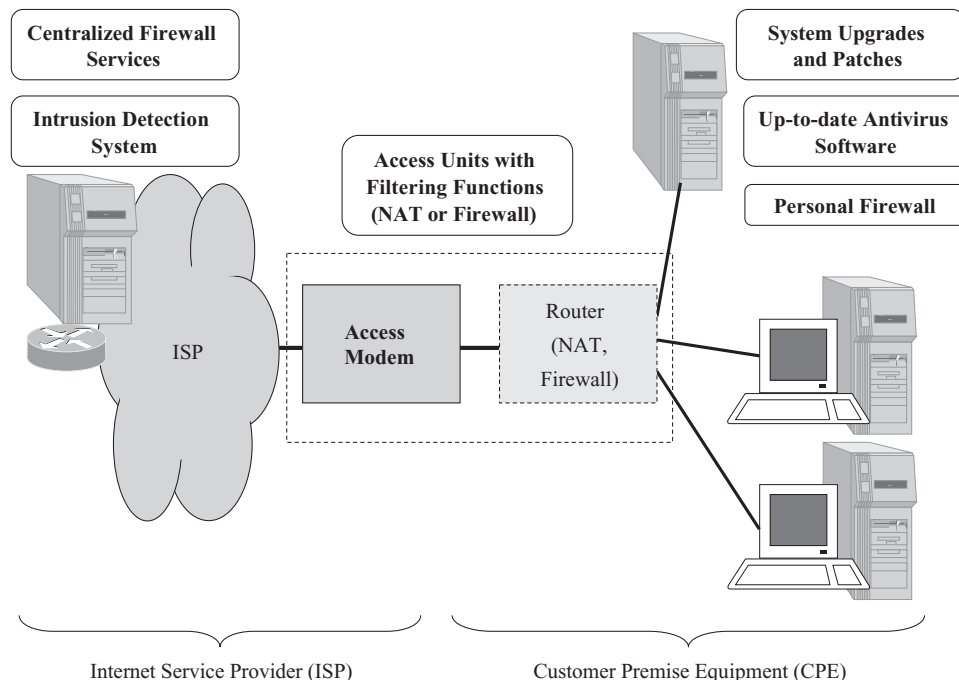

Figure 11: Measures to improve the security of broadband Internet access.

Table 2 Security Measures

Measures	Avoided Attack or Problem
NAT router or appropriate default installation or personal firewall	Access to Windows shares is not possible
NAT router or updated system software (patches installed) or updated antivirus software	Worms (e.g., Blaster) will not install themselves on the system and will not propagate

Handbook). They should update their operating system and install patches. Both antivirus software vendors as well as operating system vendors offer “automatic updates” to download the latest signature files and security updates. Before getting connected to the Internet, subscribers should block Windows file and print sharing over TCP/IP. The subscriber might also install a firewall (hardware and/or a software firewall; Kessler, 2000). However, as long as most users are not willing or not able to take at least the simplest security measures, they need support from the other involved parties (i.e., ISPs and software and equipment manufacturers; Meyer, 2003).

The ISPs should only promote access devices with NAT or firewall functionality (see volume 3, part 2, of the *Handbook*). Furthermore, they should take the opportunity and offer managed security services such as the following:

- centralized firewall services,
- subscriber security checking (offer tools and/or checks),
- identify problems (e.g., detect sources of attacks automatically) (see volume 3, part 3 of the *Handbook*).

Building Awareness

Many home users are not aware of the exposures when using the Internet. This became obvious after Swiss and German TV programs showed how simple it is to access Windows shares or subscriber systems in February and June 2004. The programs initiated a very heated debate with reports in newspapers and journals. Some ISPs reacted with immediate measures to improve security. Other ISPs denied any need to take security measures. At least the Swiss TV awareness-building exercise had a great effect. All ISPs added or improved the information about security problems on their Web sites and many people installed hardware firewalls or NAT routers, learned how to update their systems, and installed patches. Many subscribers installed personal firewalls and antivirus software (see volume III, part 3 of the *Handbook*).

Combination of Security Measures

One basic principle in security engineering is to combine multiple measures to protect exposed resources. This principle is also known as “layered security” or “in-depth defense” (see volume III, part 3 of the *Handbook*). Table 2 shows how the multiple measures protect against typical attacks or problems seen in broadband networks when at least one of them is implemented.

NAT routers do significantly improve security without requiring special skills of the subscribers. The default installation of NAT routers delivered to residential

subscribers does not offer any port forwarding, and most residential users will not change the default configuration of the shipped access devices. Security could even be further improved if the access device would automatically terminate the Internet connection after a certain inactivity period (timeout).

Of course, the installation of a NAT device does not guarantee absolute protection: subscribers may change their access device default configuration to provide direct access to certain computers (e.g., local servers). There might be configuration problems or vulnerabilities of the access device itself. (A few years ago, a widely used NAT router was shipped with a default configuration that allowed telnet access via the Internet with the default password of “1234.”)

Note that the NAT routers and firewalls do not protect against malicious code received by e-mail or Web pages. Here again the combination with other measures is recommended (e.g., user awareness education and virus scanning at e-mail servers and subscribers’ computers).

CONCLUSION

The multitude of unprotected (residential) broadband network subscribers’ computers offers high speed, always-on data sources that are a very attractive base for malicious code distribution. Therefore, broadband access requires better security measures of all involved parties: subscribers, software and equipment manufacturers, and ISPs. Without appropriate security measures there will be increasing problems with worms, DDOS attacks, and spam.

Many residential subscribers are not aware of security issues and are not capable of taking appropriate security measures. Measurements at Swiss and German ISP networks showed that up to 60% of the broadband subscriber systems can be accessed directly from the Internet and that a high percentage of those systems offer open Windows shares. Obviously, software vendors, equipment manufacturers, and ISPs must help the subscribers and offer tools and services to improve the security of the overall system.

There are little principle differences between ADSL and DOC broadband access security concerns. On one hand, ADSL has a minor advantage with regard to wire-tapping at the subscriber’s site because only those signals addressed to the specific subscriber get to the subscriber’s site. DOC, on the other hand, offers encryption of all transmitted data packets.

For both ADSL and DOC, the access device should provide some filtering function (i.e., have a firewall or NAT function) to prevent direct access to customer premise

equipment. The positive effect of NAT devices on broadband access network security was demonstrated based on measurements at Swiss and German ISP networks. There is a clear correlation between the number of NAT devices installed and the activity of certain worms (e.g., e-blaster): The more NAT and firewall devices installed, the fewer security problems are present.

GLOSSARY

Internet and security terms are defined at various places.

The following list is based on definitions from Gartner (2003), SearchSecurity.com (n.d.), and SANS (n.d.).

ADSL Asymmetric digital subscriber line (ADSL) is a method for moving data via regular phone lines. A typical configuration of ADSL creates asymmetric transmission channels; for example, a subscriber can receive data (download) at 600 Kb/s and send (upload) data at 128 Kb/s.

AES The advanced encryption standard (AES) is a new Federal Information Processing Standard (FIPS) Publication that specifies a cryptographic algorithm for use by U.S. government organizations to protect sensitive (unclassified) information. AES is also widely used on a voluntary basis by organizations, institutions, and individuals outside of the United States.

BPI+ The baseline privacy interface (BPI) is defined as a set of extended services within the DOCSIS MAC sublayer. BPI gives subscribers data privacy across the CATV network by encrypting traffic flows between the CMTS and CM.

BPI of DOCSIS 1.0 uses RSA key management protocol and the electronic codebook (ECB) mode of DES to secure key exchanges between the CMTS and a CM. Privacy is in the form of 56-bit (the default) or 40-bit encryption.

BPI+ of DOCSIS 1.1 gives enhancements such as digital certificates to provide user authentication, key encryption with 168-bit triple DES (3DES), and 1024-bit public key with Pkcs#1 version 2.0 encryption.

CM The cable modem (CM) is the client device for providing data via a cable TV network. It is an end-user CPE device with Ethernet or USB ports and network interface functions. An external cable modem device that incorporates some type of router functionality it is also called CPE cable router.

CMTS The cable modem's termination system (CMTS) is the central device for connecting the CATV network to the Internet. The CMTS is located in the head end of the CATV system. It creates a communication link (similar to a local area network) with the CMs at the subscribers' sites. CMTS is also known as cable broadband access platform (CBAP).

CPE The customer premise equipment (CPE) is located at the end user's home or business site and is connected to a PC that receives DOC- or DSL-based digital data communications service. Most CPE connect to PCs through a standard 10Base-T Ethernet card or USB connection.

DA Destination address (DA) is the address of a network device that is receiving data.

DDOS In a distributed denial-of-service (DDoS) attack, there are a multitude of compromised systems that attack a single target. The flood of incoming attacks to the target system denies the service to legitimate users.

DES Data encryption standard (DES) is an encryption block cipher developed in 1977 by IBM. It applies a 56-bit key to each 64-bit block of data, providing strong encryption based on symmetric cryptography. If DES is used with three keys, it is known as "triple DES" or 3DES. The standard was endorsed as an official standard by the U.S. government in 1977. In 2003, it was replaced by AES.

DOCSIS Data over cable service interface specification (DOCSIS) is the dominating cable modem standard. It defines the various interfaces between the radio frequency- (RF-) based cable network and the CM at the customer premises, as well as the associated CMTS at the head end. DOCSIS was accepted as a worldwide standard by the International Telecommunication Union (ITU) with technical variations for Europe and Japan.

DOS A denial-of-service (DoS) attack creates a situation in which users do not get the services they would normally get. Typically, the loss of service is the unavailability of a Web site, e-mail, or network connectivity. DOS can sometimes happen accidentally.

DSL The digital subscriber line (DSL) technologies provide remote access to the subscriber via the telephone companies' copper lines. There are various DSL technologies, for example, asymmetric DSL (ADSL), symmetric DSL (SDSL), ITU-standardized SDSL (G.SHDSL and SHDSL), ISDN-DSL (IDSL), and very high-speed DSL (VDSL).

DSLAM The digital subscriber line access multiplexer (DSLAM) is a traffic aggregation device that multiplexes upstream and downstream information in a DSL network. The DSLAM is usually located in a central office and connects to the central office switch to support voice service. On the network side, a DSLAM can interface with ATM, IP, or any other broadband service.

FTTL Fiber in the loop (FITL) means the provision and operation of fiber-optic media in the subscriber loop. FITL cable plants are of the "fiber to the curb" (FTTC) or "fiber to the home" (FTTH) type.

HDSL High bit-rate DSL systems (HDSL) enable full duplex transmission at up to 2 Mb/s via ordinary copper twisted pairs in unshielded cables. HDSL products can use up to three twisted copper pairs for transmission.

IDS An intrusion detection system (IDS) is a type of security management system for computers (host-based IDS) and networks (network-based IDS). It gathers and analyzes information from various areas within a computer or a network to identify possible security breaches.

ISP An Internet service provider (ISP) is a company that provides access to the Internet and other related services to its customers (subscribers). An ISP focusing on access is sometimes referred to as an Internet access provider (IAP). An ISP with focus on application services is also called application service provider (ASP).

MPLS Multiprotocol label switching (MPLS) is a technology for speeding up network traffic and for managing network quality of service (QoS). MPLS sets up a specific path for a given sequence of packets. The path is identified by a label put in each packet. This reduces the time needed for a router to look up the address to the next node to which to forward the packet.

NAT Network address translation (NAT) maps one or more global (outside) IP network addresses to local (inside) IP network addresses. NAT reduces the number of global IP addresses needed. The address mapping can be statically or dynamically defined.

Phishing Phishing is a type of attack (sometimes called carding or brand spoofing) where the attacker sends out legitimate-looking e-mails appearing to come from a Web site. This attack prepares for identity theft by faking a Web site that normally asks the target user for personal information, including credit card numbers, personal identification numbers, social security numbers, banking numbers, and passwords.

PLC Power line communication (PLC) uses existing electrical power lines for symmetric Internet access. In the United States, it is called broadband over power lines (BPL); the Europeans use the term power line communication (PLC). The industrial “HomePlug” alliance was formed to standardize data networking via electrical wiring inside the premises.

SNMP Simple network management protocol (SNMP) is the protocol governing network management and the monitoring of network devices and their functions. SNMP is described formally in the Internet Engineering Task Force (IETF) Request for Comment (RFC) 1157.

TCP/IP Transmission control protocol/Internet protocol (TCP/IP) is the transport/network layer protocol typically used for many Internet applications (e.g., http, mail, ftp). TCP provides for connection-oriented, reliable data transport and includes also flow and congestion control functions. Data flows are identified by port number/IP address quadruples.

TFTP Trivial file transfer protocol (TFTP) is a simple protocol to transport files via the Internet. It does not offer directory browsing and has no user authentication. TFTP uses the user datagram protocol (UDP) rather than the transmission control protocol (TCP). TFTP is described formally in Request for Comment (RFC) 1350.

UDP User datagram protocol (UDP) is the connectionless transport layer protocol widely used in the Internet (e.g., for applications such as DNS, TFTP, and SNMP). UDP provides port numbers to help distinguish different user requests.

USB Universal serial bus (USB) is a plug-and-play interface between a computer and add-on devices. USB supports 12 Mb/s data speed. Today, most new computers and peripheral devices are equipped with USB.

WLL Wireless local loop (WLL), also known as radio in the loop (RITL), is a point-to-multipoint radio-based transmission scheme. WLL systems can be based on a range of different technologies and standards, for example, local multipoint distribution service (LMDS).

xDSL x Digital subscriber line (xDSL) is a transmission scheme in the local loop of the plain old telephony service (POTS) network. The x signifies various standard types, for example, asymmetric DSL (ADSL), symmetric DSL (SDSL), high-speed DSL (HDSL), very high-speed DSL (VDSL), and rate-adaptive DSL (RADSL).

INTRODUCTION

An ad hoc network consists of a set of wireless nodes that act both as data terminals and data transfer equipment to spontaneously form a temporary network without relying on any dedicated infrastructure. Security of ad hoc networks recently received much attention from the research community and a large number of solutions to protect ad hoc networks against various types of attacks have been published. Security in ad hoc networks is a severe problem because of the conjunction of several factors:

- Vulnerabilities resulting from radio communications: the lack of physical security and the ease of eavesdropping and spoofing call for strong security mechanisms in order to get security that is equivalent to standard wireline communications.
- Lack of a priori trust: most ad hoc networks consist of a set of nodes that are not part of any shared organization thus classical security paradigms based on preestablished trust among the parties are not applicable.
- Lack of infrastructure: security solutions based on dedicated components with predefined roles such as trusted third parties and key servers are not compatible with the basic definition of ad hoc networks whereby no component has a preassigned role.
- Requirement for cooperation: because of the lack of dedicated components such as routers and servers that implement network services, basic networking functions have to be carried out in a distributed fashion by the collaboration of a set of ordinary nodes, thus the performance of basic network operations such as packet forwarding and routing can be strongly affected by malicious or accidental lack of cooperation.

Research on ad hoc network security initially focused on routing protocols because these were deemed the most critical part of network control. The Key Management section is an overview of prominent routing security solutions that are based on various versions of ad hoc routing protocols. A close analysis of routing security work reveals that the majority of the requirements needed

for the solutions and the suggested mechanisms are not new or specific to ad hoc networks, apart from a fundamental problem that was often left aside by routing security solutions, that is, key management with no a priori trust and lack of infrastructure. The Cooperation Enforcement section presents research proposals that address the key management problem in the context of ad hoc networks with various original approaches that generally aim at setting security associations in a collaborative way without relying on existing trust relationships. The Conclusion section gives a detailed overview of cooperation enforcement mechanisms and their validation. Figure 1 provides a schematic view of security requirements for mobile ad hoc networks (MANETs).

ROUTING SECURITY

Security of ad hoc routing protocols has recently become an important topic in the research community: unlike wired networks where routing functions are performed by dedicated nodes or routers, in MANET routing functions are carried out by all available nodes. Common routing security mechanisms consist of node and message authentication that refer to an a priori trust model in which legitimate routers are believed to perform correct operations. In contrast, authentication of a node or its messages does not guarantee the correct execution of routing functions in open environments with lack of a priori trust, such as MANET.

Security exposures of ad hoc routing protocols are due to two different types of attacks: *active attacks* through which the misbehaving node has to bear some energy costs to perform some harmful operation, and *passive attacks* that mainly consist of lack of cooperation with the purpose of saving energy. Furthermore, misbehaving nodes can be part of the network and perform attacks by exploiting compromised nodes or by disrupting the normal routing operation (*insider attacks*) or can be unauthorized nodes that aim to cause congestion, propagate incorrect routing information, prevent services from working properly, or shut down them completely (*external*

Figure 1: Security requirements for ad hoc network layer and corresponding solutions.

attacks). These threats exist because of the inherently limited physical security of mobile ad hoc networks. Indeed, it is easier to intercept communications and inject messages in the wireless communication medium than in an equivalent wired network.

Malicious nodes (i.e., active attackers) can disrupt the correct functioning of a routing protocol by modifying routing information, by fabricating false routing information, and by impersonating other nodes. Recent research studies (Perrig, Hu, & Johnson, n.d.) also brought up a new type of attack that goes under the name of *wormhole attack*. On the other side, selfish nodes can severely degrade network performances and eventually partition the network (Michiardi & Molva, 2002c) simply by not participating in the network operation.

In the existing ad hoc routing protocols, nodes are trusted in that they do not maliciously tamper with the content of protocol messages transferred among nodes. Malicious nodes can easily perpetrate integrity attacks by altering protocol fields to subvert traffic, deny communication to legitimate nodes (denial of service), and compromise the integrity of routing computations in general. As a result, the attacker can cause network traffic to be dropped, to be redirected to a different destination, or to take a longer route to the destination, thereby increasing communication delays. A special case of integrity attacks is spoofing, whereby a malicious node impersonates a legitimate node, which is possible because of the lack of authentication in the current ad hoc routing protocols. The main result of spoofing attacks is the misrepresentation of the network topology, which possibly causes network loops or partitioning. Lack of integrity and authentication in routing protocols can further be exploited through “fabrication,” which refers to the generation of bogus routing messages. Fabrication attacks cannot be detected without strong authentication means and can cause severe problems, ranging from denial of service to route subversion.

A more subtle type of active attack is the creation of a tunnel (or wormhole) in the network between two colluding malicious nodes linked through a private connection bypassing the network. This allows a node to short-circuit the normal flow of routing messages, creating a virtual vertex cut in the network that is controlled by the two colluding attackers.

Another exposure of current ad hoc routing protocols is node selfishness that results in lack of cooperation among ad hoc nodes. A selfish node that wants to save battery life for its own communication can endanger the correct network operation by simply not participating in the

routing protocol or by not forwarding packets. Current ad hoc routing protocols do not address the selfishness problem.

It has become obvious that security has to be taken into account at the early stages of the design of ad hoc routing protocols. However, if the design of secure routing protocols for MANET has not been a particularly demanding task, the provision of basic security services needed as building blocks for the secure routing protocol itself is still the greatest challenge that researchers are facing. To mitigate the complexity introduced by the pure ad hoc paradigm, the solutions proposed in the following sections rely on particular (and frequently limiting) assumptions that ease the task of bootstrapping security associations needed prior to the secure routing protocol execution. The attention of the research community is now focusing on the provision of self-organized key management services that can be used by secure routing protocols: this topic will be addressed in the Key Management section.

Secure Routing Proposals

Secure Routing Protocol (SRP)

The secure routing protocol (SRP; Papadimitratos & Haas, 2002) is designed as an extension compatible with a variety of existing reactive routing protocols. SRP combats attacks that disrupt the route discovery process and guarantees the acquisition of correct topological information: SRP allows the initiator of a route discovery to detect and discard bogus replies. SRP relies on the availability of a security association (SA) between the source node (S) and the destination node (T). The SA could be established using a hybrid key distribution based on the public keys of the communicating parties. S and T can exchange a secret symmetric key (KS,T) using the public keys of one another to establish a secure channel. S and T can then further proceed to mutual authentication of one another and the authentication of routing messages.

SRP copes with noncolluding malicious nodes that are able to modify (corrupt), replay, and fabricate routing packets. In the case of the dynamic source routing (DSR) protocol (Johnson & Maltz, 1996), SRP requires a six-word header containing unique identifiers that tag the discovery process and a message authentication code (MAC) computed using a keyed hash algorithm. To initiate a route request (RREQ), the source node has to generate the MAC of the entire IP header, the basic protocol RREQ packet, and the shared key KS,T.

The intermediate nodes that relay the RREQ toward the destination measure the frequencies of queries received from their neighbors to regulate the query propagation process: each node maintains a priority ranking that is inversely proportional to the query rate. A node that maliciously pollutes network traffic with unsolicited RREQ will be served last (or ignored) because of its low priority ranking.

Upon reception of a RREQ, the destination node verifies the integrity and authenticity of the RREQ by calculating the keyed hash of the request fields and comparing them with the MAC contained in the SRP header. If the RREQ is valid, the destination initiates a route reply (RREP) using the SRP header the same way the source

did when initiating the request. The source node discards replays that do not match with pending query identifiers and checks the integrity using the MAC generated by the destination.

The basic version of SRP suffers from the route cache poisoning attack: routing information gathered by nodes that operate in promiscuous mode to improve the efficiency of the DSR protocol could be invalid, because of potential fabrication by malicious nodes. The authors propose two alternative designs of SRP that use an intermediate node reply token (INRT). INRT allows intermediate nodes that belong to the same group that share a common key (KG) to validate RREQ and provide valid RREP messages.

SRP suffers also from the lack of a validation mechanism for route maintenance messages: route error packets are not verified. However, to minimize the effects of fabricated error messages, SRP source-routes error packets along the prefix of the route reported as broken: the source node can thus verify that each route error feedback refers to the actual route and that it was originated at a node that is part of the route. A malicious node can harm only routes to which it actually belongs.

Assuming that the neighbor discovery mechanism maintains information on the binding of the medium access control and the IP addresses of nodes, SRP is proven to be essentially immune to IP spoofing (Papadimitratos & Haas, 2002).

SRP is, however, not immune to the wormhole attack: two colluding malicious nodes can misroute the routing packets on a private network connection and alter the perception of the network topology by legitimate nodes.

ARIADNE

Hu, Perrig, and Johnson (2002) present an on-demand, secure, ad hoc routing protocol based on DSR that withstands node compromise and relies only on highly efficient symmetric cryptography. ARIADNE guarantees that the target node of a route discovery process can authenticate the initiator, that the initiator can authenticate each intermediate node on the path to the destination present in the RREP message, and that no intermediate node can remove a previous node in the node list in the RREQ or RREP messages.

As for the SRP protocol, ARIADNE needs some mechanism to bootstrap authentic keys required by the protocol. In particular, each node needs a shared secret key (KS,D is the shared key between a source S and a destination D) with each node with which it communicates at a higher layer, an authentic TESLA (Perrig, Canetti, Song, & Tygar, 2001; 2000) key for each node in the network, and an authentic “route discovery chain” element for each node for which this node will forward RREQ messages.

ARIADNE provides point-to-point authentication of a routing message using a message authentication code (MAC) and a shared key between the two parties. However, for authentication of a broadcast packet such as RREQ, ARIADNE uses the TESLA broadcast authentication protocol. ARIADNE copes with attacks performed by malicious nodes that modify and fabricate routing information, with attacks using impersonation, and, in an advanced version, with the wormhole attack. Selfish nodes are not taken into account.

In ARIADNE, the basic RREQ mechanism is enhanced by eight additional fields used to provide authentication and integrity to the routing protocol as follows:

<ROUTE REQUEST, initiator, target, id, time interval, hash chain, node list, MAC list>

The initiator and target are set to the address of the initiator and target nodes, respectively. As in DSR, the initiator sets the id (identifier) to an identifier that it has not recently used in initiating a route discovery. The time interval is the TESLA time interval at the pessimistic expected arrival time of the request at the target, accounting for clock skew. The initiator of the request then initializes the hash chain to $MAC_{KS,D}$ (initiator, target, id, time interval) and the node list and MAC list to empty lists.

When any node A receives a RREQ for which it is not the target, the node checks its local table of <initiator, id> values from recent requests it has received to determine if it has already seen a request from this same route discovery. If it has, the node discards the packet, as in DSR. The node also checks whether the time interval in the request is valid: that time interval must not be too far in the future, and the key corresponding to it must not have been disclosed yet. If the time interval is not valid, the node discards the packet. Otherwise, the node modifies the request by appending its own address (A) to the node list in the request, replacing the hash chain field with $H[A, hash\ chain]$, and appending a MAC of the entire REQUEST to the MAC list. The node uses the TESLA key K_{Ai} to compute the MAC, where i is the index for the time interval specified in the request. Finally, the node rebroadcasts the modified RREQ, as in DSR.

When the target node receives the RREQ, it checks the validity of the request by determining that the keys from the time interval specified have not been disclosed yet, and that the hash chain field is equal to

$$H[\eta_n, H[\eta_{n-1}, H[\dots, H[\eta_1, MAC_{KSD}(\text{initiator, target, id, time interval})] \dots]]]$$

where η_i is the node address at position i of the node list in the request and where n is the number of nodes in the node list. If the target node determines that the request is valid, it returns a RREP to the initiator, containing eight fields:

<ROUTE REPLY, target, initiator, time interval, node list, MAC list, target MAC, key list>

The target, initiator, time interval, node list, and MAC list fields are set to the corresponding values from the RREQ, the target MAC is set to a MAC computed on the preceding fields in the reply with the key KDS, and the key list is initialized to the empty list. The RREP is then returned to the initiator of the request along the source route obtained by reversing the sequence of hops in the node list of the request.

A node forwarding a RREP waits until it is able to disclose its key from the time interval specified; then, it appends its key from that time interval to the key list field in the reply and forwards the packet according to the source route indicated in the packet. Waiting delays the return

of the RREP but does not consume extra computational power.

When the initiator receives a RREP, it verifies that each key in the key list is valid, that the target MAC is valid, and that each MAC in the MAC list is valid. If all of these tests succeed, the node accepts the RREP; otherwise, it discards it.

To prevent the injection of invalid route errors into the network fabricated by any node other than the one on the sending end of the link specified in the error message, each node that encounters a broken link adds TESLA authentication information to the route error message, such that all nodes on the return path can authenticate the error. However, TESLA authentication is delayed, so all the nodes on the return path buffer the error but do not consider it until it is authenticated. Later, the node that encountered the broken link discloses the key and sends it over the return path, which enables nodes on that path to authenticate the buffered error messages.

ARIADNE is protected also from a flood of RREQ packets that could lead to the cache poisoning attack. Benign nodes can filter out forged or excessive RREQ packets using route discovery chains, a mechanism for authenticating route discovery, which allow each node to rate-limit discoveries initiated by any other node. The authors present two different approaches that can be found in Hu, Perrig, and Johnson (2002).

ARIADNE is immune to the wormhole attack only in its advanced version: by using an extension called TIK (TESLA with Instant Key disclosure) that requires tight clock synchronization between the nodes, it is possible to detect timing discrepancies caused by a wormhole.

ARAN

The ARAN secure routing protocol proposed by Dahill, Levine, Royer, and Shields (2002) is conceived as an on-demand routing protocol that detects and protects against malicious actions carried out by third parties and peers in the ad hoc environment. ARAN introduces *authentication*, *message integrity*, and *nonrepudiation* as part of a minimal security policy for the ad hoc environment and consists of a preliminary certification process, a mandatory end-to-end authentication stage, and an optional second stage that provides secure shortest paths.

ARAN requires the use of a trusted certificate server (T): before entering in the ad hoc network, each node has to request a certificate signed by T. The certificate contains the IP address of the node, its public key, a time stamp of when the certificate was created, and a time at which the certificate expires along with the signature by T. All nodes are supposed to maintain fresh certificates with the trusted server and must know T's public key.

The goal of the first stage of the ARAN protocol is for the source to verify that the intended destination was reached. In this stage, the source trusts the destination to choose the return path. A source node, A , initiates the route discovery process to reach the destination X by broadcasting to its neighbors a route discovery packet called RDP:

$$[\text{RDP}; \text{IP}_X; \text{cert}_A; N_A; t]K_{A-}$$

The RDP includes a packet type identifier ("RDP"), the IP address of the destination (IP_X), A 's certificate (cert_A), a nonce N_A , and the current time t , all signed with A 's private key. Each time A performs route discovery, it monotonically increases the nonce.

Each node records the neighbor from which it received the message. It then forwards the message to each of its neighbors, signing the contents of the message. This signature prevents spoofing attacks that may alter the route or form loops. Let A 's neighbor be B . It will broadcast the following message:

$$[[\text{RDP}; \text{IP}_X; \text{cert}_A; N_A; t]K_{A-}]K_{B-}; \text{cert}_B$$

Nodes do not forward messages for which they have already seen the $(N_A; \text{IP}_A)$ tuple. The IP address of A is contained in the certificate, and the monotonically increasing nonce facilitates easy storage of recently received nonces.

Upon receiving the broadcast, B 's neighbor C validates the signature with the given certificate. C then re-broadcasts the RDP to its neighbors, first removing B 's signature:

$$[[\text{RDP}; \text{IP}_X; \text{cert}_A; N_A; t]K_{A-}]K_{C-}; \text{cert}_C$$

Eventually, the message is received by the destination, X , who replies to the first RDP that it receives for a source and a given nonce. There is no guarantee that the first RDP received traveled along the shortest path from the source. The destination unicasts a reply (REP) packet back along the reverse path to the source. Let the first node that receives the RDP sent by X be node D . X will send to D the following message:

$$[\text{REP}; \text{IP}_A; \text{cert}_X; N_A; t]K_{X-}$$

The REP includes a packet type identifier ("REP"), the IP address of A , the certificate belonging to X , the nonce and associated time stamp sent by A . Nodes that receive the REP forward the packet back to the predecessor from which they received the original RDP. All REPs are signed by the sender. Let D 's next hop to the source be node C . D will send to C the following message:

$$[[\text{REP}; \text{IP}_A; \text{cert}_X; N_A; t]K_{X-}]K_{D-}; \text{cert}_D$$

C validates D 's signature, removes the signature, and then signs the contents of the message before unicasting the following RDP message to B :

$$[[\text{REP}; \text{IP}_A; \text{cert}_X; N_A; t]K_{X-}]K_{C-}; \text{cert}_C$$

A node checks the signature of the previous hop as the REP is returned to the source. This avoids attacks where malicious nodes instantiate routes by impersonation and re-play of X 's message. When the source receives the REP, it verifies that the correct nonce was returned by the destination as well as the destination's signature. Only the destination can answer an RDP packet. Other nodes that already have paths to the destination cannot reply for the destination. Whereas other protocols allow this network optimization, by disabling this option ARAN removes

several possible exploits and cuts down on the reply traffic received by the source.

The second stage of the ARAN protocol guarantees in a secure way that the path received by a source initiating a route discovery process is the shortest. Similar to the first stage of the protocol, the source broadcasts a *shortest path confirmation* (SPC) message to its neighbors: the SPC message is different from the RDP message only in two additional fields that provide the destination X certificate and the encryption of the entire message with X 's public key (which is a costly operation). The onion-like signing of messages combined with the encryption of the data prevents nodes in the middle from changing the path length because doing so would break the integrity of SPC the packet.

Also, the route maintenance phase of the ARAN protocol is secured by digitally signing the route error packets. However, it is extremely difficult to detect when error messages are *fabricated* for links that are truly active and not broken. Nevertheless, because messages are signed, malicious nodes cannot generate error messages for other nodes. The nonrepudiation provided by the signed error message allows a node to be verified as the source of each error message that it sends.

As with any secure system based on cryptographic certificates, the key revocation issue has to be addressed to make sure that expired or revoked certificates do not allow the holder to access the network. In ARAN, when a certificate needs to be revoked, the trusted certificate server T sends a broadcast message to the ad hoc group that announces the revocation. Any node receiving this message rebroadcasts it to its neighbors. Revocation notices need to be stored until the revoked certificate would have expired normally. Any neighbor of the node with the revoked certificate needs to reform routing as necessary to avoid transmission through the now distrusted node. This method is not failsafe. In some cases, the distrusted node that is having its certificate revoked may be the sole connection between two parts of the ad hoc network. In this case, the distrusted node may not forward the notice of revocation for its certificate, which results in a partition of the network, because nodes that have received the revocation notice will no longer forward messages through the distrusted node, while all other nodes depend on it to reach the rest of the network. This only lasts as long as the distrusted node's certificate would have otherwise been valid, or until the distrusted node is no longer the sole connection between the two partitions. At the time that the revoked certificate should have expired, the distrusted node is unable to renew the certificate and routing across that node ceases. Additionally, to detect this situation and to hasten the propagation of revocation notices, when a node meets a new neighbor, it can exchange a summary of its revocation notices with that neighbor; if these summaries do not match, the actual signed notices can be forwarded and rebroadcasted to restart propagation of the notice.

The ARAN protocol protects against exploits using *modification*, *fabrication*, and *impersonation* but the use of asymmetric cryptography makes it a very costly protocol to use in terms of central processing unit (CPU) and energy usage. Furthermore, ARAN is not immune to the *wormhole* attack.

SEAD

Hu, Perrig, and Johnson (2002) present a *proactive* secure routing protocol based on the destination-sequenced distance vector protocol (DSDV). In a proactive (or periodic) routing protocol, nodes periodically exchange routing information with other nodes in attempt to have each node always know a current route to all destinations (Perkins & Bhagwat, 1994). Specifically, SEAD is inspired by the DSDV-SQ version of the DSDV protocol. The DSDV-SQ version of the DSDV protocol has been shown to outperform other DSDV versions in previous ad hoc networks simulations (Broch, Maltz, Johnson, Hu, & Jetcheva, 1998; Johansson, Larsson, Hedman, Mielczarek, & Degermark, 1999).

SEAD deals with attackers that *modify* routing information broadcasted during the update phase of the DSDV-SQ protocol: in particular, routing can be disrupted if the attacker modifies the sequence number and the metric field of a routing table update message. *Replay attacks* are also taken into account.

To secure the DSDV-SQ routing protocol, SEAD makes use of efficient *one-way hash chains* rather than relying on expensive asymmetric cryptography operations. However, like the other secure protocols presented in this chapter, SEAD assumes some mechanism for a node to distribute an authentic element of the hash chain that can be used to authenticate all the other elements of the chain. As a traditional approach, the authors suggest relying on a trusted entity that signs public key certificates for each node to ensure key distribution; each node can then use its public key to sign a hash chain element and distribute it.

The basic idea of SEAD is to authenticate the sequence number and metric of a routing table update message using hash chains elements. In addition, the receiver of SEAD routing information also authenticates the sender, ensuring that the routing information originates from the correct node.

To create a one-way hash chain, a node chooses a random initial value $x \in \{0, 1\}^\rho$, where ρ is the length in bits of the output of the hash function, and computes the list of values $h_0, h_1, h_2, h_3, \dots, h_n$, where $h_0 = x$ and $h_i = H(h_{i-1})$ for $0 < i \leq n$ for some n . As an example, given an authenticated h_i value, a node can authenticate h_{i-3} by computing $H(H(H(h_{i-3})))$ and verifying that the resulting value equals h_i .

Each node uses a specific authentic (i.e., signed) element from its hash chain in each routing update that it sends about itself (metric 0). Based on this initial element, the one-way hash chain provides authentication for the lower bound on the metric in other routing updates for that node. The use of a hash value corresponding to the sequence number and metric in a routing update entry prevents any node from advertising a route to some destination claiming a greater sequence number than that destination's own current sequence number. Likewise, a node cannot advertise a route better than those for which it has received an advertisement, because the metric in an existing route cannot be decreased because of the one-way nature of the hash chain.

When a node receives a routing update, it checks the authenticity of the information for each entry in the update using the destination address, the sequence number,

and the metric of the received entry, together with the latest prior *authentic* hash value received from that destination's hash chain. Hashing the received elements the correct number of times (according to the prior authentic hash value) assures the authenticity of the received information if the calculated hash value and the authentic hash value match.

The source of each routing update message in SEAD must also be authenticated, because otherwise, an attacker may be able to create routing loops through the *impersonation* attack. The authors propose two different approaches to provide node authentication: the first is based on a broadcast authentication mechanism such as TESLA, the second is based on the use of message authentication codes, assuming a shared secret key between each couple of nodes in the network.

SEAD does not cope with *wormhole* attacks although the authors propose, as in the ARIADNE protocol, to use the TIK protocol to detect the threat.

Notes on the Wormhole Attack

The wormhole attack is a severe threat against ad hoc routing protocols that is particularly challenging to detect and prevent. In a wormhole attack, a malicious node can record packets (or bits) at one location in the network and tunnel them to another location through a private network shared with a colluding malicious node. Most existing ad hoc routing protocols, without some mechanism to defend them against the wormhole attack, would be unable to find consistent routes to any destination, severely disrupting communication.

A dangerous threat can be perpetrated if a wormhole attacker tunnels all packets through the wormhole honestly and reliably because no harm seems to be done: the attacker actually seems to provide a useful service in connecting the network more efficiently. However, when an attacker forwards only routing control messages and not data packets, communication may be severely damaged. As an example, when used against an on-demand routing protocol such as DSR, a powerful application of the wormhole attack can be mounted by tunneling each RREQ message directly to the destination target node of the request. This attack prevents routes more than two hops long from being discovered because RREP messages would arrive to the source faster than any other replies or, worse, RREQ messages arriving from other nodes next to the destination than the attacker would be discarded because they were already seen. Perrig, Hu, and Johnson propose an approach to detect a wormhole based on *packet leashes* (Perrig, Hu, & Johnson, n.d.). The key element is that by authenticating either an extremely precise time stamp or location information combined with a loose time stamp, a receiver can determine if the packet has traversed a distance that is unrealistic for the specific network technology used.

Temporal leashes rely on extremely precise time synchronization and extremely precise time stamps in each packet. The travel time of a packet can be approximated as the difference between the receive time and the time stamp. Given the precise time synchronization required by temporal leashes, the authors propose efficient

broadcast authenticators based on symmetric primitives. In particular, they extend the TESLA broadcast authentication protocol to allow the disclosure of the authentication key within the packet that is authenticated.

Geographical leashes are based on location information and loosely synchronized clocks. If the clocks of the sender and the receiver are synchronized within a certain threshold and the velocity of any node is bounded, the receiver can compute an upper bound on the distance between the sender and itself and use it to detect anomalies in the traffic flow. In certain circumstances, however, bounding the distance between the sender and the receiver cannot prevent wormhole attacks: when obstacles prevent communication between two nodes that would otherwise be in transmission range, a distance-based scheme would still allow wormholes between the sender and the receiver. To overcome this problem, in a variation of the geographical leashes, the receiver verifies that every possible location of the sender can reach every possible location of the receiver based on a radio propagation model implemented in every node.

In some special cases, wormholes can also be detected through techniques that do not require precise time synchronization nor location information. As an example, it would be sufficient to modify the routing protocol used to discover the path to a destination so that it could handle multiple routes: a verification mechanism would then detect anomalies when comparing the metric (e.g., number of hops) associated to each route. Any node advertising a path to a destination with a metric considerably lower than all the others could raise the possibility of a wormhole.

Furthermore, if the wormhole attack is performed only on routing information while dropping data packets, other mechanisms can be used to detect this misbehavior. When a node does not correctly participate in the network operation by not executing a particular function (e.g., packet forwarding), a collaborative monitoring technique can detect and gradually isolate misbehaving nodes. Lack of cooperation and security mechanisms used to enforce node cooperation with the network operation is the subject of the next section.

KEY MANAGEMENT

Authentication of peer entities involved in ad hoc routing and the integrity verification of routing exchanges are the two essential building blocks of secure routing. Both entity authentication and message integrity call for a key management mechanism to provide parties involved in authentication and integrity verification with proper keying material. Key management approaches suggested by current secure routing proposals fall in two categories:

- Manual configuration of symmetric (secret) keys: the pair-wise secret keys can serve as key encryption keys in a point-to-point key exchange protocol to establish session keys used for authentication and message integrity between communicating nodes. If some dedicated infrastructure including a key server can be afforded, automatic distribution of session keys with a key distribution protocol like Kerberos can also be envisioned.

- Public key–based scheme: each node possesses a pair of public and private keys based on an asymmetric algorithm like RSA. Based on this key pair, each node can perform authentication and message integrity operations or further exchange pair-wise symmetric keys used for efficient authentication and encryption operations.

Secure routing proposals such as SRP assume manual configuration of secure associations based on shared secret keys. Most of other proposals such as ARIADNE rely on a public–key–based scheme whereby a well-known, trusted third party (TTP) issues public key certificates used for authentication. The requirement for such a public key infrastructure does not necessarily imply a managed ad hoc network environment and an open environment can be targeted as well. Indeed, it is not necessary for the mobile nodes that form the ad hoc network to be managed by the public key certification authority. However, the bootstrap phase requires an external infrastructure, which has to be available also during the lifetime of the ad hoc network to provide revocation services for certificates that have expired or that have been explicitly revoked.

Two interesting proposals presented in the next sections tackle the complexity of public key infrastructures in the ad hoc network environment through self-organization: public key management based on the concept of “web of trust,” akin to pretty good privacy (PGP), and a public key certification mechanism based on polynomial secret sharing.

Recent solutions rely on ID-based cryptography and crypto-based ID: these two approaches try to improve public–key–based solutions by reducing the need for a centralized administration at the network bootstrap phase.

A symmetric shared key distribution protocol that allows any two nodes to share a common secret key for data confidentiality is also presented. Another interesting approach outlined in the following subsections is based on the distance-bouncing technique and provides a secure encounter tracking service to a MANET. Table 1 provides a summary of key distribution techniques available in the literature.

Public Key Management

ID, Public Key Binding with Certificates
Self-Organized Public Key Management Based on PGP
 Capkun, Buttyan, and Hubaux (2002) propose a fully self-organized public key management system that can be used to support security of ad hoc network routing protocols. The suggested approach is similar to PGP (Zimmerman, 1995) in the sense that users issue certificates for each other based on their personal acquaintances. However, in the proposed system, certificates are stored and distributed by the users themselves, unlike in PGP, where this task is performed by online servers (called certificate directories). In the proposed self-organizing public key management system, each user maintains a local certificate repository. When two users want to verify the public keys of each other, they merge their local certificate repositories and try to find appropriate certificate chains within the merged repository.

The success of this approach very much depends on the construction of the local certificate repositories and on the characteristics of the certificate graphs. The vertices of a certificate graph represent public keys of the users and the edges represent public key certificates issued by the users. The authors investigate several repository construction algorithms and study their performance. The proposed algorithms take into account the characteristics of the certificate graphs in a sense that the choice of the certificates that are stored by each mobile node depends on the connectivity of the node and its neighbors in the certificate graph.

More precisely, each node stores in its local repository several directed and mutually disjoint paths of certificates. Each path begins at the node itself, and the certificates are added to the path such that a new certificate is chosen among the certificates connected to the last node on the path (initially the node that stores the certificates) and such that the new certificate leads to the node that has the highest number of certificates connected to it (i.e., the highest vertex degree). The authors call this algorithm the maximum degree algorithm, as the local repository construction criterion is the degree of the vertices in a certificate graph.

In a more sophisticated extension called the shortcut hunter algorithm, certificates are stored into the local repositories based on the number of the shortcut certificates connected to the users. The shortcut certificate is a certificate that, when removed from the graph, makes the shortest path between two users previously connected by this certificate strictly larger than two.

When verifying a certificate chain, the node must trust the issuer of the certificates in the chain for correctly checking that the public key in the certificate indeed belongs to the node identification (ID) named in the certificate. When certificates are issued by the mobile nodes of an ad hoc network instead of trusted authorities, this assumption becomes unrealistic. In addition, there may be malicious nodes that issue false certificates. To alleviate these problems, the authors propose the use of authentication metrics (Reiter & Stybblebine, 1999): it is not enough to verify a node ID key binding via a single chain of certificates. The authentication metric is a function that accepts two keys (the verifier and the verified node) and a certificate graph and returns a numeric value corresponding to the degree of authenticity of the key that has to be verified: one example of authentication metric is the number of disjoint chains of certificates between two nodes in a certificate graph.

The authors emphasize that before being able to perform key authentication, each node must first build its local certificate repository, which is a complex operation. However, this initialization phase must be performed rarely and once the certificate repositories have been built, then any node can perform key authentication using only local information and the information provided by the targeted node. It should also be noted that local repositories become obsolete if a large number of certificate are revoked, as then the certificate chains are no longer valid; the same comment applies in the case when the certificate graph changes significantly. Furthermore, PGP-like schemes are more suitable for small communities

Table 1 Summary of Key Distribution Approaches Available in the Literature

	Identity–Public Key Binding				No Identity	
	PGP Web of Trust	Self-Organized CA Based on Secret Sharing	Identity-Based Cryptography	Crypto-Based Identity	Key Predistribution	Context-Aware
<i>Symmetric cryptography</i>					X	X
<i>Asymmetric cryptography</i>	X	X	X	X		
<i>Public key certificates</i>	YES	YES	NO	NO	NO	YES
<i>Bootstrap of security associations</i>	PGP-like	Distribution of initial shares	Secure naming for unique identifiers	Self-generated keys	Get globally trusted key–pool	Self-generated hash chains
<i>Drawbacks</i>	Initialization, storage, transitivity of trust	Distribution of initial shares, peripheral nodes	ID spoofing, distribution of initial shares, KDC knows all secret keys	Bogus identity generation	Cover-free algorithms, only shared keys, no authentication	Viable only for small networks, reliance on tight timing
<i>Advantages</i>	Distributed approach	Distributed approach	No need for certificates, distributed approach	No need for certificates, no need for certification authority	No need for certificates, distributed approach	Self-organized, distributed approach

because that the authenticity of a key can be assured with a higher degree of trustiness. The authors propose the use of authentication metrics to alleviate this problem: this approach, however, provides only probabilistic guarantees and is dependent on the characteristics of the certificate graph on which it operates. The authors also carried out a simulation study showing that for the certificate graphs that are likely to emerge in self-organized systems, the proposed approach yields good performances both in terms of the size of the local repository stored in each node and scalability.

Authentication Based on Polynomial Secret Sharing.

Luo and Lu (n.d.) present an authentication service whereby the public key certificate of each node is cooperatively generated by a set of neighbors based on the behavior of the node as monitored by the neighbors. Using a group signature mechanism based on polynomial secret sharing, the secret digital signature key used to generate public key certificates is distributed among several nodes. Certification services such as issuing, renewal, and revocation of certificates thus are distributed among the nodes: a single node holds just a share of the complete certificate signature key. The authors propose a *localized trust model* to characterize the localized nature of security concerns in large ad hoc wireless networks. When applying such trust model, an entity is trusted if any k trusted entities claim so: these k trusted entities are typically the neighboring nodes of the entity. A locally trusted entity is globally accepted and a locally distrusted entity is regarded untrustworthy all over the network.

In the suggested security architecture, each node carries a certificate signed by the shared certificate-signing key SK, whereas the corresponding public key PK is assumed to be well known by all the nodes of the network, thus certificates are globally verifiable. Nodes without valid certificates will be isolated, that is, their packets will not be forwarded by the network. Essentially, any node without a valid certificate is considered a potential intruder. When a mobile node moves to a new location, it exchanges certificates with its new neighbors and goes through mutual authentication process to build trust relationships. Neighboring nodes with such trust relationships help each other to forward and route packets. They also monitor each other to detect possible attacks and break-ins. Specific monitoring algorithms and mechanisms are left to each individual node's choice. When a node requests a signed certificate from a coalition of k nodes, each of the latter checks its records about the requesting node. If the requestor is recorded as a legitimate node, a partial certificate is computed by applying the local node's share of SK and returned to the requestor. Upon collecting k partial certificates, the requesting node combines them to generate the complete certificate of its public key as if issued by a centralized certification authority.

The multiple signature scheme used to build the certificate is based on a k -threshold polynomial secret-sharing mechanism. This technique requires a bootstrapping phase where a "dealer" has to privately send each node its share of the secret signature key SK. The authors propose a scalable initialization mechanism called "self-initialization" whereby the dealer only has to initialize the very first k nodes, regardless of the global network

span. The initialized nodes collaboratively initialize other nodes: repeating this procedure, the network progressively self-initializes itself. The same mechanism is applied when new nodes join the network.

Certificate revocation is also handled by the proposed architecture and an original approach to handle roaming adversaries is presented to prevent a misbehaving node that moves to a new location from getting a valid certificate. Roaming nodes are defeated with the flooding of “accusation” messages that travel in the network and inform distant nodes about the behavior of a suspect node.

The main drawback of the proposed architecture is the requirement for a trusted dealer that initializes the very first k nodes of a coalition to the choice of the systemwide parameter k . To cope with the first problem, the authors propose to use a distributed RSA key pair generation (Shamir, 1979) for the very first k nodes. The other major limitation of the scheme is the strong assumption that every node of the network has at least k trusted neighbors. Moreover, the authors assume that any new node that joins the system already has an initial certificate issued by an offline authority or by a coalition of k neighbors.

Implicit ID, Public Key Binding without Certificates Toward Secure Key Distribution in Truly Ad Hoc Networks. The mechanism proposed by Khalili, Katz, & Arbaugh (2003) focuses on the problem of key generation and management for peer-to-peer communication in a truly ad hoc network, that is, a network in which both an infrastructure and a centralized authority are not available.

The proposal made by Khalili et al. is based on the concept of ID-based cryptography and avoids the need for users to generate their own public keys and to distribute them throughout the network: the user’s identity acts as their public key. This significantly reduces the computation necessary to join the network. Furthermore, as opposed to a CA-based solution (Zhou & Haas, 1999) where a user is required to propagate both his public key as well as a signature (by the CA) on his public key, in an ID-based system, users need only propagate their identity (which is typically included in every message anyway). This can lead to huge savings in bandwidth.

It is important to notice that the authors do not specify either the nature of the identity to be used or a means for authenticating users’ identities before sending them (shares of) their secret key. Initial authentication of user’s identities represents an important issue that is common to CA-based solutions: the entire security of the scheme is based on the initial validation of the data (identity) that will be certified for later use. The interested reader should refer to Boneh & Franklin (2001) to gather extensive information on ID-based cryptography.

Khalili, Katz, and Arbaugh (2003) suggest that at the time of network formation, the nodes willing to form the network decide on a mutually acceptable set of security parameters. Any node that is not satisfied by the choice of parameters can choose to refuse to participate in the network. The security parameters might include a threshold t of key service nodes, the number and identity of key service nodes, particular parameters of underlying

schemes (e.g., key lengths), and a policy for key issuance. This initial negotiation is independent of the proposed scheme and the authors do not discuss it in any detail. It should be noted, though, that the initial policy negotiation is a potential target for active or byzantine adversaries, and the negotiation protocol should address this issue.

The initial set of nodes can then form a threshold key distribution center (KDC) for an ID-based scheme. These nodes will generate the master secret/public keys in a distributed manner such that fewer than t nodes cannot recover the master secret key. The master public key is given to all members of the network when they join, and the KDC can start issuing personal secret keys to nodes (including themselves) based on their identities and the key issuance policy. An identity can be something usually present in transmitted messages, like a MAC (or other network layer) address. To receive the private key corresponding to some identity, a node presents this identity and any extra material specified by the key issuance policy to t (or more) nodes forming the KDC and receives a share of their personal private key from each of them. With t correct shares, the node can then compute its personal private key within the network’s ID-based system. It is important to notice that an efficient local mechanism to check the correctness of the individual shares and the computed private key has to be provided, but the authors do not provide any further information about which mechanism should be used.

Distributing the key generation and the KDC service prevents a single point of failure and resists compromise or insider attack (up to the threshold k). In addition, distributing the KDC in a t -out-of- n fashion makes the scheme flexible when some nodes are unreachable because of ad hoc conditions (mobility, link breaks, etc.) as long as at least k are still reachable.

The authors stress that the proposed scheme makes no assumption about the “security” of users’ identities, for example, that they are set in hardware or cannot be spoofed. However, spoofing only needs to be prevented or detected by the nodes forming the KDC at the time of key issuance (and this can be done by requiring some “unspoofable” supporting material to be presented at the time of a key request). For completeness, the authors recommend a number of possibilities for user identities. One possibility is to use statistically unique cryptographically verifiable (SUCV) addresses (Montenegro & Castelluccia, 2002; applied to ad hoc networks by Bobba, Eschenauer, Gligor, & Arbaugh, 2002).

The solution presented by Khalili, Katz, & Arbaugh (2003) offers an interesting alternative to the classical certificate-based systems presented in this section and it should be noted that the authors target a fully independent ad hoc network where nodes act in a self-organized way. However, the initial establishment of a KDC using threshold cryptography *needs* the presence of an external authority or management that decides the threshold system parameters and that elects trusted nodes to participate to the initial set of nodes that form the KDC. This is obviously in contrast with the targeted self-organization characteristic of the network and a fully self-organized network setup is far from being achieved. It is important to remember that introducing new cryptographic techniques or an

original combination of existing techniques could have the sole effect of moving the problem (self-organization) one step further and only giving the illusion of a security scheme adapted to a truly self-organized network.

Bootstrapping Security Associations for Routing in Mobile Ad Hoc Networks

Bobba et al. (2002) show how to bootstrap secure associations for the routing protocols of MANETs online, without assuming any trusted authorities or distributed trust-establishment services. The proposed scheme relies on the use of *statistically unique and cryptographically verifiable* (SUCV) identifiers (Montenegro & Castellucia, 2002) and public–secret key pairs generated by the nodes themselves, in much the same way that SUCVs are used in MobileIPv6 (MIPv6) to solve the address “ownership” problem (Montenegro & Castellucia, 2002). The authors present the bootstrapping solution in the context of the dynamic source routing (DSR) protocol and argue that the solution is applicable to other secure routing protocols, such as SEAD (Hu, Johnson, & Perrig, n.d.) and ARIADNE (Hu, Perrig, & Johnson, 2002).

Bobba et al. (2002) describe a method in which, to produce an IP address that is securely bound to a public key, a node generates a 64-bit pseudorandom value by applying a one-way, collision-resistant hash function to the public key of its (uncertified) public–private key pair. Then, the IP address is generated as the concatenation of a network-specific identifier (64 bits in MIPv6) and the hash of the public key (64 bits). The binding between this IP address and the public key is secure because it is computationally unfeasible for an attacker (a) to create another <public, private> key pair whose hash generates the same IP address (because of the second preimage resistance of one-way, collision-resistant hash functions), and (b) to discover the secret key, or create a different one, for a given public key (by definition).

Because of the size of the resulting address space, this IP address is also statistically unique.

A source node can then use the secure binding to authenticate its IP address and the contents of its packets to an arbitrary destination node as follows. The node signs a packet with its private key and sends the signed packet to the destination address together with its public key (and IP address). The destination node verifies that the IP address is securely bound to the public key by computing the hash function of the received public key and comparing the result with the lower 64-bit field of the IP address. (Thus, the IP address “certifies” the validity of the public key, thereby preventing an attacker from spoofing the source address.) Then, the destination node authenticates the content of the packet by verifying the signature with the public key.

Bobba et al. (2002) propose the application of their ideas to the DSR route discovery phase, both in an asymmetric version and in a symmetric version, and analyze the performances and computational overhead of a MANET using cryptographically generated IP addresses.

It should be noted that other security solutions (Khalili, Katz, & Arbaugh, 2003) for MANET suggest relying on such a scheme to protect against spoofing attacks. However, the absence of a certification authority that validates

the information locally generated by every node can have a drastic consequence on the overall security of the scheme. Indeed, there is nothing that prevents a malicious node from generating as many public–private key pairs as needed to produce bogus IP addresses for which it can securely prove possession. The only guarantee that the scheme proposed by Bobba et al. (2002) offers is that a legitimate node can be assured to be the only owner of an IP address. As another example, the scheme proposed in Montenegro & Castellucia (2002) and in Bobba et al. (2002) could not be used to protect a MANET from identity spoofing using a cooperation enforcement mechanism based on reputation (see the Cooperation Enforcement section). Indeed, the scheme would only prevent a misbehaving node from using a legitimate node IP/ID to steal a positive reputation rating. It would allow, however, a misbehaving node to get rid of a bad reputation record simply by generating a new (verifiable) IP/ID and impersonating a new node joining the network.

Distribution of Symmetric Keys

Key Predistribution

Zhu, Xu, Setia, & Jajodia (2003) propose a symmetric pairwise secret key establishment protocol for ad hoc networks. Excluding a set-up phase where an offline key distribution center is needed, the main features of the proposed protocol are these:

- It is fully distributed—no online key server is required.
- It is computationally efficient—it relies only on symmetric cryptography.
- It is storage scalable—the storage requirements per node are independent of the size of the network.

The basic functioning of the protocol is the following: the pre-key distribution server deterministically selects a set of keys from a common key pool and delivers them to any node that wants to participate in the ad hoc network. The key selection is deterministic and based on the node identity, thus allowing any node to determine intersection/common keys with other nodes of the network.

When forming the network, any node that needs to establish a secret shared key with any other node in the network has to determine whether there is any *direct path* or *indirect path* to the desired recipient.

Consider as an example two nodes, u and v , that wish to communicate privately. Note that u and v may already share one or more keys from the pool of keys after the key predistribution phase. However, these keys are not known *exclusively* to u and v because every key of the key pool may be allocated to multiple nodes; hence, they cannot be used for encrypting any message that is private to u and v .

The goal of the proposed algorithm is to establish a key, sk , that is known exclusively to u and v . To establish sk , a sender node (say u) splits sk into multiple shares using a threshold secret-sharing scheme. It then transmits to the recipient (v) all these shares, using a separate secure *logical path* for each share. The recipient node then reconstructs sk after it receives all (or a certain number of) the shares and acknowledge the correct reception with a ciphered hello message using the common shared key.

There are *logical paths* between two nodes when (a) the two nodes share one or more keys (*direct path*) and (b) the two nodes do not share any keys, but through other intermediate nodes (called *proxies*) they can exchange messages securely (*indirect paths*). The protocol always uses any direct paths that exist between nodes in preference to indirect paths, because the use of an indirect path incurs additional computational and communication overhead.

Logical paths between two nodes can be easily found since the key predistribution algorithm is public and deterministic; a node u can independently compute the set of key IDs corresponding to a node v 's key set. Therefore, without proactively exchanging the set of its key IDs with others, a node knowing the IDs of its neighbors can determine not only which neighbors share or do not share keys with it, but also which two neighbors share which keys. The latter knowledge is very valuable when node u does not share any keys with a node v , because node u can use a neighbor (say x) that shares keys with both of them as a *proxy*. For example, suppose node u shares a key k_{ux} with node x , node v shares a key k_{vx} with node x , but no shared key exists between node u and node v .

To transmit a message M to node v securely, node u executes the following steps:

$$\begin{aligned} u &\rightarrow x : \{M\}_{k_{ux}} \\ x &\rightarrow v : \{M\}_{k_{vx}} \end{aligned}$$

The node x in the above example is called node u 's *one-hop proxy* to v . More generally, node x is said to be node u 's *i-hop proxy* if x is i hops away from u and x shares a key with both u and v respectively. If u and v do not have any direct paths or one-hop proxies to each other, they can resort to a proxy node of multiple hops away. Note that it is also possible to establish a logical path with multiple proxies involved. For example, if there is a shared key between u and x , between x and y , between y and v respectively, u and v can establish a logical path as well.

The idea proposed by Zhu, Xu, Setia, and Jajodia (2003) represents a distributed and efficient way of establishing a shared secret key between two nodes in a MANET but relies on the presence of an external authority and/or centralized management to compute and distribute the large amount of initial preshared keys. Furthermore, this limitation is accentuated by the need of undeniable and unspoofable node identities. The overall system security relies on the fact that every node is able to compute a pool of preshared keys with its neighbors to initiate a logical-path discovery to reach the desired recipient. As an example, by generating fake identities, a node could contact the pre-key distribution center and gather enough keying material to decrypt all the shares of a shared secret key and compromise the confidentiality of communication.

Context-Aware Key Management

SECTOR: Secure Tracking of Node Encounters in Multihop Wireless Networks

Chapkun, Buttyan, and Hubaux (2003) present a set of mechanisms for the secure verification of the time of encounters between nodes in multihop wireless networks with the aim of enabling any node to prove to any other

node (or base station) its encounters with other nodes before or at some specific time. SECTOR can be used as a basic mechanism to prevent the wormhole attack (see the previous discussion on wormholes), to help securing routing protocols based on history of encounters (Dubois-Ferriere, Grossglauser, & Vetterli, 2003), or to provide topology monitoring both in pure ad hoc systems and in cellular networks.

The system model and the basic assumptions made by the authors require *loose time synchronization* between all the nodes forming the network and that nodes can measure time locally with nanosecond precision. Furthermore, the authors also assume that each node is equipped with a *special hardware module* that can temporarily take over the control of the radio transceiver unit of the node from the CPU. A node can be put in a special state where it is capable of responding to a one-bit challenge with a one-bit response essentially immediately, without the delay imposed by the usual way of processing messages. Lastly, the authors assume that the bits are correctly transmitted, meaning that there are no collisions and no jamming.

Security associations are provided prior to the network formation so that each node shares a symmetric, secret key with any other node and a central authority controls the network membership and assigns a unique identity to each node.

To provide a basis for secure and authenticated proofs of encounters, the MAD (mutual authentication with distance-bounding) protocol is introduced. Based on the Brands–Chaum technique (Brands & Chaum, 1993), the MAD protocol enables any two nodes to determine their mutual distance at the time of encounter and enhances the basic scheme by avoiding the use of a digital signature in favor of a more efficient symmetric scheme. Furthermore, the commitments bits that are used in the distance-bounding technique are firstly sent in the initialization phase of the protocol and then gradually revealed when the distance evaluation takes part: this ensures that the parties cannot send bits too early, and thus cannot cheat the other party by appearing to be closer than they really are.

The MAD protocol has to be used in conjunction with the GTE (guaranteed time of encounter) mechanism that consists in the construction of a particular type of Merkle hash tree (Merkle, 1980) in which leaves also contain time information about the disclosure of the hash-chain element. The root of the tree is then distributed in an authentic way to every other node of the network.

Any two nodes willing to exchange secure proof of the time of their encounter, verifiable by any other node of the network, will have to run first the MAD protocol to mutually authenticate themselves. Then they will disclose the element of the Merkle tree that corresponds to the actual time (every node is loosely synchronized): after authentication of the disclosed proof, the nodes have to store the released tree element to subsequently prove their encounter. The authors provide a detailed study that focuses on possible enhancements of the SECTOR protocol suite to meet specific requirements resulting from the presence of an infrastructure or a limited storage capacity of the devices. The interested reader should refer to Chapkun,

Buttayan, & Hubaux (2003) to understand the different applications of SECTOR.

Although SECTOR provides a first tentative step to cope with secure tracking of node encounters in MANET, its application could be narrowed by the limiting requirements imposed by the design. The need for a deployed security infrastructure, preestablished security associations between nodes, or, in its advanced version, the use of TESLA keys for broadcasting authentic roots of the Merkle hash trees render SECTOR not adaptable to a short-lived, highly mobile, and dynamic network. In addition, the security of SECTOR relies on the presence of an external trusted authority that provides unique identities (and certificates) to the nodes of the network. If such an authority were not available, SECTOR would be vulnerable to attacks such as the forgery of proof of encounters.

Furthermore, as the authors suggest, storage requirements can be very demanding depending on the size of the network: this can be a serious limitation when considering heterogeneous MANETs formed by portable devices.

COOPERATION ENFORCEMENT

Selfishness is a new type of misbehavior that is inherent to ad hoc networks and cooperation enforcement is the countermeasure against selfishness. A selfish node does not directly intend to damage other nodes with active attacks (mainly because performing active attacks can be very expensive in terms of energy consumption), but instead it simply does not contribute to the network operation and saves battery life for its own communications. Selfishness can cause serious damage in terms of global network throughput and delay as shown by a simulation study of the effect of selfish behavior on the DSR routing protocol (Michiardi & Molva, 2002).

Current cooperation enforcement proposals for MANET can be classified as follows:

- Approaches based on threshold cryptography.
- Approaches based on micropayment.
- Approaches based on reputation.

The most significant proposals in each category are outlined in the following section. See Table 2 for a summary.

Cooperation Enforcement Mechanisms Based on Threshold Cryptography

Self-Organized Network-Layer Security in Mobile Ad Hoc Networks

Yang, Meng, & Lu (2002) suggest a mechanism whereby each node of the ad hoc network is required to hold a token to participate in the network operations. Tokens are granted to a node collaboratively by its neighbors based on the monitoring of the node's contribution to packet forwarding and routing operations. Upon expiration of the token, each node renews its token through a token-renewal exchange with its neighbors: the duration of a token's validity is based on the duration of the node's correct behavior as monitored by the neighbors granting/renewing the token. This mechanism typically allows

a well-behaved node to accumulate credit and to renew its token less frequently as time evolves.

The token-based cooperation enforcement mechanism includes four interacting components: neighbor verification through which the local node verifies whether neighboring nodes are legitimate, neighbor monitoring that allows the local node to monitor the behavior of each node in the network and to detect attacks from malicious nodes, intrusion reaction that assures the generation of network alerts and the isolation of attackers, and security-enhanced routing protocol that consists of the ad hoc routing protocol including security extensions.

A valid token is constructed using a group signature whereby a mechanism based on polynomial secret sharing (Shamir, 1979) assures that at least k neighbors agree to issue or renew the token. The key set-up complexity of polynomial secret sharing and the requirement for at least k nodes to sign each token both are incompatible with high mobility and call for a rather large and dense ad hoc network. Furthermore, the duration of a token's validity increases proportionally with the duration of the node's correct behavior as monitored by its neighbors; this feature again calls for low mobility. The token-based cooperation enforcement mechanism is thus suitable for ad hoc networks where node mobility is low. Spoofing attacks, through which a node can request more than one token by claiming a different identity, are not taken into account by the proposal even if the authors suggest that MAC addresses can be sufficient for node authentication purposes.

Cooperation Enforcement Mechanisms Based on Micropayment Schemes

Nuglets

Buttayan and Hubaux (2001) present two important issues targeted specifically at the ad hoc networking environment: first, end users must be given some incentive to contribute in the network operation (especially to relay packets belonging to other nodes) and second, end users must be discouraged from overloading the network. The solution consists of a virtual currency called nuglets, which is used in every transaction. Two different models are described: the packet purse model and the packet trade model. In the packet purse model, each packet is loaded with nuglets by the source and each forwarding host takes out nuglets for its forwarding service. The advantage of this approach is that it discourages users from flooding the network, but the drawback is that the source needs to know exactly how many nuglets it has to include in the packet it sends. In the packet trade model, each packet is traded for nuglets by the intermediate nodes: each intermediate node buys the packet from the previous node on the path. Thus, the destination has to pay for the packet. The direct advantage of this approach is that the source does not need to know how many nuglets need to be loaded into the packet. On the other hand, because the packet generation is not charged, malicious flooding of the network cannot be prevented. There are some further issues that have to be solved: in the packet purse model, the intermediate nodes are able to take out more nuglets than they are supposed to; in the packet trade model, the

Table 2 Summary of Cooperation Enforcement Techniques Available in the Literature

	Token Based	Nuglets	Sprite	I-Pass	CONFIDANT	CORE
<i>Incentive</i>	Participation Token	Virtual currency	Virtual currency	Auctions	Reputation	Reputation
<i>Punishment</i>	Impact on route selection	Network utilization prevented	Network utilization prevented	Low bandwidth	Impact on route selection	Gradual exclusion from network utilization
<i>Monitoring Technique</i>	Watchdog	N/A	N/A	N/A	Watchdog	Watchdog
<i>Reintegration</i>	Not provided	N/A	N/A	N/A	Need for specific mechanism	Inherent
<i>Need for Security Infrastructure</i>	YES	YES	YES	YES	NO	NO
<i>Drawbacks</i>	Need for security infrastructure	Tamper proof hardware Need for security infrastructure Need for tamper proof hardware Credits per route evaluation	Credit Clearance Service Need for security infrastructure Credit Service Low mobility required	Credit Clearance Service Reliance on watchdog Credit Service Complexity of auction scheme	Need for a reintegration mechanism Reputation propagation can be a weakness	Reliance on watchdog No reputation propagation
<i>Advantages</i>	No need for watchdog	No need for a Credit Service	No need for tamper proof hardware	Integration in real business scenarios	Reputation propagation	Low storage and computational requirements Functional reputation evaluation

intermediate nodes are able to deny the forwarding service after taking out nuglets from a packet.

Sprite

As opposed to the Nuglets approach, the proposal presented by Zhong, Chen, & Yang (2003) does not require a tamper-proof hardware. At a high level, the basic scheme of sprite can be described as follows. When receiving a message, a node keeps a signed receipt of the message generated by the source node. Later, when the node has a fast connection to a credit clearance service (CCS), it reports to the CCS the messages that it has received and forwarded by uploading its receipts. The CCS then determines the charge and credit to each node involved in the transmission of the message, depending on the reported receipts.

The main objectives of sprite consist in stimulating nodes to cooperate and preventing cheating by making it unattractive. The overall system architecture can be described as follows. To identify each node, the authors assume that each node has a public key certificate issued by a scalable certificate authority such as those proposed by Zhou & Hass (1999) and Luo and Lu (n.d.). When a

node sends its own messages, the node will lose credit (or virtual money) to the network because other nodes incur a cost to forward the messages. On the other hand, when a node forwards others' messages, it should gain credit and therefore be able to send its messages later. There are two ways for a node to get more credit. First, a node can pay its debit or buy more credit using real money, at a variable rate to the virtual money, based on the current performance of the system. However, the preferred and dominant way to get more credit is by forwarding others' messages. To get credit for forwarding others' messages, a node needs to report to the CCS which messages it has helped to forward by presenting a valid message receipt. The choice of charging only the source (and not the destination) of a message derives from the fact that it prevents nodes to flood the network with useless messages.

The authors provide a detailed study of the payment/charging scheme parameters to make cooperation attractive and cheating behavior unappealing based on game theory. However, it can be argued that the basic assumptions made when providing an analytical study of the solution of the game are somehow misleading: indeed, the

authors assume that a node is following the truth-telling strategy when a node truly received a message and reports a valid receipt to the CCS. Unfortunately, the key feature of the sprite protocol, namely the receipt used as a proof of forwarding, could constitute a weak point of the system. A receipt is generated by the source of a message, signed with the source's secret key and appended to the message that needs to be forwarded. Subsequent nodes on the path just need that receipt that can be gathered both by receiving the message (but not necessarily forwarding it) and by colluding with other nodes. The authors took into account this possibility when modeling the problem in game theoretical terms: indeed, system parameters are designed and tuned such that collusion does not pay. However, if the nodes had other means of exchanging receipts other than using their radio interfaces, then collusion and cheating could become attractive.

iPass

In the following approach, the authors adopt the "pay for service" model of cooperation and propose an auction-based incentive scheme to enable cooperative packet forwarding behavior in MANET. In iPass, each router constitutes a "smart market," where an auction process runs continuously to determine who should obtain how much of the bandwidth and at what price. The bidders are the set of traffic flows currently passing that router. Each flow carries a bid indicating its willingness to pay for the forwarding service. Based on these bids, the router runs a "generalized Vickrey auction" to determine the bandwidth allocation for the flows. A remarkable property of this auction is that it is *incentive compatible* for the users to place a bid equal to their true utilities for bandwidth. A user's utility for bandwidth reflects the valuation (or satisfaction) of the user if she is given such bandwidth, which may depend on the application being used.

Incentive compatible means that a user has no incentive to deviate from this bidding strategy, because it leads to higher payoff for the user, defined as the user's utility of winning the goods less the price to pay. Therefore, the user's bidding strategy is greatly simplified, and the outcome of the auction is *efficient*, meaning that it gives bandwidth to those users who need them the most.

From an end-to-end point of view, a flow usually travels through multiple hops (or auction markets) where it is allocated different amounts of bandwidth. This information is carried with each data packet to the receiver and returned to the sender as feedback, part of a *signaling protocol*. The sender should then police its rate in compliance with the allocated bandwidth. Therefore, besides creating an incentive for packet forwarding, the iPass scheme also assumes the task of flow control and possesses certain "differentiated service" capabilities based on the bids of the flows.

The reader interested in details of the generalized Vickrey auction scheme is advised to refer to Chen and Nahrstadt (2004) and MacKie-Mason and Varian (1994, 1995). It is important to notice here that the design of the iPass mechanism is incomplete: the authors suggest referring to Zhong, Chem & Yang (2003) to find guidelines to complete it with a payment protocol that allows the

router node to claim a reward for forwarding the packet, for example, by saving a "receipt" of the packet, similar to sprite. Detail integration of the iPass scheme with a secure payment and auditing system remains a future direction.

As opposed to other cooperation enforcement schemes presented in this chapter, iPass appears very interesting because its inherent features makes it easy to integrate in real business scenarios. However, the main drawback of iPass is the general complexity of the auction scheme. It is sometimes important to keep in mind that a cooperation enforcement scheme is designed to cope with node selfishness that derives mainly from a limited quantity of energy available to mobile nodes. The continuous execution of a heavy cooperation enforcement mechanism could have serious consequences on the energy consumption of a node, which in turn would have the tendency to behave selfishly.

Cooperation Enforcement Mechanisms Based on Reputation

CONFIDANT

Buchegger and Le Boudec (2002, n.d.) proposed a technique called CONFIDANT (cooperation of nodes, fairness in dynamic ad hoc networks) that aims to detect malicious nodes by combining monitoring and reporting and by establishing routes by avoiding misbehaving nodes. CONFIDANT is designed as an extension to a routing protocol such as DSR. CONFIDANT components in each node include a network monitor, reputation records for first-hand and trusted second-hand observations about routing and forwarding behavior of other nodes, trust records to control trust given to received warnings, and a path manager to adapt the behavior of the local node according to its reputation and to take action against malicious nodes. The term reputation is used to evaluate routing and forwarding behavior according to the network protocol, whereas the term trust is used to evaluate participation in the CONFIDANT metaprotocol.

The dynamic behavior of CONFIDANT is as follows. Nodes monitor their neighbors and change their reputation accordingly. If they have a reason to believe that a node misbehaves, they can take action in terms of their own routing and forwarding and they can decide to inform other nodes by sending an ALARM message. When a node receives such an ALARM either directly or by promiscuously listening to the network, it evaluates how trustworthy the ALARM is based on the source of the ALARM and the accumulated ALARM messages about the node in question. It can then decide whether to take action against the misbehaving node in the form of excluding routes containing the misbehaving node, reranking paths in the path cache, reciprocating by noncooperation, or forwarding an ALARM about the node.

The first version of CONFIDANT was, despite the filtering of ALARM messages in the trust manager, vulnerable to concerted efforts of spreading wrong accusations. In a recent enhancement of the protocol, this problem has been addressed by the use of Bayesian statistics for classification and the exclusion of liars.

Simulations with nodes that do not participate in the forwarding function have shown that CONFIDANT can cope well, even if half of the network population acts maliciously. Further simulations concerning the effect of second-hand information and slander have shown that slander can effectively be prevented while still retaining a significant increase in detection speed as compared with using merely first-hand information.

The limitations of CONFIDANT lie in the assumptions for detection-based reputation systems. Events have to be observable and classifiable for detection, and reputation can only be meaningful if the identity of each node is persistent; otherwise, it is vulnerable to spoofing attacks.

CORE

The security scheme proposed by Michiardi and Molva (2002a, 2002b) stimulates node cooperation by a collaborative monitoring technique and a reputation mechanism. Each node of the network monitors the behavior of its neighbors with respect to a requested function and collects observations about the execution of that function: as an example, when a node initiates a route request (e.g., using the DSR routing protocol), it monitors its neighbors' processing of the request, whether with a route reply or by relaying the route request. If the observed result and the expected result coincide, then the observation will take a positive value; otherwise, it will take a negative value.

Based on the collected observations, each node computes a reputation value for every neighbor using a sophisticated reputation mechanism that differentiates between subjective reputation (observations), indirect reputation (positive reports by others), and functional reputation (task-specific behavior), which are weighted for a combined reputation value. The formula used to evaluate the reputation value avoids false detections (caused for example by link breaks) by using an aging factor that gives more relevance to past observations: frequent variations on a node behavior are filtered. Furthermore, if the function that is being monitored provides an acknowledgement message (e.g., the route reply message of the DSR protocol), reputation information can also be gathered about nodes that are not within the radio range of the monitoring node. In this case, only positive ratings are assigned to the nodes that participated to the execution of the function in its totality.

The CORE mechanism resists attacks performed using the security mechanism itself: no negative ratings are spread between the nodes, so it is impossible for a node to maliciously decrease another node's reputation. The reputation mechanism allows the nodes of the MANET to gradually isolate selfish nodes: when the reputation assigned to a neighboring node decreases below a predefined threshold, service provision to the misbehaving node will be interrupted. Misbehaving nodes can, however, be reintegrated in the network if they increase their reputation by cooperating to the network operation.

As for the other security mechanism based on reputation, the CORE mechanism suffers from the spoofing attack: misbehaving nodes are not prevented from changing their network identity, which allows the attacker to elude the reputation system. Furthermore, no simulation results

prove the robustness of the protocol even if the authors propose an original approach based on game theory to come up with a formal assessment of the security properties of CORE.

VALIDATION OF COOPERATION ENFORCEMENT MECHANISMS THROUGH GAME THEORY

The main issue encountered when validating cooperation enforcement mechanisms is that in general they cannot be analyzed with the common validation techniques used for conventional security protocols. The reason that makes cooperation enforcement mechanisms difficult to assess is that a large fraction of current proposals provide only a fuzzy discrimination between legitimate nodes and misbehaving nodes: in general, it is hard to obtain a formal description of a mechanism that does not offer a boolean output.

Furthermore, especially for those mechanisms based on virtual currency or on reputation, a natural way to model the basic functioning of cooperation schemes that emerged in the literature is based on principles that take inspiration from microeconomic theory.

In particular, game theory appeared to be a very useful tool to validate and analyze cooperation enforcement mechanisms because it can be used to model conflict situations in which two or more parties have to evaluate which strategy they should follow to reach higher degrees of satisfaction. Specifically, players of a game can be modeled as rational and selfish entities; this modeling aims to maximize a utility function that grasps the nature of the interaction between them. The similarities of game theoretical models with the node selfishness problem in MANET recently attracted many researchers, and a growing number of proposals are available in the literature.

Before giving the details of the most significant proposals, it is interesting to answer the following question. If game theory can be used to model the interactions between nodes in a MANET, even with a high accuracy, is it better to begin with the design of a cooperation enforcement mechanism and then analyze it using game theory, or use game theory to provide a general model of an ad hoc network and derive the guidelines to design a cooperation enforcement mechanism? Obviously, the answer is not simple and in the next section, both approaches will be presented. One straightforward observation is that game theoretical modeling also has some limitations and it appears from the current proposals that security-related problems cannot be fully captured by a general model. Specifically, it is hard to model the situation in which the cooperation enforcement mechanism itself can be used to perform attacks against legitimate nodes. A basic example to explain this situation and that has been highlighted in the previous section is related to identity spoofing: even if the cooperation enforcement mechanism promises to stimulate node cooperation, the absence of a security infrastructure that provides unique and provable identity can jeopardize the network operation. The direct consequence is that most of the proposals based on

a general game theoretical framework rely on restricting assumptions that are not used by mechanisms designed with security-related problems in mind.

General Framework

Srinivasan, Nuggehalli, Chiasserini, & Rao (2003) provide an analytical approach to study cooperation in MANET. The authors use a game theoretical framework to model the node selfishness problem: selfish nodes aim to preserve their available energy for their own communications but do not intentionally want to damage other nodes in the network (malicious nodes are neglected). No collusion between selfish nodes is assumed. In their work, the authors consider a finite population of N nodes. Each node, depending on its type (e.g., laptop, PDA, cell phone), is associated with an average power constraint. This constraint can be derived by dividing the node's initial energy allocation by its lifetime expectation. It is also assumed that time is slotted, that each session lasts for one slot, and that the traffic model is connection oriented. At the beginning of each slot, a source, destination, and several relays are randomly chosen out of the N nodes to form an ad hoc network. The source requests the relay nodes in the route to forward its traffic to the destination. If any of the relay nodes rejects the request, the traffic connection is blocked.

For each node, the authors define the normalized acceptance rate (NAR) as the ratio of the number of successful relay requests generated by the node to the number of relay requests made by the node. This quantity is an indication of the throughput experienced by the node. Then, the authors study the optimal tradeoff between the lifetime and NARs of the nodes. In particular, given the energy constraints and the lifetime expectation of the nodes, a set of feasible NARs is identified.

Because users are self-interested and rational, there is no guarantee that they will follow a particular strategy unless they are convinced that they cannot do better by following some other strategy. In game theoretic terms, a set of strategies which constitute a Nash equilibrium has to be identified. Ideally, the authors would like the Nash equilibrium to result in the rational and Pareto optimal operating point, that is, values of NAR such that a node cannot improve its NAR without decreasing some other node's NAR.

To achieve the equilibrium, the authors propose a cooperation enforcement mechanism (which they define as a distributed and scalable acceptance algorithm) called generous tit-for-tat (GTFT). The authors then prove that GTFT is a Nash equilibrium that converges to the rational and Pareto optimal NARs. The interested reader should refer to Srinivasan et al. (2003) for details on the modeling of node interactions in ad hoc networks.

It is important here to notice that the authors started with a generic node model and came up with a cooperation enforcement mechanism in which nothing but a well-known strategy profile can be found in the literature.

The limitations of a generic game theoretical approach to design a mechanism to cope with node selfishness clearly emerge, because some basic assumptions about the operation setting of the network cannot be taken into account following such a method. Specifically, the

authors do not specify the nature of the ad hoc network. It is well known in the literature that ad hoc networks can be classified (among the possible classifications) as "open/self-organized" or "managed." In the first case, which is the one that attracted recent studies on cooperation enforcement mechanisms, no a priori trust can be assumed among the nodes of the network. If the network is completely self-organized, it means also that no external authority or infrastructure can be used to set up trust relationships among the nodes. There is no security mechanism available in the literature that solves (in a fully self-organized way) the interesting problem of key distribution in this type of networks. This means that it would be impossible to securely provide the "energy class" information that is a necessary requisite for the system model presented by the authors: in the discussion session, they admit the need for such a secure mechanism.

This first important observation confirms that the basic functioning of a cooperation enforcement mechanism derived from a game theoretical modeling could be jeopardized in the realistic scenario in which nodes do not correctly advertise their energy class. It follows the need for a complementary security mechanism to cope with this new type of misbehavior introduced by the cooperation enforcement mechanism itself.

By studying the GTFT acceptance algorithm, it is possible to evince some other interesting observations. The GTFT has been proposed to promote cooperation in the classical iterated prisoner's dilemma (Myerson, 1991; Axelrod, 1984; Osborne & Rubinstein, 1994) and is based on the tit-for-tat (TFT) strategy. In the general TFT policy selection for an iterated prisoner's dilemma game, a player cooperates on the first move and then copies her opponent's last move for all subsequent moves. The information on the other players' moves is gathered by an acknowledgment mechanism introduced by the authors in the "system model" section of Srinivasan et al. (2003). However, the network load is increased with some "control" traffic with the aim of providing a feedback mechanism for the decision-making algorithm. Every extra packet that needs to be sent costs some additional energy that has to be spent by the nodes of the network. When considering selfish nodes that are inclined to save energy for their own communications, it is questionable to think that they would spend more energy to "execute" the cooperation algorithm. However, thanks to theorem 2 through theorem 4, it is proved that a selfish node is better off executing correctly the acceptance policy algorithm. What happens if the acknowledgement messages used to estimate the other players' strategies are lost? Which is the consequence on the policy guessed by the "observing" node? What happens if the feedback information is fabricated to cheat? Again, the answer to these basic questions has to be found in some additional security mechanisms that render the initial cooperation enforcement mechanism heavier and more complex.

Game Theoretical Analysis of CORE

Michiardi and Molva (2003, n.d.) propose a game theoretical analysis of CORE (Michiardi & Molva, 2002a), which is outlined in a previous section. As opposed to the analysis proposed in that section, the authors first design

the cooperation enforcement mechanism and then propose an analysis based on both uncooperative and cooperative game theory to assess the features of CORE.

With the uncooperative game theory approach, the authors model the interaction between any pair of nodes that belong to a valid path from a source to a destination, focusing on the strategy selection phase (forwarding policy) when a node requests that the other node forward packets that belong to a traffic flow. In a first phase, only selfish nodes are taken into account, and the game theoretical model is based on a node-centric evaluation of the action (fraction of packets that will be forwarded) that has to be selected. In this particular scenario, the authors demonstrate that without the support of a cooperation enforcement mechanism, the best strategy for a selfish node that tries to maximize its utility function is to save energy by refraining to forward packets on behalf of the requesting nodes. In a second phase, two random neighboring nodes involved in forwarding packets from a source to a destination are considered, where one node is selfish and the other one uses CORE to stimulate and eventually enforce the cooperation of its selfish neighbor. The authors only provide numerical results that highlight the behavior of the selfish node when asked to forward different type of traffic flow (uniform and random). Results are then compared with the TFT strategy.

By using a cooperative game theory approach, the authors model the selfishness problem, both with a node-centric and network-centric perspective, by adopting the ERC theory. In this setting, the authors aim to find a lower bound to the size of a coalition of cooperating nodes and to assess the ability of CORE to stimulate nodes to join the coalition. Although the formalization of the CORE mechanism in the function that defines the strategy selection of nodes is somewhat vague, it is interesting to notice how cooperative game theory can be used to assess the features of a cooperation enforcement mechanism as a coalition formation algorithm. Furthermore, the authors demonstrate that under the hypothesis that CORE can be used to balance the weight that a selfish node gives to the network-centric metric, as compared with the node-centric metric, the minimum size of a coalition of cooperating nodes corresponds at least to half of the network population.

A first observation that can be derived from the work presented by Michiardi and Molva is that game theory can be used not only as a powerful tool to understand the functioning of a particular cooperation enforcement mechanism but also as an effective technique for the fine-tuning of the mechanism under study. The advantage of the approach proposed by Michiardi and Molva (2003, n.d.) as opposed to a generic game theoretical framework is that the cooperation enforcement mechanism can be tailored to meet the security and robustness requirements of the particular environment of operation. As an example, the CORE mechanism does not suffer from attacks exploiting messages exchanged by nodes as in the one derived by Srinivasan et al. (2003), and this is because the authors designed the system without having to deal with the limitations imposed by a prior simplification resulting from the game theoretical modeling.

However, the drawback of the approach proposed by Michiardi and Molva consists in the complexity of

introducing an analytical representation of a cooperation enforcement mechanism that is not designed to fit in a game theoretical framework. Precisely, the main criticism directed to the approach in Michiardi and Molva (n.d.) is that the function describing the way nodes decide which is the strategy to be taken in a particular situation (the utility function) is not compliant with the desirable properties of the classical utility functions used in game theory. The implication is that the authors were able to obtain some interesting numerical results, but no analytical results were provided.

CONCLUSION

Despite the lack of maturity of ad hoc networks, the security thereof has gathered much attention from the research community because of the novelty of their requirements as compared with classical networks. Research activities in ad hoc network security fall in one of three areas: routing security, key management, and cooperation enforcement. In spite of the large number of solutions, ad hoc routing does not seem to raise any new security requirements with respect to routing in classical networks, apart from key management problems that are addressed by a large class of original work in a specific category.

Key management approaches try to answer the hard question of how to establish security associations with no a priori knowledge, no a priori trust, and lack of infrastructure. Several original key management schemes based on advanced cryptographic constructs such as threshold cryptography and ID-based cryptography are suggested but they all fall short of meeting the ultimate goal of building a keying infrastructure “from scratch” because they all involve an initial key set-up phase. Cooperation enforcement is another original requirement raised by ad hoc networks. Several approaches are suggested to tackle this problem but solutions still are in their infancy with respect to real-life scenarios and integration with basic networking functions.

GLOSSARY

Ad Hoc Routing Routing is a core concept of the Internet and many other networks. Routing provides the means of forwarding logically addressed packets from their local subnetwork toward their ultimate destination. In large networks, packets may pass through many intermediary destinations before reaching their destination. Routing occurs at layer 3 of the OSI seven-layer model. Ad hoc network routing protocols appear in networks with no or little infrastructure.

Asymmetric In the context of encryption, a type of cryptographic system in which a participant publishes an encryption key and keeps private a separate decryption key. These keys are respectively referred to as public and private. RSA and D-H are examples of asymmetric systems. Asymmetric is synonymous with public key.

Digital Signature In cryptography, digital signatures are a method of authenticating digital information.

Game Theory Game theory is a branch of mathematics that uses models to study interactions with formalized

incentive structures (“games”). It has applications in a variety of fields, including economics, evolutionary biology, political science, and military strategy. Game theorists study the predicted and actual behavior of individuals in games, as well as optimal strategies. Seemingly, different types of interactions can exhibit similar incentive structures, thus all exemplifying one particular game.

Hash Function A hash function is a function that converts an input from a (typically) large domain into an output in a (typically) smaller range (the hash value, often a subset of the integers). A good hash function is one that experiences few hash collisions in the expected domain of strings it will have to deal with; that is, it would be possible to uniquely identify most of these strings using this hash.

Key A short data string parameterizing the operations within a cipher or cryptosystem and whose distribution determines relationships of privacy and integrity among communicating parties.

Key Pair The combination of a public and private key.

MAC In cryptography, a message authentication code (MAC) algorithm (also keyed-hash function) is an algorithm for generating a short string of information used to authenticate a message.

PKI In computing, a PKI (public key infrastructure) is an arrangement, usually carried out by software at a central location and other coordinated software at distributed locations, which provides for third-party (often termed a “trusted third party”) vetting and vouching for user identities and for binding of public keys to users and vice versa. The term is used to mean both the certificate authority and related arrangements as well as, more broadly and somewhat confusingly, to mean use of public key algorithms in electronic communications. The later sense is erroneous because PKI methods are not necessary to use public key algorithms.

Private Key In an asymmetric or public key cryptosystem, the key that a communicating party holds privately and uses for decryption or completion of a key exchange.

Public Key In an asymmetric or public key cryptosystem, the key that a communicating party disseminates publicly.

Public Key Certificate A public key certificate is a block of bits containing, in a specified format, the public half of an asymmetric key algorithm key pair (the “public key”), together with identity information, such as a person’s name, e-mail address, title, phone number, etc., together with the digital signature of all the data of some person or entity. They are also called identity certificates. In a typical PKI scheme, the signature will be of a certificate authority (CA). In a web of trust scheme, the signature is of either the user (a self-signed certificate) or other users (“endorsements”). In either case, the signature(s) on a certificate attest that the identity information and the public key belong together.

Secret Sharing In cryptography, secret sharing is a technique to distribute trust among a group of

participants, allowing access to the secret only by those who share some predetermined number of parts of a secret. Adi Shamir and George Blakley independently invented it in 1979.

Spoofing In computer networking, the term Internet protocol spoofing (IP spoofing) is the creation of IP packets with a forged (spoofed) source IP address.

Symmetric A symmetric key algorithm is an algorithm for cryptography that uses the same cryptographic key to encrypt and decrypt the message. Symmetric key algorithms are generally much faster to execute electronically than asymmetric key algorithms. The disadvantage of symmetric key algorithms is the requirement of a shared secret key, with one copy at each end. Because keys are subject to discovery by a cryptographic adversary, they need to be changed often and kept secure during distribution and in service.

Tamper-Proof Hardware A system is said to be tamper-resistant if it is difficult to modify or subvert, even for an assailant who has physical access to the system. A common form of tamper resistance is a device or subsystem that contains information that is difficult to extract even with direct physical access. Tamper resistance finds application in smart cards and set-top boxes.

Wormhole A wormhole is a hypothetical topological modification of the network that is essentially a “short-cut” from one point to another point in the network, which allows packets to travel between them faster than it would take through a normal route.

INTRODUCTION

Defining the concept of a “security product” is a difficult issue. Certain products are designed with security as their primary purpose. For example, the existence of firewalls, smart cards, or intrusion detection systems can only be explained by security reasons. On the other hand, products such as operating systems, word processors, or e-mail clients have other functionalities they must fulfill; otherwise, they cannot be sold, regardless of their security. However, security is still a critical issue in this latter group, too. Security is often not a product by itself, but a requirement that all products should fulfill to a certain degree. In this sense, every IT product can be considered a security product.

It might be relatively easy to evaluate the usability of a product by testing some of the most frequent scenarios. However, the security of a product is a lot harder to assess. Although it can be easy to predict and examine scenarios users are most likely to come across, we often do not know in advance what strategy the future malicious attacker will follow (Anderson & Needham, 1996).

In this chapter, an overview of existing security standards is presented. Several approaches exist for the assessment of the security of a product or a system; the main points are summarized in the second section. In the third section, an overview of Common Criteria, the internationally accepted criteria for the technical evaluation of security products, is presented. We introduce the key definitions and give some insight into the Common Criteria approach to security evaluation. In the fourth section, some practical aspects of Common Criteria are presented. International treaties and schemes that allow the mutual acceptance of the criteria are introduced, and the trends in Common Criteria evaluations are also examined. Finally, criticism from literature on the Common Criteria approach is reviewed.

APPROACHES FOR ASSESSING SECURITY

Approaches

The evaluation of the security of an IT product is a complex issue. Even professionals who specialize in IT security require a significant amount of time and resources to perform such a task. Many customers have neither the knowledge nor the resources to perform an in-depth evaluation. Moreover, it is often up to investors or managers and not IT professionals to make the decisions of choosing among various competing IT products. Such people may seek guidance from security standards to determine which product is more secure. On the other hand, developers may also choose to develop their product in accordance with these standards to ensure that it will fulfill them, so that they can claim that their product is secure. Several standards offer tools for security evaluation. Although they may vary in scope and technological detail they all follow one or more of the following three main approaches:

1. Evaluation of the *security of a product* is the simplest approach. In the case of tangible products, customers are primarily interested in the results of this approach, because they may easily rely on such evaluations when choosing among various competing products. However, if the product is complex, such evaluation may not be feasible. Unfortunately, IT products are not only very complex, but their life cycle is very short, too. Even if an IT product is not evaluated as a black box which means evaluators gain insight into its internal mechanisms, its security evaluation may still be very complex. For example, evaluating the source code of software products is not only long and time-consuming but is unlikely to uncover all errors unless formal methods are used.

Thus, the task is often simplified and is performed on a higher level of abstraction, so not the product but its production is evaluated.

2. Evaluation of the *security of production* may prove that the product was designed with security in mind. In this case, the manufacturer has to prove that threats and security issues were considered at each step of production. Note that in this case, the target of evaluation is not the product that the customer may buy but rather a business process of the manufacturer. Although customers may still rely on the results of such an evaluation to choose among products with security based on indirect proofs, it is often more useful for the investor who invests capital into the production. This way the investor can be convinced that no fatal mistakes were made during design or production. Manufacturers may also rely in court on the results of such evaluation if customers complain that the product is insecure.

In a case of intangible products (such as services), customers are more interested in such evaluations, because in this case the product and the production are highly interconnected. They may gain confidence that the manufacturer (or service provider) outputs products (or services) with a constant quality.

3. Evaluation of the *security of the producer* (the company) is a generalization of the previous approach that extends evaluation to all business processes of a company. Such evaluation gives confidence that the management of the company considers security a critical issue, and the company outputs products that were designed with quality and security in mind. Some companies choose suppliers that have undergone such an evaluation.

In the preceding paragraphs, the words *quality* and *security* were used in parallel. Although they are not synonyms of each other, they are strongly interconnected. Although quality is difficult to define, one thing seems to be obvious: an insecure product cannot have high quality. For example, one widespread definition of quality is “conformance to specifications” (Crosby, 1995). Another definition for quality is “conformance to customer expectations” (Oakland, 1992). Thus, if customers expect a product to be secure, and find it insecure, they perceive that it has bad quality. Because security is a vital component of quality, quality management methods are also going to be considered as methods to increase security.

How Can We Assess the Security of a Production?

Because most products are too complex to be assessed directly, many methods choose to assess the process of production (or all processes in the organization that perform the production) instead. When assessing a process, it is examined to determine if certain principles of security engineering were used when the product was designed and created.

The design of a secure product should involve some kind of risk analysis. It is hard to speak about the security of a product unless it is—at least informally—examined

against which threats it is supposed to be secure. Usually, a risk analysis needs to be performed that involves the identification of threats, the estimation of the amount of damage they cause, and the probability that they are likely to occur. Based on these values, a certain degree of risk can be assigned to each threat. The designer of the product should implement countermeasures to reduce such risks.

When the security of the production is assessed, it should be determined if such a risk analysis has been performed. It should also be determined if the set of risks the designer chose to reduce is sound and if the selected countermeasures cost-effectively reduce the selected risks.

Today’s systems are usually not monolithic: they consist of components. Certain countermeasures require dedicated components in a system with security as their main purpose. (For example, a dedicated component for user authentication or one for the management of the access rights of a user.)

Generally, it is very hard to make a product secure *after* its production is finished. It is also considered to be very hard to increase the security of the system simply by adding components to it. Most methods of assessing the security require that security was a main concern from the very beginning. Based on the risk analysis, certain principles have to be formulated at the first stages of design, and formulation of principles at further stages (of design and implementation) may not be sufficient. Introducing security to a product in the early stages of design not only makes it more secure, it also lowers the cost of creating a secure product.

When the security of the production is assessed, it should be determined if these principles were formulated at the beginning and consciously followed throughout the entire process of production.

Other countermeasures are not restricted to one component but can be best practices or principles applied in components that have other purposes in the system. Some vulnerabilities do not originate from bad design but merely from bad implementation. These vulnerabilities should be reduced in the whole system.

Buffer overflow attacks are typical examples for this phenomenon. A buffer overflow vulnerability originates from a local blunder in the implementation, and sometimes it compromises the security of a whole system. In well-designed systems, an attacker who exploits a buffer overflow vulnerability does not gain access to other components of a system. However, a buffer overflow vulnerability can be combatted locally too.

A developer may choose to use tools and environments that simply do not allow this kind of attack. For example, the Java language always checks if an index is outside the boundaries of an array and raises an exception if it is so. If for some reason it is not possible to use such tools to prevent the attack, the developer should introduce policies to reduce this vulnerability. For example, programmers should be made conscious of this attack, they should be trained how to write code that does not have such vulnerabilities, and they should be motivated to follow these instructions. Still, it is advised to check or inspect the code they write for buffer overflow vulnerabilities.

When the security of the production is assessed, it should be determined if known best practices and principles were applied during the production and how they were enforced and documented.

Several standards exist that give a wide range of tools and methods both for development and assessments.

Overview of Standards

Various standards exist to evaluate security. In the rest of this section, a brief overview of the most important security standards follows. For a more detailed comparison see Initi@tive D²¹ (2001).

Common Criteria

The Common Criteria (CC) are result of an international cooperation to formulate mutually recognized common criteria for standardized security evaluation. The CC were founded by the sponsoring organizations of the existing U.S. (TCSEC), European (ITSEC), and Canadian (CTCPEC) criteria in 1996 (CC, 2004). The Common Criteria are “a library of standard security requirements to aid the specification and evaluation of IT products and systems” (Towns, 2000). The CC can be applied to any kind of product (or system), regardless of its type. Unlike previous standards (e.g., TCSEC), CC differentiates between which security features a product has (functional requirements) and how much confidence we have in these features (assurance requirements). A Common Criteria evaluation examines to what extent the target of evaluation fulfills the appropriate security requirements. The CC define seven evaluation assurance levels, where lower levels require functional testing, middle levels require documentation of high-level design and development environment controls, and high assurance levels require mathematical proofs and the use of formal methods for product verification.

Another major aim of Common Criteria is that evaluations of different products of the same type (e.g., operating systems or firewalls) should be comparable. Thus, products or systems can be evaluated against *protection profiles* that contain general, product-independent security requirements for a certain product types.

The Common Criteria are internationally accepted; version 2.0 became the ISO/IEC standard 15408. The current version of Common Criteria is 2.1.

The official Web site of Common Criteria is <http://csrc.nist.gov/cc> (Unfortunately the popular information portal <http://www.commoncriteria.org> was closed at the end of 2003.) See the third section for more details on the Common Criteria.

CobiT

CobiT (Control Objectives for Information and Related Technology) provides principles to improve control over IT-oriented and accompanying processes at an organization. It is nontechnical and provides managerial guidelines and control objectives to manage IT-related organizations with security as a primary focus.

The first version of CobiT was released by the Information Systems Audit and Control Foundation (ISACF);

the current edition is the third one, published by the IT Governance Institute (ITGI).

The official website of CobiT is <http://www.isaca.org/cobit>

ISO 9000

The ISO 9000 series is set of standards that define methods to improve quality management at an organization. Although it provides a framework for quality assurance, it does not focus on security. It is a very general standard, so it can be applied to any company or organization.

ISO 9000 provides assurance to customers that the product was produced in a way that it will meet their requirements. According to ISO 9000, the best way to do this is to define the procedures, standards, and characteristics of the quality control system. This way the quality is “built into” the product or service (Slack, Chambers, & Johnston, 2001).

ISO 9000 follows the paradigm (Peters, Waterman, & Peters, 1988; Oakland, 1992) that an organization cannot only gain competitive advantage by improving its quality, but is also able to reduce its costs this way (e.g., by the elimination of waste from the production or by the reduction of customer complaints). Thus, ISO 9000 claims to be beneficial for both the organization adopting it and its customers.

By today, most countries have adopted ISO 9000 as their own quality management standard. The current version of the standard is ISO 9000:2000.

BS 7799

BS 7799 (ISO/IEC 17799) was developed by British industry, government, and commerce stakeholders in 1995. The standard describes several security controls under 10 major headings and addresses information security management issues. It not only raises information security problems but offers solutions to them, too. The standard stresses the importance of risk management and underlines that there is no need to implement all security controls, only those that are relevant to the specific scenario.

BS 7799 consists of two documents: Part 1, “The Code of Practice” is a collection of advice. It provides guidance to organizations on implementing an information security management system (ISMS) based on “the best practices” of the industry. Part 2, “Specification for Information Security Management Systems” sets out a rigorous set of requirements, so that it is possible for a third-party auditor to verify if a company complies with BS 7799. Many evaluators prefer BS 7799 over other standards for security assessment, because, for example, of certain reasons listed in the fourth section. Unfortunately, BS 7799 is not available free of charge. BS 7799 has undergone several revisions; the current version is BS 7799:2002. Part 1 is now an international standard as ISO 17799:2000 (Larson, 1999).

BSI IT Baseline Protection Manual

The IT Baseline Protection Manual was published by BSI (German Information Security Agency) in 1994. The

Baseline Protection manual recommends various security measures for typical IT systems with medium-level protection requirements (Schultz, 2001). Although this manual is system-specific, it is more technical than BS 7799 and CC. The Baseline Protection manual considers typical threats and gives detailed safeguards for these. The current version (October 2003) can be downloaded from the Web site of BSI: <http://www.bsi.bund.de/gshb/english/etc/titel.htm>

FIPS 140

Federal Information Processing Standard 140-2 (FIPS 140-2) describes U.S. government requirements that cryptographic modules should meet. It was developed by the NIST and is currently recognized as a de facto international standard for cryptographic modules. The four security levels of FIPS 140 cover a wide range of potential applications and environments in which cryptographic modules may be deployed. The standard also addresses the secure design and implementation of a cryptographic module.

The original version, 140-1, was superseded by 140-2, which is the current version of the standard. The official Web site of FIPS 140 is <http://csrc.nist.gov/cryptval>

Two Groups of Standards

As is shown in Figure 1, there are basically two groups of security (and quality) standards. One group (standards such as Common Criteria and FIPS 140) provides methods for the *assessment of a security product*. These methods usually describe *technical security requirements* and assess the security of a *product* or its *production*. The other group (standards such as CobiT, ISO 9000, and BS 7799) describes methodologies for the *assessment and evaluation of a company or a system* and its IT infrastructure. These standards usually provide managerial guidelines and do not go into technical details. They provide tools to assess the company, the *producer*, and its methods of *production*. Thus, the aim of these standards is to describe how a security-oriented company should operate without going into the details of specific products. (The IT Baseline Protection Manual seems to be the exception; it is system-specific but still gives technical advice [Initiative D²¹, 2001.])

These two groups of standards should not be viewed as competing ones but rather as standards that should be used together. Evaluation against system-specific nontechnical standards (such as CobiT) may give confidence that an organization’s managers consider security an important issue. However, these standards do not provide guidance on technical details. For example, a CobiT audit requires that an organization prepares certain important security policies (e.g., how to select or procure software, how to apply patches regularly, how to register users, how to select and train system administrators, and how to control that the system administrator keeps the regulations). However, the security of a system can be breached because of a single mistake even if the above policies are kept (e.g., because of the incompetence or mistakes of the system administrator or because of a critical bug in a purchased operating system, etc.). Naturally, standards describing an organization, a community of humans, can never give 100% assurance.

On the other hand, evaluation against a product-specific and technical standard (such as Common Criteria) provides confidence that a certain product (e.g., an operating system) is secure or secureable. However, no matter how secure a device is on its own, it does not necessarily make a system secure because no one can guarantee that it will be *used in a secure way*. Product-specific nontechnical standards give little or no guidance on how to train staff, how to formulate security policies, and so forth. For example, a security system of a company can be breached if the registration of users is inadequate, regardless of the security of the operating system. Nevertheless, these standards can give very strong confidence in the product itself. If formal methods are used (such as on high evaluation assurance levels of Common Criteria), mathematical proofs can be given that the product fulfills its specifications. On the other hand, whenever these standards describe the product’s environment, they have to make assumptions about the organizational structure too. Although mathematical proofs can theoretically give 100% assurance, even formal verification has its own pitfalls.

The two groups of standards may be used together. For example, a company preparing for a CobiT audit may decide in its procurement policy to purchase only those products that have at least a certain Common Criteria evaluation assurance level.

Although the objectives of Common Criteria and FIPS 140 may seem similar in Figure 1, they are different in abstraction and focus of tests. Assessment against FIPS 140 means *conformance testing* against a cryptographic module, whereas assessment against Common Criteria means *evaluation* against a protection profile or security target (NIST, CSE, 1995). Moreover, FIPS 140 is only applicable in the case of cryptographic modules and requires evaluated (by TCSEC or by Common Criteria) operating systems.

Thus, Common Criteria are practically the only existing standards today that enable the assessment of any security product without placing restrictions on its type. In the rest of this chapter, a detailed introduction is presented on Common Criteria. In the third section, the scope and general approach of Common Criteria is introduced

	ISO 9000 CobiT BS 7799	Nontechnical
Common Criteria FIPS 140	IT-BSM	Technical
Product specific	System specific	

Figure 1: Two groups of security standards.

along with an overview of its main concepts. In the fourth section, some practical issues of Common Criteria are considered.

COMMON CRITERIA PARADIGM

The Common Criteria are the result of an international collaboration to develop a standard to evaluate the security of IT products and systems. After the Trusted Computer System Evaluation Criteria (TCSEC) was developed in the United States in the early 1980s, other nations started to elaborate their own evaluation criteria. Later, the Information Technology Security Evaluation Criteria (ITSEC) was published in Europe in 1991 as a joint effort of France, Germany, the Netherlands, and the United Kingdom. Canada published the Canadian Trusted Computer Product Evaluation Criteria (CTCPEC) in 1993, combining the merits of TCSEC and ITSEC. The United States published another criteria, the Federal Criteria for Information Technology Security (FC) in 1993, combining the European and North American concepts for evaluation criteria. Finally, the sponsoring organizations of TCSEC, ITSEC, CTCPEC, and FC decided to join their efforts and developed the internationally accepted Common Criteria. Their aim was to make CC an ISO standard. Version 1.0 of CC was published in 1996. The official name of CC in the ISO context is Evaluation Criteria for Information Technology Security. The current version of CC is 2.1.

Scope of Common Criteria

“The CC is a catalog of criteria and a framework for organizing a subset of the criteria into security specifications” (McEville, 2000). CC claim to aid consumers in the selection and comparison of IT products and systems. CC claim to aid developers and integrators in creating more secure and more valuable products and systems. CC also claim to aid evaluators by giving common evaluation criteria.

The value of information—and any other kind of good—is determined by the benefit a party can gain from receiving it (or the benefit a party can lose from not receiving it). This can be expressed as a monetary value by determining how much an external or internal (Slack, Chambers, & Johnston, 2001) customer would be willing to pay for the given good. (The work of Shapiro and Varian (1998) describes the economic mechanisms that drive economies of information goods.) Apart from its contents, three main attributes determine the value of information: confidentiality, integrity, and availability. CC address the protection of information for these three attributes.

- *Availability* means that the authorized users of an information system are able to access, deliver, or process the required data. The availability of information is breached when the authorized users cannot access the data needed for their work.
- *Confidentiality* means that only authorized users are able to access certain classified information. Confidentiality is violated if unauthorized people read or copy such classified information.
- *Integrity* means that information is unmodified, authentic, complete, and can be relied upon. Information can

lose its integrity if it is modified by accident or by a malicious attack.

Thus, the more parties know a piece of information, the less valuable it is. The less reliable the information is, the less valuable it is. When a customer cannot access a piece of information, the customer is not willing to pay for it. Although availability is provided by the reliable operation of the system, confidentiality and integrity are limitations on the operations. These limitations are imposed to provide protection against attacks (either natural disasters or deliberate attacks of a malicious adversary).

Common Criteria do not deal with the following:

- CC do not deal with *administrative security measures* that are not directly related to IT security. However, administrative measures can be an important part of security implementation. Moreover, weak administrative measures can undermine an otherwise secure system. CC evaluations make assumptions about the *environment* but do not evaluate if the environment met fulfills these assumptions. Although it cannot be required from a product-specific security standard to *assess the environment* of the product, neglecting human-related aspects of security is a major weakness of CC.
- CC do not deal with administrative, legal, and procedural issues such as accreditation, certification, and mutual recognition of CC evaluations in different countries.
- CC do not deal with *physical security implementations*, because it focuses on IT security, that is, the protection of information by means of logical security. However, in some cases physical features of a device can be used to attack logical security. For example, although the CC declare electromagnetic emanation control as out of scope, Agrawal et al. (2002) show methods to attack the logical security (uncover bits from a secret key) of a smart card based on its electromagnetic emanations. Such attacks against cryptographic devices, that based on their unintentional outputs (such as timing, power consumption, or electromagnetic emanations) are called side-channel attacks (Muir, 2001; Kelsey et al., 2000).
- *Evaluation methodology* is outside the scope of CC, because it is discussed in a separate document.
- *Definition of cryptographic algorithms*: Cryptography is one of the most important tools of IT security; thus, cryptography is not outside the scope of CC. However, CC relies on cryptographic algorithms as black boxes and assumes them to be secure. The evaluation of a cryptographic algorithm is a very hard problem, and no ultimate tool or method exists that can uncover all of the problems. Formal mathematical proofs exist for the security of only a few cryptographic algorithms. The confidence we have in their security originates from the guessed hardness of mathematical problems. The accepted evaluation method for a cryptographic algorithm is its publication, where it is evaluated by the broad academic (and industrial) community. Use of “home grown” cryptographic algorithms is usually strongly discouraged. Thus, declaring the evaluation of cryptographic algorithms to be outside the scope of CC is a reasonable assumption.

Approach

The Common Criteria address security as a degree of protection of certain assets. The assets belong to owners (e.g., consumers of a product), who value them. In the case of an information technology system, assets are information that should be protected for confidentiality, availability, and integrity. Unfortunately, these assets are subject to threats. Threats can be attacks or disasters or any undesired event that threaten these properties (confidentiality, availability, integrity) of the assets. They are raised by threat agents, who can range from abstract entities such as “forces of nature” to real attackers. They may raise threats maliciously, consciously, or just probabilistically. Owners would like to minimize the risk of these threats by successfully exploiting vulnerabilities in the protection of assets, so they impose countermeasures to reduce the vulnerabilities. This approach is illustrated in Figure 2.

One of the major aims of Common Criteria is to enable the comparison of evaluations of similar products. For such comparison, a common ground is required, and it should be expressed with CC terminology that the products are in fact similar. Thus, CC define the following concepts:

- A *target of evaluation* (ToE) is an IT product or system that is to be evaluated. Any associated documentation may also be considered as part of the ToE. Sometimes it is not the ToE itself that is evaluated, but the ToE description that the vendor has to prepare.
- A *protection profile* (PP) encapsulates the security requirements for a type of product at an abstract, vendor- and device-independent level. Protection profiles can be elaborated by a community of users or anyone else who would like to state security requirements for a type of

product. Products evaluated under the same PP can be compared. Naturally, a single PP can be used for more than one evaluation.

- A *security target* (ST) is a representation of implementation-dependent requirements of a specific product. It is written by the product vendor. The ToE is always evaluated against an ST, and an ST may conform to a PP.

Thus, a community of users of a certain product can formulate a protection profile to state their security requirements for the product. For example, the Secure Signature Creation Device Protection Profile applies to smart cards, so different smart cards evaluated under this PP can be compared.

Naturally, it is not enough to evaluate that a ToE conforms to an ST; the ST (or PP) also has to be evaluated.

Thus, CC define the following three types of evaluation:

- *Evaluation of a PP* means assessing that the PP is complete, technically sound, and suitable for use as a statement of requirements for a ToE. CC define evaluation criteria for PPs in Part 3. After the evaluation, the PP is catalogued (in context of the applied evaluation scheme) so it can be used in the evaluation of ToEs.
- *Evaluation of a ST* is carried out against evaluation criteria for STs in CC Part 3. In such an evaluation, the ST is assessed if it is complete and technically sound. Moreover, if the evaluation is performed against a PP, then it also has to be assessed if the ST conforms to the specification of the PP. ST evaluation provides intermediate results only: the results of this evaluation are part of the documentation of the ToE evaluation. However, the vendor may reuse the ST when preparing the ST for the next version of the product.

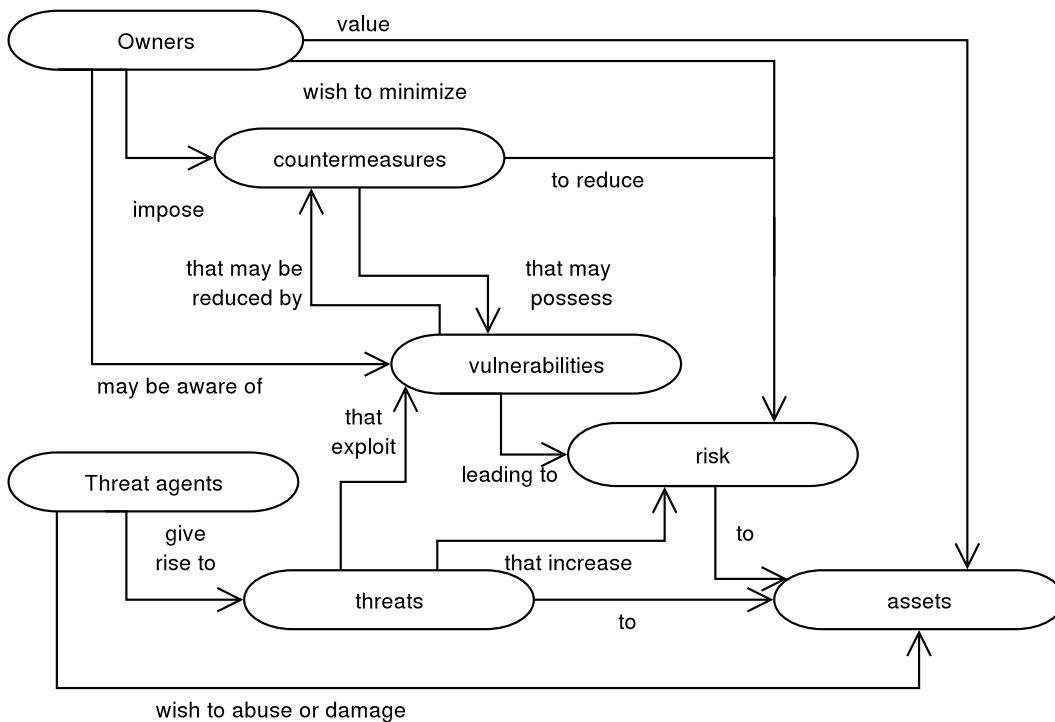

Figure 2: Security concepts and relationships.

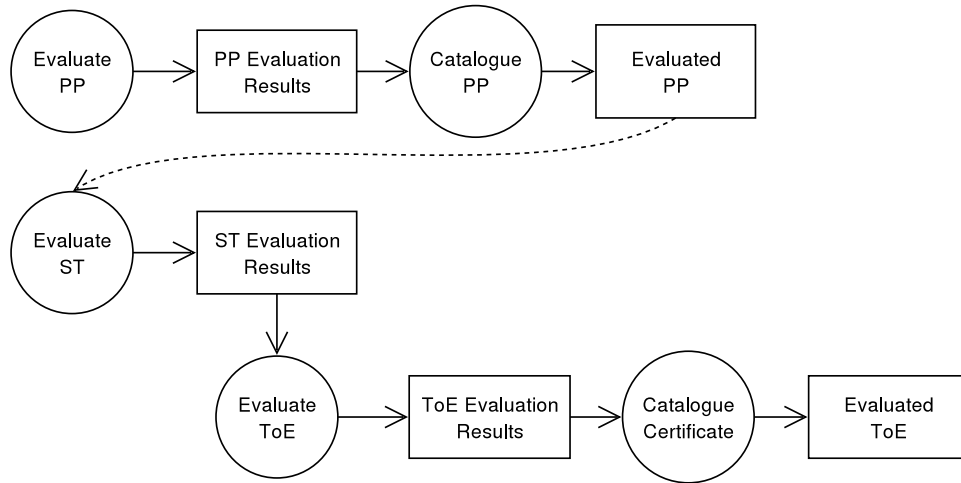

Figure 3: Evaluation results (source: CC, 2004).

- *Evaluation of a ToE* is the primary goal of Common Criteria. It is carried out against the evaluation criteria in CC Part 3. In such an evaluation, the ToE is always evaluated against an evaluated ST. Evaluated ToEs are catalogued in context of the applied evaluation scheme.

Figure 3 illustrates how the three types of evaluation are interconnected.

Security Requirements

Part 1 of Common Criteria gives an introduction and describes the general model. Parts 2 and 3 describe the

security requirements in a catalogue format. Part 2 describes *functional* requirements that express what security features an IT product or system may have. Part 3 describes *assurance* requirements that express ways that could be used for gaining confidence that an IT product or system works according to the functional requirements.

Both functional and assurance requirements are organized into a hierarchical structure of *families* and *classes* (see Figure 4).

Each requirement has a unique CC name. The initial character of the name is "F" in case of functional and "A" in case of assurance requirements. This character

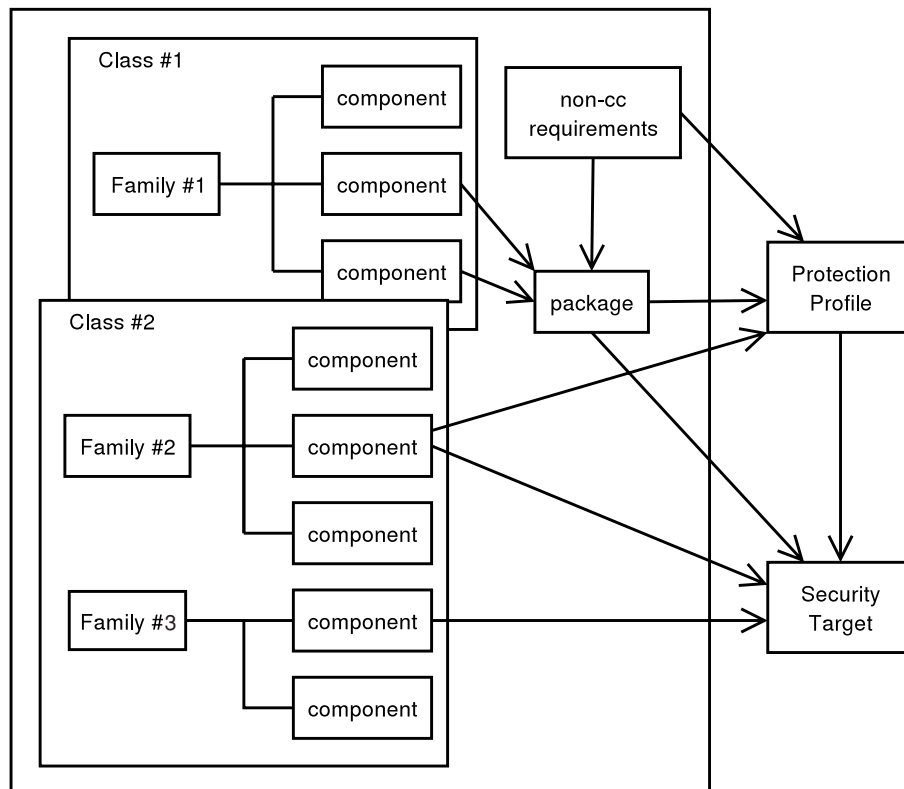

Figure 4: The security requirement components are organized into classes and families.

is followed by the two-character-long identifier of the class and the name of the family, separated by an underscore. The name of the requirement is terminated by the dot separated numbers of the component and the element.

For example, security requirement *FIA_UID.1.2* denotes element 2 from component 1, family of *User Identification (UID)* from the functional class of *Identification and Authentication (FIA)*.

To define the security requirements, a subset of these requirements have to be selected and grouped into a PP or an ST. Requirements can also be organized into packages that can be reused in future evaluations.

Derivation of Requirements

In this section, a summary of an advised CC approach is presented that could be used to derive security requirements when developing a PP or ST (see Figure 5). This is the process that establishes the ToE specification as its final output.

Security Environment

Whenever a PP or ST is specified, a security environment has to be established in which the ToE is going to operate. Naturally, because PPs are generic and vendor- and product-independent, a specific ToE does not have to exist when this environment is specified.

The security environment includes all the relevant laws, organizational security policies, customs, expertise, and knowledge and thus defines the context in which the TOE is going to be used. The security environment also includes threats and attacks from the environment that have to be countered.

The following have to be taken into account when establishing the security environment:

- The CC are applicable when IT is used to guard certain *assets*. The protection of these assets is the goal of every security function in the ToE. Thus, a risk analysis should be performed about the threats that may arise to these assets.
- The *purpose of the ToE* is also a vital input to an evaluation, because its implications have to appear on every level of abstraction from high-level design to the implementation.
- The context, that is, the *physical environment*, of the ToE also has to be considered when establishing the security environment.

Three additional statements are prepared when the security environment is established:

- A statement of *assumptions*, which is a list of security aspects of the environment in which the ToE is going to be used. This statement contains assumptions of secure usage, assumptions on the scope and boundary of the ToE, and assumptions on its placement in the environment. These assumptions cover the relation of the ToE to humans. The assumptions are the circumstances in which the ToE will prove to be secure if it passes the evaluation.

- A list of *threats*, which is one of the outputs of the risk analysis. A threat is an ability of a so-called threat agent to exploit a vulnerability in the ToE intentionally or unintentionally. A threat can be any circumstance or event that may cause harm to the assets of the ToE in terms of confidentiality, integrity, or availability.
- *Organizational security policies*, which are the rules, practices, procedures, or guidelines imposed by the organization in which the ToE operates.

Security Objectives

The security environment could be used to define security objectives that could counter threats and address or rely on assumptions and policies when appropriate. Threats can be countered by the ToE or by its IT or non-IT environment. Certain countermeasures allow total elimination of certain threats, whereas others reduce the probability or magnitude of the damage a threat may cause. Some countermeasures only allow us to monitor (and thus better manage) the threat.

Only security objectives defined at this step are going to be addressed by security requirements.

Security Requirements

The security requirements are a refinement of the security objectives using the concepts of the CC. Thus, security requirements can be expressed using elements from the security classes in the CC. Functional requirements (CC Part 2) define the desired security behavior, such as identification or authentication, so they describe the security features a product has.

The assurance requirements can be used to specify a minimum strength level that should be consistent with the security objectives. Thus, the degree of assurance and rigor can be expressed with assurance requirements. CC Part 3 defines seven evaluation assurance levels (EALs) that provide a scale for security assurance.

Generally, two types of security requirements exist: requirements for the presence of desired behavior and requirements for the absence of undesired behavior. Normally, it is possible to prove that the former group of requirements is met to a certain level—for example, by testing. However, it can be very hard to demonstrate that requirements from the latter group are met, too. Although it is possible to prove or demonstrate that a product or system works properly, it might be very hard to prove that it does not have backdoors and hidden features.

ToE Summary Specification

The ToE Summary Specification in the ST defines the security requirements for the ToE. It also provides a high-level definition of security functions and assurance measures that are claimed to meet functional and assurance requirements.

ToE implementation

The implementation of the ToE is the realization of the ToE based on its security functional requirements and the ToE Summary Specification. The ToE meets its security objectives if it correctly implements all the security requirements of the ST (McEvelly, 2000).

Figure 5: Derivation of security requirements.

Evaluation Assurance Levels

The result of an evaluation is a statement of to what extent a ToE can be trusted to conform to the requirements. CC define seven evaluation assurance levels. Basic levels such as EAL 1 and 2 require limited vendor involvement and functional testing. Medium levels such as EAL 3 and 4 require evidence that the vendor considered and minimized threats during the development. High levels such as EAL 5–7 require formal mathematical proofs that the ToE meets its security requirements.

EAL 1—functionally tested: The ToE is tested as it is available to the consumer. The evaluator tests if it works as described in its documentation. The testing is casual and can be performed without the aid of the vendor.

EAL 2—structurally tested: In addition to the testing of EAL 1, the vendor's development documentation is also examined. Although this requires cooperation from the vendor, it does not require any special investment.

EAL 3—methodically tested and checked: The vendor has to prove that it looked for vulnerabilities during the development phase. This EAL requires the vendor to have security engineering at the development phase but does not require changing the existing practices.

EAL 4—methodically tested, designed, and reviewed: This level requires rigorous testing and the thorough examination of the design control documentation. This is the last level that does not require specialist skills such as formal verification. A product can reach this level if its vendor consciously uses security engineering but did not specifically aim for a higher EAL (when the product was designed). According to CC (2004), "EAL 4 is the highest level at which it is likely to be economically feasible to retrofit an existing product line."

EAL 5—semiformally designed and tested: EAL 5 is the first level where it is not enough for the vendor to provide documentation and test results but has to (mathematically) *prove* statements about the security of the product. At this level, the statements are allowed to be semiformal.

EAL 6—semiformally verified design and tested: At this EAL the vendor has to prove that the product functions according to specifications. At this level, the statements are still allowed to be semiformal.

EAL 7—formally verified design and tested: This final EAL requires the vendor to provide *formal proofs on key parts of the ToE*. The complexity of the ToE has to be minimized. The evaluator is also required to repeat all tests the vendor has performed. Although EAL 7 is very rigorous, only this EAL could give 100% guarantee that the ToE is secureable if the assumptions about the security environment hold. (Note that EAL7 has its limitations, too.) Unfortunately, very few products qualify for EAL 7.

Although a product may receive EAL 1 certification without the help of the vendor, a product is unlikely to receive a certification higher than EAL 3 if it was designed before

Common Criteria appeared. Today, most products receive EAL 4 certification. Levels above EAL 4 are highly infrequent.

COMMON CRITERIA IN PRACTICE

Common Evaluation Methodology (CEM)

The CC do not deal with evaluation methodology; it is discussed in a separate document, the Common Evaluation Methodology (CEM), which is a companion document to CC. The first part of CEM describes general principles about evaluation methodology, and the second part gives a detailed methodology for evaluations. It starts with PP and ST evaluation methodology and continues with methodology for EAL 1–4 evaluations. CEM is currently in version 1.0, but it is mandatory for the mutual recognition of certificates (CEM, 1999).

Common Criteria Recognition Arrangement (CCRA)

The international community has accepted CC through the Common Criteria Recognition Arrangement (CCRA), which is an international treaty about the mutual acceptance of CC certifications (CCRA, 2000). Countries can participate in CCRA as certificate *consumers* and certificate *authorizers*. Certificate-authorizer participant countries may elaborate a national CC evaluation scheme. This scheme should define the systematic organization for evaluation and certification. The Common Criteria, the scheme, and the methodology form the context of the evaluation (see Figure 6). Certificates issued in the context of such schemes are accepted by certificate-consuming participants. Typically, certificate authorizers are certificate consumers, too. Certificate-consuming participants cannot issue internationally accepted certificates. The list of CCRA participants can be found at <http://niap.nist.gov/cc-scheme/ccra-participants.html>. *International acceptance* is perhaps the greatest merit of CC. Thus, if a product received a certain level of CC evaluation in one CCRA participant country, there is no need to perform a reevaluation when introducing the product in another one. This treaty is beneficial for vendors, because it not only saves money but also provides shorter time-to-market intervals. Because several organizations (typically governments) follow the policy of procuring products with a certain EAL, having to reevaluate a product in each country also acts as a nontariff barrier of trade (Salvatore, 1995). This way, the international recognition of CC certificates also catalyzes the free flow of IT security goods.

Unfortunately, mutual recognition only works for EAL 4 and lower levels. One possible reason for this is that an evaluation is accepted via CCRA only if the methodology in the CEM companion document was used. However, CEM only describes methodologies for levels not higher than EAL 4. Perhaps it is due to the scarcity of products—and lack of experience—with high EALs that such methodology has not been elaborated for higher levels. The other possible reason is that countries wish to retain the right to certify products at high EALs because of the high value added by high-level certifications.

Figure 6: Evaluation context.

The home page of the Common Criteria evaluation and validation scheme (CCEVS), the U.S. CC evaluation scheme, is at <http://niap.nist.gov/cc-scheme/>.

Trends in Evaluations

Richard E. Smith, (2000a; 2000b) has collected data on government-endorsed security evaluations in the United States and in the United Kingdom from 1984 to 2000. Because his work embraced the early years too, when CC did not exist, his work was not limited to CC evaluations and therefore was based on previous standards such as TCSEC and ITSEC, too. Smith has come to the following key observations:

- Although several security products appear on the market, relatively *few products undergo security evaluation*. According to Smith, not more than one tenth of security products are evaluated.
- Despite the fact that the United States pioneered security evaluation, *most products are not evaluated in the United States*, and this trend is increasing. Often U.S. products are evaluated overseas. Smith argues that security evaluations are more expensive in the United States.
- The vast majority (more than 90%) of evaluations seek *EAL 3 or EAL 4* (or equivalent levels at other standards). Lower ratings are scarce, just as are higher ratings (which are mainly sought by military products).
- Although the main purpose of TCSEC was to establish security standards for operating systems and related access control products, Smith observed that *operating system evaluations no longer dominate*. Network security products (such as firewalls) and encryption devices account for most evaluations.

The four years that have passed since Smith performed his investigation have brought changes in this field. In the year 2000, CC were relatively young and the vast majority of evaluations were performed against ITSEC (in spite of the pioneering role of TCSEC in the field of security evaluation). Today, CC seem to be the most dominant set of

evaluation criteria because of international acceptance. Many evaluators have even stopped performing evaluations against previous criteria.

Today, the proportion of evaluated products seems to have increased in the market (Rouchouze, 2002), perhaps because security evaluation starts to give a competitive advantage for products. More prestigious vendors have learned how to prepare their products for an evaluation, and enough time has passed to adopt development practices to the evaluation criteria. Some important consumers such as governments also tend to acknowledge security evaluation and prescribe it in policies and in laws. For example, in the European Union (EU, 1999) a digital signature can only become a “qualified signature” (accepted as fully equivalent with the traditional signature) if the signature creation device qualifies for a certain EAL against the SSCD (secure signature creation device) protection profile.

However, most evaluations still aim for EAL 4, even today. Perhaps the industry fails to achieve higher levels, or perhaps consumers do not require them. This question is examined in the next subsection.

Criticisms of CC

On one hand, CC have been used successfully since they were published. Year to year, more and more products are evaluated. On the other hand, despite CC evaluations, products in general do not tend to be more secure. Moreover, sometimes notoriously insecure products receive EAL 4 certification, practically the highest level a commercial product can receive.

EAL 4 is a level of assurance where the evaluator needs to perform little examination on the product itself but rather examines its documentation and the controls and business practices that were used during development. This means that if a vendor sacrifices enough funds and consciously focuses on producing CC-related documentation when developing the product, then it will pass a CC evaluation at EAL 4. (In contrast to this, no matter how secure a product is perceived to be, if the vendor did

not lay emphasis on CC-related documentation in the development phase, because, for example, the product was developed before CC was published, the product cannot pass a CC evaluation at EAL 4.)

- *If a product has passed a security evaluation (e.g., against CC), it does not mean that it is secure; it means that it is secureable* (i.e., it is possible to configure it in a way to use it securely in a certain environment). The paradigm of product-based security evaluation (like that of CC and FIPS 140) can only consider a product in a certain environment. According to the CC, assumptions of secure usage are made when the security environment is established (see Figure 5), and any statement about the security of the ToE is only valid in context of these assumptions. For example, if an operating system is evaluated and certified against a protection profile, the evaluation is considered on a specific hardware of a specific vendor and is based on several assumptions about security measures and policies users are going to keep. Moreover, the evaluation is performed with a certain configuration of the OS, which might be significantly different from the default one. If any of these circumstances do not hold (the OS runs on a different hardware or in another configuration), the EAL the OS was certified at does not apply to the current situation.
- *If one product has a higher level of evaluation than another one, it does not mean it is more secure.* It means that the vendor was able to provide confidence about a higher level of security. Evaluation gives confidence that the manufacturer designed the product to be secure. However, only formal verification can guarantee that it works according to specifications. (Note that formal verification has its own pitfalls too. In the case of formal verification, an abstract mathematical model is constructed on the behavior of the product. Formal verification is able to prove that this abstract model conforms to the specifications. However, if the formal model does not describe the real product properly, the proof becomes irrelevant to the security of the product.)

Because a security evaluation requires significant funds and paperwork, having a lower level of assurance only means that the manufacturer did not or could not aim for a higher level of assurance. For example, free open-source software is often developed and maintained by nonprofit organizations. Such organizations are unlikely to redesign and redevelop their product to be certified at a higher EAL. However, open source software has a very powerful security management system: volunteers from the open source community from all around the world continuously monitor the source code.

- It is not enough to check at which EAL a product was certified; the PP the product was evaluated against also has to be taken into account. For example, Shapiro (1996) reviews the evaluation of a well-known product and states that the PP it was evaluated against does not address the threats the community of users would like protection against. Results of evaluation against inappropriate criteria are useless for consumers, regardless of how high an EAL the product was certified against. Shapiro also questions the level of assurance an EAL 4 evaluation may provide and claims that because the

vendor invested millions of dollars in this certification, it (or the fact that the vendor failed to achieve a higher level of certification or a certification against a better PP) proves the *insecurity* of the product. Naturally, a successful certification always gives confidence in security.

The situation is even more critical if the evaluation is performed against an ST only. Because the ST was developed by the vendor, it often tends to be more consistent with marketing brochures than customer requirements (Naaman, 2003).

- Another major weakness of the CC is that they do not address human-related security issues. Although these issues are included in the CC as assumption of secure usage, humans are far from being a stable and secure point of a system.

It is generally accepted that humans are a very weak link in the security chain. (For example, Anderson [1996] performed a survey on frauds against ATM machines and found that most attacks were performed by insiders or made use of human mistakes, ignorance, or implementation blunders.) CC can give extremely strong confidence about the security of a product, but only at higher EALs if formal methods are used. However, few products are able to reach these levels.

The CC can give assurance on the security of components of a system, but this does not say anything about humans—the link that connects these components. Perhaps a security standard that does not abstract out this weak link but tries to address it with control objectives and security policies might give more confidence in the security of a system.

Although in certain cases a CC certification may have little relevance to the security of a product, it surely means *added value*. Managers tend to buy products that have passed a CC evaluation even if they are more expensive and perceived to be less secure than their competitors. Thus, if the security of the system the manager is responsible for is breached, the manager is less likely to be held responsible for it, because the system relied on evaluated products.

Anderson also criticizes CC because the expenses of a CC evaluation (unlike those of a TCSEC evaluation) are paid by the vendor. He expresses distrust in the security of a system where security implementation and security evaluation are not paid by those parties who would suffer the consequences from inadequate security. Anderson (2001) argues that the IT market encourages vendors to sell insecure products, and he supports his statements with examples.

The CC provide internationally accepted criteria for performing security evaluations, and thus the CC are supposed to inhibit this trend by giving consumers more information on the quality and security of products. Unfortunately, the CC (and security evaluation in general) are used as a business method to add value to products, and thus perhaps might even catalyze this negative trend.

CONCLUSION

Security evaluation is an important concept because this is the only approach an individual consumer can rely on to gain confidence in the security of a product or system.

Today, the Common Criteria represent the only internationally accepted product-specific security standard that can be applied to any IT (security) product regardless of its type. It also enables the comparison of products of the same type from different vendors.

A Common Criteria evaluation is not only important as a mean of assessing the security of a product, but it is also a business method for gaining competitive advantage. The more confidence consumers gain in the security of a product, the more value is added to it. This is why the Common Criteria are not only accepted by users, but are also supported and sponsored by vendors and governments. Being the first internationally accepted criteria for security evaluation, the Common Criteria strongly determine the future of IT security.

GLOSSARY

Common Criteria (CC) A standard for security assessment.

Countermeasure Countermeasures are means to decrease vulnerabilities in a product or system.

Evaluation Assurance Level The degree of confidence that can be gained on how well a target of evaluation (TOE) meets the assurance requirements.

Protection Profile A product-independent statement of the security requirements of a certain class of products.

Security Evaluation The process of assessing if a product or service meets its security requirements.

Security Target A representation of implementation-dependent requirements of a specific product.

Target of Evaluation The product or service under evaluation.

Threat An undesired event that may reduce the value of certain assets.

Threat Agent A threat agent is an abstract entity that raises a threat. A threat agent may not only be a conscious human attacker, it can be a natural disaster, for example.

Vulnerability Threats exploit vulnerabilities to decrease the value of assets.

INTRODUCTION

Public key cryptography has become popular in information and telecommunication security. Algorithms in this family use two different, but related, keys. One of them is kept private by the key owner, and the other is made public. The private key is used to decrypt messages as well as to sign digital information. The corresponding public key is used to encrypt messages and to verify digital signatures. Because these latter operations can be done by anyone, public keys need to be made public. Although public keys are widely known, it is not computationally feasible to obtain a private key using the corresponding public key.

Public key distribution is not an easy task. Public keys can be distributed through global directories or servers, but the key must be bound to the holder's identity. Without binding, the key holders could use any name they wanted. For example, suppose *Charlie* creates a key pair and publishes the public key as if he is *Bob*. Later *Alice* wants to obtain the *Bob's* correct public key. She queries the server and obtains the public key that seemingly belongs to *Bob*, but was actually uploaded by *Charlie*. In this way, *Charlie* can masquerade as *Bob*. This method of cheating is called *name spoofing*. The possible dangers of name spoofing are the following:

- Suppose *Charlie* has intercepted the encrypted messages from *Alice* to *Bob*. *Alice* has encrypted these messages using the fake public key of *Bob*, which actually belongs to *Charlie*. Because *Charlie* also knows the corresponding private key, he is now capable of decrypting these messages.
- Suppose *Bob* has digitally signed a message using his private key and sent it to *Alice*. Because the public key that *Alice* has for *Bob* is in fact incorrect, she cannot verify the signature on the message, even if it is legitimate.

There are some methods proposed in the literature to overcome the name-spoofing problem. When public key cryptography was first proposed by Diffie and Hellman (1976), the proposed method for public key distribution

was a "public file" where the public keys and the corresponding owners were listed. The write access was limited to authorized users, but the read access was not limited. This idea would have been useful for small communities where there was no need to update the public file very often, but it was never realized because the demand was to provide for larger communities. Later, centralized online mechanisms were proposed to distribute public keys on demand (Popek & Kline, 1979), but such a service was never widely implemented mainly because of the dependency on online servers.

The concept of *certificate* was first proposed by Kohnfelder (1978) as a distributed public key distribution mechanism that did not need online servers. The idea was to employ trusted entities that would validate and endorse the *public-key-to-owner* binding with a digital signature.

A public key certificate (or identity certificate) is a digital binding between the identity and the public key of a user. Sometimes certificates are used to bind a credential or a permit to a public key without using the identity of the owner. This type of certificate is called an *attribute certificate* (or *authorization certificate*). The binding in a certificate is digitally signed by a trusted *certification authority* (CA). Anyone who wants to find a legitimate public key verifies the CA signature on the certificate. The verifier must trust that the CA has correctly bound the public key to the holder. The CA is responsible for verifying the holder's identity before issuing the certificate.

Obtaining legitimate public keys via certificate verification allows encrypted and authentic communication between two parties. Moreover, the signer cannot later deny sending a signed message, because his public key has been certified by a trusted CA. Nonrepudiation is very important in e-commerce and e-banking.

An example certificate issuance model is depicted in Figure 1. In this model, first, the user applies to a CA by providing his or her public key and some proof of identity. The CA verifies the identity and makes sure that the public key really belongs to the user. After that, the CA creates a certificate by digitally signing the necessary information. This certificate is stored in some public servers or databases.

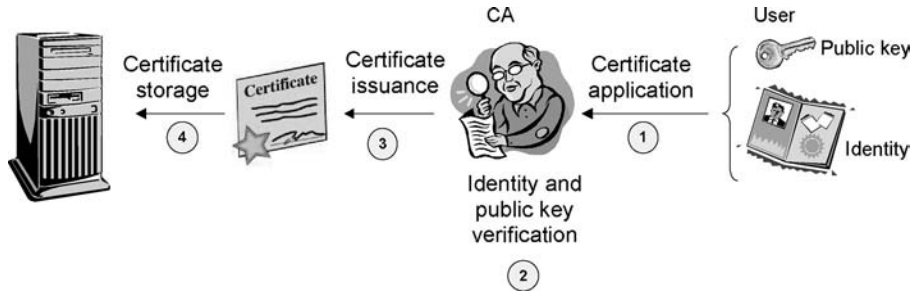

Figure 1: Example certificate issuance model.

A simple signed document verification scenario is depicted in Figure 2. Suppose the signer (not shown in the figure) previously signed a document using his or her private key. The verifier needs the correct public key of the signer for verification of this signature. To do so, first, the verifier obtains the signer's certificate from the public key server or database. Then, the signer verifies the signature of the CA on this certificate. This verification yields the correct public key of the signer. Using this public key and the signed document, the verifier verifies the signature on the document.

In this simple scenario, verification of the signer's certificate requires knowing the CA's public key and we assume that this public key is known to the verifier. However, in most cases, a series of certificates might be verified in a chain to reach the signer's certificate. This mechanism, called *certificate path*, is explained in a subsequent section.

As the public key cryptosystems and their applications become more widespread, the need for a secure public key distribution method became more and more important. At this point, the industry took up Kohnfelder's idea and practicalized the concept of certificates for commercial use. Since then, several standards have been issued and several secure applications have either adopted a standard or defined their own certification mechanism. Today digital certificates offer a promising market and are an enabler technology in Internet security for a wide range of applications from e-commerce to e-mail.

CERTIFICATE STRUCTURE

Attempts to standardize certificates were started in the late 1980s. The first standard was published by ITU-T (International Telecommunications Union) in 1988 as the X.509 recommendation (ITU-T, 1988). The same standard was also published by ISO/IEC (International Organization for Standardization/International Electrotechnical Commission) as International Standard 9495-8.

Other than X.509 certificates that bind an identity to a public key, there are other relatively less common certificate types. These are detailed in this section. First we start with classical X.509 identity certificates.

X.509v3 Certificate Characteristics and Structure

The X.509 recommendation was revised three times: in 1993, 1997, and 2000 (ITU-T, 1993, 1997, 2000). The certificate structure of the original 1988 recommendation is named version 1 (v1). Version 2 (v2) is the structure defined in the 1993 edition. X.509v2 is not so different than v1 (the details are given later in this subsection). The X.509 version 3 (v3) certificate structure is defined in the third edition of X.509 in 1997. The main distinguishing feature of the X.509v3 certificate structure is the extension fields, which are explained in the subsequent section in detail. The X.509 recommendation was revised once

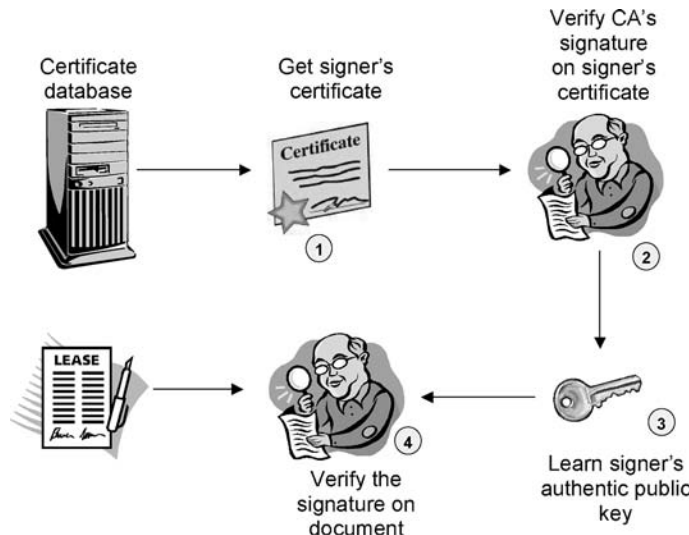

Figure 2: Simple signed document verification scenario.

Figure 3: Example certificate path.

more in 2000, but the certificate structure was not updated in this revision.

The X.509v3 certificate structure includes identification and public key information for the *subject* (the entity for which the certificate has been issued) and identification for the *issuer* (authority who signed the certificate). In addition, the certificate structure includes some managerial fields such as serial number, version, and so forth.

A certificate is signed by a CA with a digital signature covering all applicable certificate fields. The signature algorithm and its parameters are included in a header to facilitate the verification process. The digital signature, which is a binary stream, is appended to the certificate.

Certificates are processed as a chain known as the *certificate path*, as exemplified in Figure 3. The last certificate of this path (c_0) is the certificate of the end user (T) whose public key is sought. Other certificates are CA certificates, that is, certificates issued by CAs to other CAs. The verifying agent starts the verification process with the first CA (CA_6) certificate (c_6). Generally, the first CA certificates are known as root CAs and their certificates are *self-signed* certificates, that is, both issuer and subject entities are the same. If such a self-signed certificate of a root CA is deemed trustworthy by the verifying agent, then the verification process can safely start with it. Such a root CA is called the *trust anchor* of the verification process. Verification of a self-signed certificate yields the verified public key of the root CA, which in turn is used to verify the next CA certificate. Verification of the next CA certificate yields its public key, and so on. Verifications continue until the last certificate on the path—which is for the end user—is verified and the end user’s public key is found. In the example in Figure 3, once the verifier verifies c_6 , he or she finds the public key of CA_5 and then, using this public key, verifies c_5 . Verification of c_5 yields the public key of CA_4 , and the chain goes on until c_0 is verified to find the public key of T.

In X.509, there is a clear distinction between CA certificates and end-user certificates. CA certificates, as the name suggests, are used for CAs, and CAs can issue certificates for other CAs. End-user certificates are issued for ordinary clients; end users can never issue certificates for other entities.

The certificates that are described in this subsection are identity certificates. Identity certificates are used to bind a public key to an owner who is explicitly identified

in the certificate. The public key certificate framework defined in the X.509 specification mainly addresses identity certificates. This type of certificate is a critical component of a public key infrastructure (PKI). However, X.509 does not define a PKI in its entirety.

Names of the certificate issuer and subject are specified in X.509 using the X.500 family’s distinguished name (DN) structure. A DN is simply a set of attribute and value pairs that uniquely identify a person or entity. It is a tree-based naming structure with a root at the top and a naming authority at every node. Assuming that each node ensures the uniqueness of the names that it assigns, the overall DN structure will yield globally unique entity names.

X.509 uses abstract syntax notation 1 (ASN.1) notation to describe certificates and related structures, and the ASN.1 *distinguished encoding rules* (DER) to encode these objects for sending.

The details of the X.509 certificate fields are given here and depicted in Figure 4. First we start with the fields included in the X.509v1 certificate structure and then continue with the additional fields of X.509v2 and v3.

Version: this determines the version of the certificate.

Currently this value could be 1 (default value), 2, or 3.

Serial number: an integer value identifying the certificate. This value should be unique for each CA, but global uniqueness is not required. Thus, there is no need to have an authority for the distribution of certificate serial numbers.

Signature algorithm: the algorithm identifier for the algorithm and hash function used by the CA in signing the certificate.

Figure 4: X.509 certificate fields.

Issuer name: DN of the CA that issued the certificate. This field identifies the CA but not necessarily in a unique way.

Validity: this specifies the time period during which the certificate is valid and the CA warrants that it will maintain information about the status of the certificate. This field contains two date and time values that determine the starting and the ending date and time.

Subject name: this identifies the owner of the certificate using the DN structure.

Subject public key information: the public key of the subject (owner of the certificate). Actually, the binding between this value and subject name fields are endorsed by the CA. This field also contains the algorithm corresponding to the key.

These fields exist in all three versions of X.509 and are the core fields of the certificates. In X.509v2 two more optional fields are added:

Issuer unique identifier and **subject unique identifier:** these fields are needed in case the subject and/or issuer DNs are assigned to two or more different users.

During the preparation of the third edition of X.509, it became apparent that more fields were needed. The X.509 committee put forward the concept of extension fields as a way to continue the expansion of the standard into the future. Because these extension fields were generic, it was possible to make use of them for different purposes without changing the certificate structure. Several extension fields were defined in the third edition of X.509 recommendation, where the extension fields were first included in the certificate structure (X.509v3). Later, some other extension fields were added in the fourth edition, but the certificate structure remained the same.

X.509v3 Extension Fields

An extension field consists of a unique extension identifier, a criticality flag, and the data part of the extension. Extensions are optional. The criticality flag determines how the verifier of the certificate reacts if it does not recognize the extension (this is possible when the particular extension is not implemented by the verification system). If the criticality flag is TRUE, then the certificate is treated as invalid. In contrast, if the flag is FALSE, then the extension is ignored.

In the third and fourth editions of the X.509 recommendation, several extensions were defined. These can be grouped in five categories, as listed:

1. Basic certificate revocation list (CRL) extensions
2. CRL distribution points and delta CRLs
3. Key and policy information
4. Subject and issuer attributes
5. Certification path constraints

The first two groups of extensions, which deal with CRLs, are discussed briefly in a subsequent section. The third and the fourth groups of extensions can be applied both

to public key certificates and to CRLs. The last group is only for public key certificates. The latter three groups are briefly explained in the following sections.

Key and Policy Information

Additional information about the keys involved, including key identifiers for subject and issuer keys, indicators of intended or restricted key usage, and indicators of certificate policy, are contained in this group of extensions.

The **certificate policies** extension specifies the policies applied by the CA during the creation of the subject certificate. Each policy is identified by unique policy identifiers. In practice, policies map to certification practice statements (CPS) declared by the CAs. The verifying entity may put restrictions on certificate policies and, as a result, may not accept some certificates even if the signature is valid. This mechanism is a way to circumvent the blind trust that was inherent in the first two versions of the X.509 recommendation.

The **authority key identifier** extension is used to identify the public key of the CA that issued the certificate or CRL. One could argue that the issuer-unique-identifier field added to X.509v2 could solve the identification problem for the authority. However, because a CA could have more than one key pair, key-based identification was needed, and it was provided by this extension.

The **subject key identifier** extension is used to identify the public key of the subject to whom the certificate has been issued. This feature is useful when a subject has more than one public key and certificate.

The **key usage extension** limits the use of the public key to some certain cryptographic tasks such as digital signatures, key agreement, encipherment, and so forth.

The **extended key usage** extension is one of the visionary extensions. If the use of the key is not one of the basic usages described in the key usage extension field, this extension is used to specify a usage for the key. Such an extended usage is identified by an object identifier value that has to be formally registered according to ITU-T and ISO regulations.

The **private key usage period** extension is used to assign a different lifetime to the private key corresponding to the certified public key. Without this extension, the lifetimes of the public and private keys are the same. However, this is generally not the case in practice. Take, for example, the case of a digital signature application where the validity of the public key could be longer than the private key because the signed documents may have been verified after the private key expires. This extension is a mechanism that allows such flexibility. However, to utilize this extension, the signed documents should bear a time stamp that shows when the document was signed using the private key. Otherwise, it would be impossible for the verifier to check the expiration status of the private key used in the signature.

Subject and Issuer Attributes

The native naming mechanism of X.509 is the DN structure. The DN structure was specialized to the global distributed directory concept standardized by X.500 family

of recommendations. This special structure did not meet the requirements of other applications that use X.509 certificates because each application needs a different naming mechanism. For example, a secure e-mail application needs e-mail addresses; a secure WWW application needs URLs as names. Because the requirements of these types of applications were so urgent, a temporary solution was found: the common name (CN) field of the DN structure was used to include such application-specific names. Although this temporary solution is still in use, a special extension field was added to X.509v3 to support alternative names for certificate issuer and subject. Alternative names can be in a variety of forms including an e-mail address, a URL, an IP address, and so forth. Moreover, a special form of name can also be defined via the *other name* option.

Certificate Path Constraints

These certificate extensions allow constraint specifications to be included in CA certificates (certificates for CAs issued by other CAs) to facilitate the automated processing of certificate paths. The constraints may restrict the types of certificates that can be issued by the subject CA or that may occur subsequently in a certification path. In this way, trust processing can be customized according to different needs. Although these extensions are included in CA certificates, processing and interpreting these extensions is mostly the task of the certificate path verification entity, that is, an end user. Four extensions are defined in this context: *basic constraints*, *name constraints*, *policy constraints*, and *inhibit any policy*.

The **basic constraints extension** indicates whether the subject may act as a CA or not. If so, a *certification path length* constraint may also be specified. If the length of the path exceeds the specified value, then the end-entity certificate is automatically disqualified.

The **name constraints extension** indicates a name space within which all subject names in subsequent certificates in a certification path are to be located. The idea behind this extension is to be able to implement policies based on trusted and distrusted CAs known by name.

The **policy constraints extension** specifies constraints that may require explicit certificate policy identification for the remainder of the certification path. If such policy identifiers are present in a certificate, then the forthcoming certificates on the path must bear the required or equivalent policy identifiers in order for the certificate path to be validated.

Normally, a CA may assert *any-policy* identifier in certificate policies extensions to trust a certificate for all possible policies. The **inhibit any-policy extension** specifies a constraint that indicates *any-policy* is not considered as an explicit match. This rule applies for all certificates in the certification path starting with the certificate that bears this extension. In this way, explicit identification for policies is enforced.

Other Types of Certificates

Other than X.509v3 identity certificates, there are some alternative certificate structures. One issue behind developing alternatives is to address the requirements of access

control in certificates. Another issue is the unsuitability of lengthy formats for restricted applications such as WAP (wireless access protocol). Yet another issue is the belief that X.509 is not good at addressing the trust management requirements of liberal applications mainly because of the strict distinction between the concepts of CA and end users. Alternative certificate structures are discussed in this section.

Attribute Certificate Framework of X.509

Classical identity certificates (i.e., public key certificates) are used to assign a valid public key to an entity. The privileges of this entity are to be managed separately by the verifying system. This approach is criticized by the access control community, which believes that the two-step approach enforced by identity certificates is impractical. In the fourth edition of the X.509 recommendation, these concerns are addressed by the attribute certificate framework.

X.509 attribute certificates have a structure that is different than classical identity certificates. Although the identification of the certificate holder is still possible in attribute certificates, it is optional. The actual task of an attribute certificate is the binding of a privilege to an entity. After the verifying agent verifies the attribute certificate of an entity and authenticates it successfully, it gives access to the resources allowed within the certificate.

The certificate path concept is also valid for attribute certificates. However, there are some differences in terminology and roles as compared with identity certificates and PKI, because attribute certificates are used to implement PMI (privilege management infrastructure) rather than PKI. PMI defines the rules and the general concepts about using attribute certificates as a system for managing access control. Although the X.509 recommendation defines some critical components of a PMI, it does not define a PMI in its entirety.

In PMI, the root CA becomes the SOA (source of authority), which issues attribute certificates to AAs (attribute authorities). AAs, which are analogous to CAs in PKI, issue attribute certificates to end entities.

The fields of attribute certificates are briefly described as follows:

Version differentiates between the different versions of the attribute certificates.

Holder is an optional field that conveys the identity of the attribute certificate's holder.

Issuer conveys the identity of the AA that issued the certificate.

Signature identifies the cryptographic algorithm used to digitally sign the attribute certificate.

Serial number is the number that uniquely identifies the attribute certificate. The uniqueness is within the scope of the certificate issuer.

Validity period conveys the time period during which the attribute certificate is considered as valid.

Attributes contains a list of attributes (or privileges) associated with the certificate holder.

Issuer unique ID is an optional field that is used to uniquely identify the issuer of the attribute certificate when such an identification is necessary.

Similar to identity certificates, the structure of the attribute certificate allows some extension fields.

SPKI/SDSI Certificates

The simple public key infrastructure (SPKI; Ellison, 1999b; Ellison et al., 1999) was designed by an Internet Engineering Task Force (IETF) working group (Simple Public Key Infrastructure Charter, n.d.) led by Ellison (this working group is currently inactive). The SPKI certificates contain authorization information and bind the keys to that information. Thus, SPKI certificates are also called *authorization certificates*. The primary purpose of SPKI authorization certificates is to grant permissions. They also include the ability to delegate permissions to other entities. In that respect, it can be deduced that the basic aim of SPKI is quite similar to the X.509 attribute certificate framework, but the SPKI initiative started much earlier, in 1996.

Rivest and Lampson (1996) proposed simple distributed security infrastructure (SDSI). SDSI combines a simple PKI design with a means of defining groups and issuing group membership certificates. SDSI's groups provide simple, clear terminology for defining access control lists and security policies. The designs of SDSI and SPKI have merged in the SDSI 2.0 version.

Proponents of SPKI/SDSI have had two basic arguments against X.509 certificates:

- The X.509 certificate format is complicated and bulky.
- The concept of a globally unique identity (such as X.509's DN structure) will never be realized. Ellison (1999a) and Adams and Lloyd (1999) discuss some difficulties in dealing with globally unique names and DN. The main point here is the fact that globally unique names are not so meaningful without local significance. For example, "John Smith, from XYZ Co., NYC" may be unique, but does not help you to figure out that he is the person that you met on vacation unless you locally store the extra information "from the Canary Islands" in your address book.

SPKI certificates used public keys as the identities. Later, SPKI inherited the local name concept from SDSI. SDSI allows each user to define his or her own local name space and issue his or own certificates in that name space. SPKI associated SDSI local names with the keys. In this way, the SPKI/SDSI initiative avoided using global names in certificates.

The SPKI specifications developed by the IETF working group (Ellison, 1999b; Ellison et al., 1999) discuss concepts and provide detailed certificate formats, signature formats, and associated protocols. SPKI RFCs use S-expressions, a LISP-like parenthesized expression, as the standard format for certificates and define a canonical form for those S-expressions.

An SPKI authorization certificate has a number of fields similar to X.509 certificates, such as issuer, subject, and validity. However, the syntax and, most of the time,

the semantics are different. Moreover, SPKI has a number of fields for access control and delegation. The structure of these fields is not strictly defined in the specifications. This is done deliberately to provide enough flexibility to applications that proliferate SPKI certificates.

The SPKI working group of the IETF (Simple Public Key Infrastructure Charter, n.d.) mentions "the key certificate format and associated protocols are to be simple to understand, implement, and use." However, according to Adams and Lloyd (1999), the sophisticated certificate structure of SPKI has diminished the intended simplicity.

The IETF work on SPKI was completed in 1999. Some libraries and prototype implementations have been developed (Ellison, n.d.). However, it is very hard to say that there is an important demand for SPKI certificates in the market (Adams & Lloyd, 1999).

WTLS Certificates

WAP (wireless access protocol; WAP Forum, 2001b) is a framework for developing applications to run over wireless networks. WAP, which was developed by an international industrywide organization called the WAP Forum, has a layered structure. WTLS (wireless transport layer security; WAP Forum, 2001a) is the security protocol of the WAP protocol suite. WTLS operates over the transport layer and provides end-to-end security, where one end is the mobile client and the other end is the WAP gateway. The WAP gateway acts as a proxy for the mobile client to access an application server, which is hosted somewhere on the Internet. The handicaps of the wireless environment are basically the limited processing power of mobile clients and the limited data transfer rate of the mobile communication environment. Thus, classical X.509 certificates are not so feasible for WTLS because of their lengthy format.

The WTLS standard (WAP Forum, 2001a) defines a special certificate structure, so-called WTLS certificates, that can be used in this restricted environment. In essence, a WTLS certificate is the light version of a X.509 certificate. The infrastructural rules of WTLS certificates are more or less the same as X.509, but some fields are either removed or simplified. WTLS certificate fields are explained in the following:

Certificate version determines the version of the certificate. Currently it is 1.

Signature algorithm describes the public key algorithm used for signing the WTLS certificate.

Issuer defines the CA who signed the certificate. Several name formats are available including the DN format employed by classical X.509 certificates.

Subject identifies the owner of the WTLS certificate. As with the issuer field, several name formats can be used.

Not valid before, not valid after: these fields determine the validity period of the WTLS certificate.

Public key type, parameters, public key: these three fields determine the public key to be certified along with its type and parameters.

WTLS certificates do not include any extension fields.

The use of elliptic curve cryptosystems (ECC; Menezes, 1993) is encouraged because of smaller key and signature sizes as compared to the RSA cryptosystem. Moreover, ECC implementations are known to be faster than those of its rivals.

PGP Key Signatures (Certificates)

Although PGP (Pretty Good Privacy) is known as an e-mail security software, its unique public key management offers a new certificate-like structure (although it is not 100% correct to name this structure *certificate*, we do so for the sake of consistency in terminology). The philosophy of PGP is to allow the utmost freedom to its users in selecting their trust anchors and trust policy. In such a system, there is no distinction between the CA and the end user. Indeed, in PGP, every end user can also be an authority resulting in a mesh-like certificate graph, known as a **web of trust**.

Actually, PGP's liberal approach has changed over time. Together with the commercialization of the software, commercial concerns have impaired the original liberal approach. This section highlights the original approach of version 2.6.

In PGP, every user, as verifier, determines his or her trusted entities and accepts certificates issued by them. A particular entity may be trusted by one user, but may not be trusted by another one. Moreover, this trust is not binary; the verifier may partially trust an entity as an authority. To deem a public key P belonging a user X as valid, the verifier should either (a) know X and issue the certificate for P or (b) obtain valid certificates for P issued by entities trusted by the verifier. In the latter case, the verifier should obtain one such certificate if the issuer is fully trusted or two such certificates if the issuers are partially trusted.

A PGP public key is stored together with all of the certificates issued for it. That is why obtaining a certificate is quite straightforward.

The structure is explained as follows:

Time stamp: the time stamp indicates the date and time that the key was generated. This is not lifetime. Original PGP does not grant lifetimes for keys and certificates. See the Certificate Revocation section for more details.

Key ID: key ID is an identifier for the key. This is actually the least significant 64 bits of the public key.

Public key: the public key of the owner together with necessary parameters.

User ID: this identifies the owner of the key. This field generally contains a textual name and an e-mail address.

Signatures: the digital signatures over this public key. These are issued by several people. Each signature entry also includes the identification of the signer.

Apart from these data that can be downloaded from public key servers, each user (verifier) adds some more information after storing a public key and its signatures into his or her local public key ring file. These are explained as follows:

Owner trust: this indicates how much the verifier trusts the owner of the public key as a certificate issuer for other people.

Signature trust: there is a signature trust field for each signature over a public key. This field indicates how much the verifier trusts the issuer of the signature. This field's value is copied from the owner trust value of the entry for the public key of the signature issuer.

Key legitimacy: this is a computed value that indicates whether the subject public key is deemed to be legitimate or not. It is computed by the PGP software using other fields of the public key entry in the key ring file and parameters set by the verifier.

ISSUES AND DISCUSSIONS

Apart from the structure and basic characteristics of certificates, there are several other issues that must be addressed. These issues are discussed in this section.

Certificate Revocation

X.509-based certificates have specific validity periods and a certificate is valid only within this period. However, various circumstances may cause a certificate to become invalid prior to the expiration of the validity period. Such circumstances might include change of name, change of association between the certificate owner and CA, and compromise or suspected compromise of the corresponding private key. Under such circumstances, the CA or the certificate owner needs to revoke the certificate.

The method for certificate revocation in X.509 is to employ the certificate revocation list (CRL) concept. A CRL is a signed list of unexpired but revoked certificates. The CRL structure includes serial numbers and the revocation dates of the revoked certificates. This list is signed by the corresponding CA. CRLs are issued periodically by the CAs. Each CRL invalidates the previous CRL. The certificate entries in a CRL are removed when the expiration dates of the revoked certificates are reached. A certificate, for which the validity period has not yet expired, should not appear in the most recent CRL of the issued CA to be verified successfully.

A supplementary approach to the CRL is the delta-CRL approach where the idea is to transfer incremental information when the revocation lists are updated and not to repeat the previously sent revocation information. This is done to save both time and bandwidth.

In addition to the base CRL message structure, two extension groups are dedicated for CRLs as well. These are *basic CRL extensions* and *CRL distribution points and delta-CRLs*.

Basic CRL extensions allow a CRL to

- Include indications of the reason for revocation.
- Include the date when the authority posted the revocation (for each revoked certificate).
- Provide flexibility for temporary suspension of a certificate.
- Include the scope of certificates covered by that list.
- Include CRL issue sequence numbers for each CRL issue to help certificate users to detect missing CRLs.

CRL distribution points and delta-CRLs extensions allow the complete set of revocation information from one CA to be partitioned into separate CRLs and allow revocation information from multiple CAs to be combined in one CRL. These extensions also support the use of delta CRLs described previously.

Online certificate status protocol (OCSP) is published as an RFC (Myers et al., 1999). It is a simple request/response protocol that requires online servers, so-called OCSP responders, to distribute the certificate status on demand. Each CA must run its own OCSP responder, unless several CAs collaborate on this issue. The main advantage of using OCSP is that the most up-to-date certificate status information, which is stored in the OCSP responder system, is returned because of the real-time response feature of the OCSP. However, in the CRL approach, there is latency between a particular revocation time and the next CRL or delta CRL issuance time. It should also be noted that the promptness of the response in the OCSP is only as good as the source of the revocation information. Here there might be some delays in storing the revocation data in the OCSP responder system, but this delay is not as large as in the CRL case.

Kocher (1998) has proposed certificate revocation trees (CRTs). CRTs are used to compile the revocation information on a single hash tree. CRTs provide an efficient and scalable mechanism to distribute revocation information. As Kocher mentions, CRTs are gaining increased use worldwide for several reasons. They can be used with existing protocols and certificates, and they enable the secure, reliable, scalable, and inexpensive validation of certificates (as well as digital signatures and other data). The main disadvantage of CRTs is that any change in the set of revoked certificates results in recomputation of the entire CRT.

PGP (Zimmermann, 1994) public keys and certificates may optionally have validity periods, but it is more common not to have them and to make them nonexpiring. Therefore, PGP public keys and certificates are valid until they are revoked. PGP public keys can be revoked only by the public key owner and by issuing a key revocation certificate. Similarly, certificates can be revoked by revocation certificates issued by the certificate signers. These revocation certificates invalidate the public keys/certificates; however, the revoked objects do not disappear. Moreover, there is no revocation list concept in PGP. Revocation certificates are distributed like the public keys and certificates. The most common approach is to use public key servers. The revocation certificates are kept in the public key servers together with the keys and certificates. If a key or certificate has a revocation certificate, then the verifier understands that this key or certificate is invalid.

Yet another and extreme approach to certificate revocation is not to have the revocation concept at all as in the SDSI (Rivest & Lampson, 1996) and SPKI (Ellison et al., 1999) systems. There is no CRL in these systems. Instead, each certificate is assigned an appropriate validity period. The certificate times out after this period and needs revalidation. Revalidations are performed either by the certificate issuers or by specific revalidation authorities.

To revalidate a certificate, the certificate issuer re-signs the certificate content with a new time stamp. In contrast, revalidation authorities sign the whole certificate content and the original signature on it to revalidate a certificate.

A similar approach is also used for WTLS certificates. Because of the significant cost of existing revocation schemes in mobile environments, Verisign, Inc., a leading WTLS certificate provider, has chosen to issue short-lived certificates and reissue them within short intervals (say one day). In this way, the servers update their certificates every so often, but the mobile clients need not download anything for revocation control.

Certificate Distribution

The problem of certificate distribution is mostly addressed by the applications that use the certificates. In most cases, applications exchange necessary certificates at the beginning of the interaction or when needed; they do not rely on some other mechanism for the procurement of certificates. Some of these applications are discussed in the next section.

When the X.509 certificates were first proposed, the main idea was to make use of X.500 distributed directories for certificate distribution. The CAs would serve as directory servers, or they would publish the certificates that they issued to other directory servers. The verifier would query the directory to get the certificates on a certificate path to verify the public key of a specific end user. Although it is not exactly the same as the X.500 directories, DNSSEC (domain name system security extensions; Eastlake, 1999) also assumes a distributed approach. It may be too early to comment on the DNSSEC approach, but it is fairly clear that the X.500 directory approach is unlikely ever to come to fruition, as discussed by Ellison (n.d.). The main reason Ellison put forward is that collections of directory entries (such as employee lists, customer lists, contact lists, etc.) are considered valuable or even confidential by their owners and are not likely to be released to the world.

As described, PGP makes use of centralized databases (public key servers) for the distribution of keys and certificates. There are numerous PGP key servers all over the world. They are synchronized and keep the same information. Thus, it is sufficient to communicate with one of them for public key transfers. To see an example key server, readers may refer to <http://www.keyserver.net>, which currently holds more than 1.6 million PGP public keys. The main disadvantage of these key servers is that they keep the keys and certificates without any control and verification of authenticity; users should therefore verify the authenticity of these public keys on their own. As an alternative, PGP Corp. has recently announced a verified key service, called PGP Global Directory (PGP Corp., n.d.). The PGP Global Directory is a verified directory of PGP keys. Unlike previous servers that stored PGP keys indiscriminately, the PGP Global Directory allows users to upload and manage their keys in a verified manner. When uploading a key or performing other key management features, PGP Global Directory verifies a key by requiring a response to a verification e-mail sent to each

e-mail address specified on the key. Because this is not a 100% secure authentication mechanism, there is always a risk that the verified key in the PGP Global Directory is not actually owned by the person who appears to own it. Thus, the PGP Global Directory should not be considered as a replacement for the PGP web of trust, but as an additional mechanism.

Peer-to-peer certificate transfer is another mechanism that should not be underestimated. Here the basic idea is the transfer of the certificate from one peer to another via an online/offline link such as an e-mail attachment or on a CD.

Certificates as Electronic IDs

One of the marketing strategies of certificates is to promote them as electronic versions of IDs. This analogy is intuitively appealing. There are, indeed, similarities between IDs and certificates: both are endorsed by authorities, both bear the name of the owner, both are small. However, a detailed analysis of certificates shows that there is a difference between certificates and IDs in terms of the participation of the holder in subsequent authentication and authorization transactions. The verification of an ID via the picture on it and the recognition of the authority's endorsement are sufficient for the owner to obtain privileges; the person holding the ID need not do anything extra. However, the verification of a certificate via the verification of the CA signature on it is not sufficient to make sure that the owner is really the person he or she claims to be. Certificate verification only helps the verifier confirm the public key of the certificate holder. The certificate holder should also show that he or she knows the private key corresponding to the public key in the certificate to prove his or her identity. This requires an extra protocol run embedded in applications, and the certificate holder should actively participate in this protocol.

Privacy Concerns

Identity certificates are not designed to provide privacy-enhanced transactions. An identity certificate contains personal information, such as name, addresses, date of birth, affiliation, and so forth, about its owner. Because certificates are stored in public registers, as explained previously, and certificates are in cleartext, the personal information stored in them may be obtained by anyone. This encourages identity theft. Moreover, whenever an identity certificate is used in an application, the privacy of the certificate owner can no longer be maintained. Most people would object to having to identify themselves in every transaction and interaction they undertake. Assuming that these applications use OCSP to check certificate validity, the activities of the certificate owner can be tracked using central OCSP logs. In this way, all of an individual's actions can be linked and traced automatically and instantaneously by various parties.

This discussion points to a significant privacy problem in using certificates. Attribute certificates may be considered as a primitive step to achieving privacy because they

may not include the owner's identity. However, because these certificates are not issued anonymously (at least the AA knows to whom it issued the certificate), we cannot say that attribute certificates address all of the concerns of privacy advocates.

In this regard, Stefan Brands' contributions to anonymity and privacy-enhancing techniques in certificates are worth mentioning. Brands (2000, 2002) proposed a different conception and implementation of digital certificates, called *digital credentials*, such that privacy is protected and anonymity is provided without sacrificing security. The validity of digital credentials and their contents can be checked, but the identity of the holder cannot be extracted, and different actions by the same person cannot be linked. Holders of digital credentials have control over the information to be disclosed to other parties.

Brands' book (2000) is a very good source of information on privacy-related discussions regarding certificates and other privacy-enhancing techniques.

PKIX and X.509

PKIX (X.509-based PKI) is a working group of the IETF established in 1995 (Public-Key Infrastructure, X.509, PKIX, n.d.). The initial role of this working group was to develop Internet standards needed to support an X.509-based PKI. The scope of PKIX has since expanded, and some new protocols have been developed that are related to the use of X.509-based PKIs on the Internet.

Although it seems that PKIX is only a user of X.509, the progress of X.509 has been extensively influenced by the PKIX working group because the X.509 standard was not sufficient to address the PKI issues of the Internet.

The PKIX working group has published several RFCs. A full list of these RFCs can be obtained at the charter Web site (Public-Key Infrastructure, X.509, PKIX, n.d.). Some of them that are directly related to certificate structure and processing are listed here:

- Algorithms and Identifiers for the Internet X.509 Public Key Infrastructure Certificate and CRI Profile (RFC 3279).
- An Internet Attribute Certificate Profile for Authorization (RFC 3281).
- Internet X.509 Certificate Request Message Format (RFC 2511).
- Internet X.509 Public Key Infrastructure Certificate and CRL Profile (RFC 3280).
- Internet X.509 Public Key Infrastructure Certificate Management Protocols (RFC 2510).
- Internet X.509 Public Key Infrastructure Certificate Policy and Certification Practices Framework (RFC 3647).
- Internet X.509 Public Key Infrastructure Data Validation and Certification Server Protocols (RFC 3029).
- Internet X.509 Public Key Infrastructure Proxy Certificate Profile (RFC 3820).
- Internet X.509 Public Key Infrastructure: Qualified Certificates Profile (RFC 3739).

APPLICATION PROTOCOLS BASED ON X.509 CERTIFICATES

The development of the PKIX standards and X.509 certificates encouraged several TCP/IP-based applications to provide security mechanisms featuring certificates. In this section, some of these applications are overviewed with some detail on how they utilize certificates.

PEM (privacy-enhanced mail) was one of the first protocols to utilize X.509. PEM provides encryption and authentication features to e-mails utilizing a variety of cryptographic primitives. RFCs 1421–1424 define PEM; RFC 1422 explains the certificate-based key management employed in PEM.

Because PEM was defined during the period when X.509v1 was the only certificate structure available, it was based on X.509v1. Consequently, it did not support any custom-defined policies and end-user-centric trust management. The PKI model of PEM was a strictly hierarchical one. The verifiers could not practice their own trust policies; thus, they had to blindly trust all authorities in this hierarchy in order to participate in the system. These strict regulations discouraged people from using PEM. Thus, PEM never reached a significant population. This experience showed that the certificate structure should be flexible to be able to implement different policies and user-centric trust management. This conclusion made the X.509 designers think about a flexible certificate structure that eventually yielded X.509v3.

SSL (secure sockets layer) is the most widely used certificate-based TCP/IP security mechanism. The aim is to create an upper-TCP security sublayer that can be used for several client–server applications such as HTTP (hypertext transfer protocol), FTP (file transfer protocol), POP3 (post office protocol version 3), SMTP (simple mail transfer protocol), IMAP (Internet mail access protocol), and so forth. SSL works in a session manner. Before the data connection, the end parties create a session key and forthcoming traffic is authenticated and encrypted using this session key. Session key generation requires some public key operations. Necessary public keys are distributed via X.509 certificates at the beginning of the protocol.

There is no enforced PKI model for SSL. Generally each CA generates a local hierarchy for the certificates issued by itself. Thus, there is no global PKI for SSL. Necessary root CA certificates are pre-distributed within client software such as MS Windows and Netscape.

The reason behind the success of SSL is mainly due to its flexibility in PKI topology and support given by key players in the industry. This industry support has come not only with root CA certificate pre-distributions, but also with integration of the protocol in key products such as operating systems, browsers, and other client applications. Thus, clients do not need to make any configurations to use SSL. Moreover, SSL is a protocol such that all necessary steps that are taken are transparent to the client. This is another reason behind the success of SSL.

S/MIME (secure/multipart Internet mail extensions) is the security enhancement on top of MIME, the Internet e-mail format standard. MIME describes content types for various types of attachments to e-mail messages.

S/MIME defines secure content types for encrypted and signed e-mail messages that are to be sent peer to peer. The security functionality provided by S/MIME is not so different from its predecessor, PEM. The difference is in certificate and key management features: S/MIME uses X.509v3 certificates; a particular PKI is not assumed as in SSL; necessary root-CA certificates come with the e-mail client programs.

Although S/MIME follows the successful certificate and key management strategy of SSL, it has not achieved a significant user population. The main reason for this is that in e-mail applications, both end points are clients and they need to use certificates. Individuals generally refrain from spending time, money, and effort on such add-on utilities. This is exactly what has happened in the case of S/MIME, and the use of S/MIME has not been very significant. In contrast, the use of SSL is mostly in the form of server authentication where only the server uses certificate; clients rarely use certificates to authenticate themselves. It is quite reasonable for an organization to spend time, money, and effort to obtain certificates to secure its servers.

To improve the use of this important technology, e-mail vendors need to find a mechanism to make the system transparent to the clients so that they do not need certificates. One alternative, as in the DomainKeys proposal by Yahoo (Delany, n.d.), could be using S/MIME not end to end but between e-mail gateways (sender and receiver SMTP servers), and providing another solution (e.g., using SSL over POP3 or IMAP) in the local area. In this way, only e-mail gateways need to use certificates; clients do not. One disadvantage of this mechanism, however, is that end-to-end security is not provided.

Another e-mail security solution, which uses certificates among the servers but not for the clients, is proposed by Levi and Ozcan (2004). In this system, called PractiSES (practical and secure e-mail system), clients register to their domain servers free of cost. Once registered, they can send and accept signed/encrypted e-mails without dealing with the complexity of public key transfers. Domain servers arrange the necessary public key transfers in a collaborative way without putting an extra burden on the client side. Unlike DomainKeys, PractiSES provides end-to-end security.

SSH (secure shell) can also be considered as a secure version of telnet, that is, secure remote terminal application. In SSH, public key agreement techniques are utilized before the username/password transfer. When a common key is established, encryption is performed to ensure the confidentiality of the transferred data. In SSH, certificates may be used to facilitate public key transfers between the client and the server. When client certificates are used, authentication of the client can be performed using public key techniques rather than the classical username/password mechanism. In contrast, server certificates are used to initiate the initial key agreement and to establish server authentication to the client.

Although it may seem that at least a server certificate is necessary for an authenticated key agreement between the client and the server, this is not essential. SSH allows the transfer of the server public key to the client in clear-text form. The client checks the fingerprint of the key and

accepts this public key as valid for all subsequent communications. To make sure that the key is correct, the client should double-check its fingerprint against a known source. This may not be feasible in a large distributed client-server system, but in the case of SSH this check may be performed because the number of servers is manageable.

IPSec (IP security) is the IP (Internet protocol) layer security architecture that has been standardized by an IETF working group (IP Security Protocol Charter, n.d.). IPSec architecture contains a set of concepts and protocols for authenticity, integrity, confidentiality, and key exchange/management at the IP layer. The IKE (Internet key exchange) protocol (Harkins & Carrel, 1998) of IPSec provides authenticated key exchange using a specific profile of X.509 certificates.

Use of Certificates in the Financial Services Industry

Certificates are being used by several applications operated by the financial services industry. Nowadays, e-banking applications targeted at individual customers are mostly SSL/TLS-based because such an approach requires minimal maintenance at the client end and, thus, makes the system scalable. However, financial institutions are keen to develop and/or obtain application-specific solutions for their corporate customers. Such applications use certificate-based solutions for key exchange and management.

With regard to e-payment, SET (SET Secure Electronic Transaction LLC; n.d.) defines protocols for certificate issuance and processing in the context of credit card payments via the Internet.

In 1998, NACHA (National Automated Clearing House Association) sponsored a successful pilot for CA interoperability for the Web shopping experience. Several banks and CAs participated in this pilot. Lessons learned from this pilot activity were published by NACHA (Prince & Foster, 1999).

The ANSI (American National Standards Institute) committee X9F (Accredited Standards Committee X9, n.d.) and ISO (International Organization for Standardization) Technical Committee 68 (TC68; ISO/TC68 Financial Services, n.d.) have developed some standards to profile X.509 certificates and CRL structures to provide for the particular needs of the financial services industry.

KEY PLAYERS IN THE INDUSTRY AND THEIR CERTIFICATION PRACTICES

The CAs that issue X.509v3 certificates for different applications follow a set of rules in their certification practices. These CAs, such as Verisign, Entrust, Baltimore, Global-sign, and so forth, follow slightly different approaches; however, the main idea is generally the same. The certification practice of each CA is declared on its Web site.

Certificate Classes

Certification practices propose different levels of identity verification in different classes of certificates. In this section, a general picture of these classes is given.

Class 1 certificates: The name of the subject entity is not checked. Only an e-mail address control is performed by sending an authentication string to the mailbox address that the subject entity provides in the certificate application. To complete the certificate issuance process, the subject entity should use this authentication string. That naively proves the ability of the subject entity's access to a mailbox. That mailbox address appears in the certificate. Some CAs also include the name of the subject entity in the certificate, specifying that the name is not validated. However, the appropriate action would be not to include a name in class 1 certificates, as some other CAs do. Class 1 certificate issuance is an online process. Class 1 certificates are mostly used for S/MIME.

Class 2 certificates: Name and some other information (such as address) of the subject entity are checked against a third-party database. Mailbox access control as in the class 1 certificates is also processed. The whole process is online.

Class 3 certificates: In addition to the mailbox access control, the subject entity should personally present an identity document to a registration authority. The level of assurance in identification is the highest of all the classes, but the process is offline and it may take several days to obtain the certificate. SSL server certificates are issued in this class. CAs also perform DNS control to make sure that the certified URL really belongs to the organization that claims to have it.

As can be seen, class 1 certificates provide the lowest degree of identity assurance but are the easiest to issue, whereas class 3 certificates provide the highest degree of identity assurance but are the most difficult to issue. Having said this, it should be mentioned that the certificate issuance process is not always fail-proof even for class 3 certificates because of the human factor involved in the certificate issuance process. An example of such an incident was reported by CERT® (Computer Emergency Response Team; CERT® Advisory CA-2001-04, 2001). The overview part of this report is quoted below with no comments.

On January 29 and 30, 2001, VeriSign, Inc. issued two certificates to an individual fraudulently claiming to be an employee of Microsoft Corporation. Any code signed by these certificates will appear to be legitimately signed by Microsoft when, in fact, it is not. Although users who try to run code signed with these certificates will generally be presented with a warning dialog, there will not be any obvious reason to believe that the certificate is not authentic.

PKCS Standards Related to Certificates

The PKCS standards are specifications produced by RSA Laboratories in cooperation with secure systems developers worldwide for the purpose of accelerating the deployment of public key cryptography. Some of those standards, namely PKCS #6 (extended certificate syntax standard), PKCS #10 (certification request syntax standard), and PKCS #15 (cryptographic token information format standard), are related to certificates. These PKCS

standards, except PKCS #6, mostly deal with implementation issues rather than defining new certificate types.

PKCS #6 standard, which was issued in 1993, describes the syntax for extended certificates. An extended certificate consists of an X.509v1 public key certificate and a set of attributes, collectively signed by the issuer of the X.509v1 public key certificate. These additional attributes were needed at that time because the X.509v1 certificate structure was rather limited. With the addition of extensions to X.509v3 certificates, PKCS #6 became redundant and RSA Laboratories started to withdraw their support for PKCS #6.

PKCS #10 is an important standard that describes syntax for certification requests. A certification request consists of a distinguished name, a public key, and optionally a set of attributes, collectively signed by the entity requesting certification. Certification requests are sent to a certification authority, which transforms the request into an X.509 public key certificate.

PKCS #15 is the cryptographic token information format standard. This standard aims at using cryptographic tokens as identification devices. To do so it defines different structures for the storage of different types of certificates, such as X.509, PGP, and WTLS certificates, in tokens.

SUMMARY AND CONCLUSION

This chapter has discussed different types of certificates together with some issues and standards associated with them. There is an important trend of certificate use in security applications. Classical client-server or peer-to-peer applications have been utilizing certificates for about a decade. Apart from these conventional applications, certificates have started to be included in smart cards as well. In this way, not only electronic and mobile commerce but also conventional card-based payment and identification schemes would utilize certificates. This wide range of applications makes certificates an important market where several companies are currently competing. These companies are mostly CA companies that issue certificates for end users and organizations.

Expiration of the RSA patent has created an opportunity for generating key pairs without paying royalties. However, CA companies have not reflected these savings in the cost of certificates. To improve the attractiveness of certificate-based solutions at the client end, CA companies need to revise their revenue models to attract more clients. Moreover, certificate-based solutions should be designed such that they provide flexibility and transparency for the clients.

GLOSSARY

Attribute Authority An authority that issues attribute certificates. In this way, the authority assigns privileges to certificate holders.

Attribute Certificates A data structure signed by an attribute authority for the binding of a privilege to an entity.

Certificate (or Digital Certificate) A data structure

endorsed by an authority that binds an entity to an identity, attribute, characteristic, or privilege.

Certificate Path An ordered sequence of certificates, which is processed to obtain the public key of the last object on the path.

Certification Practice Statement (CPS) A document that describes (in detail) how a CA issues certificates and the policies observed by that CA.

Certificate Revocation List (CRL) A signed list indicating a set of certificates that are no longer considered valid by the certificate issuer.

Certificate Verification Verification of the signature on the certificate. In this way, the binding endorsed by the authority is assumed to be legitimate.

Certification Authority (CA) A well-known and trusted entity that issues public key certificates.

Delta CRL A partial certificate revocation list (CRL) that only contains entries for certificates that have had their revocation status changed since the issuance of the base CRL.

Digital Signature Digital information obtained by the application of a private key on a message.

Privilege Management Infrastructure (PMI) The infrastructure that is able to support the management of privileges in support of a comprehensive authorization service and in relationship with a public key infrastructure.

Public Key (Identity) Certificate A data structure signed by a certification authority for the binding of a public key to an entity whose identity is provided.

Public Key Infrastructure (PKI) The infrastructure for the management of public keys in support of authentication, encryption, integrity, or nonrepudiation services.

Root CA A top-level certification authority in hierarchical PKI.

S-Expression The data format chosen for SPKI/SDSI. This is a LISP-like parenthesized expression.

Self-Signed Certificate A certificate where the issuer and the subject are the same CA. Generally root CA certificates are of this type.

Subject The entity for which the certificate has been issued.

Trust Anchor An authority that is deemed trustworthy by a user.

INTRODUCTION

Electronic mail was the first mass application, now called a “killer app,” of the networked world. It dominated Internet traffic until the explosion of activity subsequent to the advent of the World Wide Web (WWW; a more complete description of the WWW is provided elsewhere in this *Handbook*). Many people incorrectly associate electronic mail with the Internet. Electronic mail predates the Internet, and even today there are electronic mail systems that use technologies other than those used on the Internet.

Today’s electronic mail landscape is an ecosystem with many inhabitants.

The history of electronic mail is a complex tapestry of give and take among the research, business, academic, and other communities. It is a story of experiments in message content, transport, addressing, composition, and reception.

The original electronic mail concept was modest, providing for transmission of simple text messages. Today, electronic mail is used as a vehicle for all forms of media, from the original text messages envisioned on the first day to audio, video, and many forms of composite messages. It has, in effect if not in fact, become a lingua franca, the common language for the offline transmission of all forms of content across the global Internet.

STRUCTURE

Any electronic messaging system consists of several inter-related elements: addressing, transport, delivery, storage, message content, and message display.

Different electronic mail systems have different perspectives on these elements. In some architectures, which are specifications of message interchange rather than complete designs, there may be multiple, parallel implementations of functionality. The Internet Simple Mail

Transfer Protocol architecture, known generally by its acronym, SMTP, is one such standard. Presently defined by the Internet Engineering Task Force’s RFCs 2821 (Klensin, 2001) and 2822 (Resnick, 2001), SMTP speaks to the issues involving message addressing and transport, as well as baseline standards for message representation. However, SMTP does not cover the details of message delivery or storage and provides only the barest definition of message content beyond the mechanism for identifying the end of a message.

The delivery mechanism, the means by which a message is actually placed in an individual mailbox associated with a particular user, is a core component of any messaging system. Delivery is a completely separate matter from issues involved in the transport, addressing, or content of the messages.

TECHNOLOGY OF SYNTHESIS

The story of electronic mail does not begin with the circulation of RFC 772 (Sluizer & Postel, 1980), an antecedent to RFC 2821 and 2822, nor does it begin with the seminal decision formulating the `<user>@<system>` syntax, nor does it begin with the first intracomputer message sent between users, although each of these is certainly a familiar and important milepost on the evolutionary pathway of electronic mail.

The true story is a complex one, with interwoven contributions from many different sources, both within the computing community and from its predecessors, the civilian and military communications communities. In some cases, the chain of descent is clear. In other cases, the apparent connection is a case of convergent evolution; two evolutionary paths that independently produced similar designs. The products of these divergent experiences and communities have resulted in a message transport system that has transformed the world.

Figure 1: Messaging evolution, 1800–2005.

HISTORY

The original freestanding Internet electronic mail standard, RFC 772, authored by Suzanne Sluizer and Jon Postel, was published in September 1980. Although RFC 772 is an important milepost in the evolution of electronic mail, it did not spring forth fully formed from the void. It had, as its antecedents, a wealth of experience gained over the millennia in the management of message transmission, a body of knowledge that has been accumulating exponentially as communication has increased in volume and rate. See Figure 1 for a time line.

Pre-Internet

Reliable communication over distances has been a challenge since the beginning of time. Writing itself is a mechanism to allow knowledge to transcend distance and time by allowing it to be replayed at a later time without relying on an individual's memory.

The issues and approaches of Internet electronic mail have their most immediate roots in the postal and telegraphic systems of the past several centuries, particularly the 19th and 20th centuries.

Telegraphy

Samuel Morse invented the serial telegraph in 1832. Portending the data communications boom of the 1960s and 1970s, the United States was soon crisscrossed with telegraph wires, each coming and going to distinct points. Armies of telegraph operators worked these circuits, sending messages that quickly became the lifeblood of government and the financial, transportation, trading, and newspaper industries.

In a relatively short time, electronic communications went from spanning a single continent to connecting continents. The first commercially viable transoceanic telegraph cable across the Atlantic Ocean, from England to Newfoundland, became operational in 1866. It increased the usefulness of telegraphic communications. The time required for intercontinental communications changed from weeks or months to less than a day. Within less than half a century, the telegraphic network spanned the globe.

The second half of the 19th century also saw numerous inventions commercialized for the purpose of increasing

the efficiency of telegraphy. Granville Woods invented the first multiplexers and repeaters in 1887. The invention of the Teletype by Charles Krum in 1906 further accelerated the volume and decreased the cost of messages.

The ever-increasing web of telegraph wires converging in important business centers led to what we would now refer to as message switching, albeit with humans doing most of the processing. The invention of the Teletype, and more important, the advent of punched paper tape, allowed the replacement of human telegraphers at what would now be called “intermediate nodes.” Named after their primary activity, “tear-tape shops” functioned as message switches, with operators removing paper tape from output punches and readying it for reading on the complementary readers that represented the next leg of the journey to the tape's ultimate destination.

Although not generally understood as such, these semi-automated networks gave rise to what is identifiable as a progenitor of packet switching. The international tariffs governing these networks had limits on long messages. Long messages were broken into multiple parts, sent independently, and reassembled at the receiver. Perhaps the most famous such message is the belatedly delivered Japanese diplomatic message of December 7, 1941, that terminated negotiations with the United States and in effect declared war on the United States.

Postal Letter Routing Systems

Throughout the developed world, postal systems are taken for granted. The daily mail is dispatched and delivered. Letters traveling across the continent take a matter of days; small letters dispatched internationally are often at their destinations in less than a week. It seems so effortless that the postal system is seen as background. Reliable, relatively fast, postal service on a large scale is a fairly recent phenomenon.

The analogy between postal and electronic mail is deeper than just the name. Letters are deposited in a collection box, and by means generally not considered, arrive at their destination. The details of the means by which a letter dropped in the corner collection box travels to its destination across town, or across the country, is complex yet almost entirely imperceptible to most people. The details of the mechanism only become visible when problems occur.

Military Communications Systems

No history of electronic messaging can be complete without a discussion of military communications systems, particularly those of World War II and those subsequently developed for the U. S. military.

By the end of World War II in 1945, the military communications systems of the Allies were handling many thousands of messages per day.

Structured military communications were constructed on the basis of telegraphy, whether wired or wireless. In turn, telegraphic practices were no more than a codification of standard office practices, specifically those for memoranda. The procedures used in radio (wireless) telegraphy were adapted from those used in conventional telegraphy, with an increased emphasis on ensuring the identification of the recipient station and the ultimate destination of the message.

Memoranda have addressees, originators, and subjects, as well as bodies and attachments. They also have multiple classes of recipients, including those identified as receiving a copy (carbon copy—"cc:") and those who were sent, but not publicly acknowledged as having been sent, a copy (blind carbon copy—"bcc:"). Military communications systems codified these patterns of civilian business practice and added some elements of their own.

The military is a bastion of the practice of assigning multiple addresses to individuals. Messages may be addressed to individuals or to one of the individual's job titles or offices. For example, an officer will get some messages personally addressed to him as an individual and other messages addressed to him in each of his organizational roles. This is a very apt parallel for the business world, where an individual may have both a personal mail address, an individual mail address within the firm, a mail address associated with their place in the organizational chart (Vice President—Finance), and a mail address associated with each of their other responsibilities.

Corporate electronic mail systems involve many of the same issues as their military cousins. The best practices for commercial messaging systems are often the same as their military counterparts.

User Agents, Protocols, Implementations, and Architectures

When examining the history and evolution of electronic mail, it is also important to be conscious of four different components, or axes of variability. (See Figure 2)

Understanding electronic mail is enhanced by considering the different axes of variability. Some issues are clearly implementation decisions affecting a particular User Agent rather than limitations inherent in the protocol. Other issues are limits in the overall design and conception of the underlying protocols and affect every implementation that employs the protocol.

User Agent

A user's primary interface to the electronic mail system is referred to as a *User Agent*, to borrow the term used by the Internet RFCs. As such, they are the component of the electronic mail system most familiar to users. User Agents have a variety of implementation limitations, which are

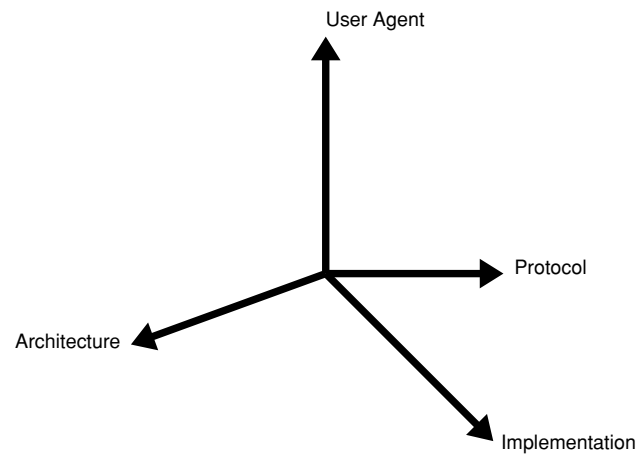

Figure 2: Axes of variability in electronic mail systems design.

the results of their specific implementation, not the requirements of the underlying protocols.

In the Internet-space, the necessary client/server aspects of Mail User Agents have resulted in the creation of dedicated purpose protocols such as POP3 (RFC 1939, Myers & Rose, 1996) and IMAP4 (RFC 1730, Crispin, 1994) for the connections between mail hosts and user clients.

Mail User Agents do not generally implement the core mail transport protocols. For the most part, they use dedicated protocols to access a user's message store on a mail host.

Protocol

An electronic mail protocol must address the fundamental issues of message content and addressing. There are many decisions possible. Some decisions are almost decorative, with many possibilities being different yet functionally equivalent. Other decisions impose presumptions about the content of electronic messages or the organizational philosophy of the senders and recipients.

In some cases, a multitude of protocols may be used when dealing with a particular message in its journey from sender to recipient. As an example, the simplest messages transmitted via the Internet make use of RFC 2821, a descendant of RFC 772, which governs the SMTP protocol itself, and RFC 2822, which governs the overall content and addressing. Messages involving more complex structures, such as attachments, will involve processing governed by additional specifications, such as the Multipurpose Internet Mail Extensions, known by its acronym, MIME (RFCs 2045–2049), which operate within the overall message structure specified by RFC 2822. Depending upon the nature of the specifications, the specifications may be only relevant to the source and destination mail user agents, or they may be relevant to intermediate nodes responsible for the transmission of the message. Another specification involved in en route processing of a message might be the CCITT's (now ITU-T's) X.400.

The systems providing interconnections and translations between one set of protocols and another are referred to as *gateways*. A message may go through any number of gateways during its journey from sender to

recipient. Gateways may provide bridges between different electronic mail protocols or they may move electronic mail messages to/from other messaging systems, such as the Short Message Service, known by its acronym SMS, which is used to transmit text messages between mobile telephones.

Implementations

It is important to understand that the differences and restrictions imposed by particular implementations are separate from those that are inherently a fundamental part of the protocol itself. As an example, there have been implementations of SMTP that run over network protocols other than TCP/IP (Transmission Control Protocol/Internet Protocol). Such implementations may have minor restrictions beyond those relevant on a TCP/IP network layer.

Architectures

Some mail architectures are designed around the concept of a host or server central to the entire implementation that uses a common message store. In such architectures, electronic mail messages are comingled in a central database. Such a system has manageability advantages when considering issues such as electronic mail preservation and monitoring. The disadvantage of such a centralized system and unified message store is that a technical or operational problem affecting the database shuts down electronic messaging for everyone connected to that system.

At the other extreme, all user messages may be stored on individual user machines (or individual user accounts on intermediate-size systems). This approach yields the highest degree of operational independence, yet it also means that each individual electronic mail archive must be included within the backup regime. Increasingly, many industries (e.g., financial services in the United States) are subject to regulatory requirements to document the reception and transmission of electronic mail. Individual message stores in this context may pose compliance complications.

Another approach is for user messages to be stored on and forwarded through some smaller number of intermediate-sized systems, for example on a departmental or divisional basis. This forced routing provides an opportunity for compliance recording and monitoring, as well as the option to implement backup and retention policies.

Intrasystem Mail

Electronic mail does not become a recognizable computer application until the advent of time-sharing systems in the early 1960s. The first recorded civilian, intrasystem electronic mail was implemented by the CTSS team at MIT in 1964.

Two system facilities are required for electronic mail:

- Individual user logins
Individual users must possess some form of distinguishable login. These logins must represent an individual or group.

- Interactive access

All electronic mail systems are based upon some model of interactive computing. Although some systems, particularly commercial and military communications systems, make extensive use of computer technology, the source and destination documents are emphatically physical documents. Although it is common to produce printed copies of electronic mail, electronic mail is electronic-copy centric, not hardcopy-centric.

Networked Electronic Mail

The predecessor of today's Internet started its life as ARPAnet, a research project in packet switching technology for the Advanced Research Projects Agency of the United States Department of Defense. The first network nodes became operational in 1969, connecting the University of California at Los Angeles and SRI. The honor of the first application using the ARPAnet was the virtual terminal facility, the descendants of which are now known by the name of the virtual terminal protocol, RFC 854, *TELNET* (Postel & Reynolds, 1983). See Figure 3 for a time line of the past 40 years.

The ARPAnet expanded over the years, adding connections to additional universities and defense contractors. In the late 1970s, the advent of other networks and intrauniversity networks gave rise to a requirement to internetwork electronic mail (and other communications). This need to gateway, route, and deliver electronic mail among dramatically disparate networks was one of the evolutionary stimuli behind the sequence of Mail Transfer Protocol RFCs beginning with RFC 772 by Postel, et al. and the Domain Name System by Paul Mockapetris (RFC 882/883, Mockapetris, 1983).

Although the ARPAnet is an important part of the networking story, it should be viewed in context. Until the mid 1990s, the TCP/IP protocol stack, and its associated upper level protocols, were seen in the majority of organizations as an interesting research experiment. The majority of commercial organizations' internal electronic mail systems used networking technologies developed by computer manufacturers, such as Digital Equipment Corporation's DECnet and IBM's SNA.

Digital Equipment Corporation's VAX/VMS had peer-to-peer network connections at initial release in 1978, and electronic mail at its first major revision in 1980.

IBM announced a VM/370-based office automation system, the Professional Office System (generally referred to by its acronym, PROFS) in 1981. Digital Equipment's All-in-1™ office system, based on the VAX/VMS operating system, was announced in 1982.

There was also an active effort in messaging standardization by traditional international standards bodies, notably the Paris-based CCITT (Comité Consultatif International de Télégraphique et Téléphonique), culminating in Recommendation X.400, originally released in 1984.

Non-Internet Electronic Mail Systems

While Internet-based technologies were evolving from simple file transfer schemes, a variety of commercial systems had independently evolved from the original

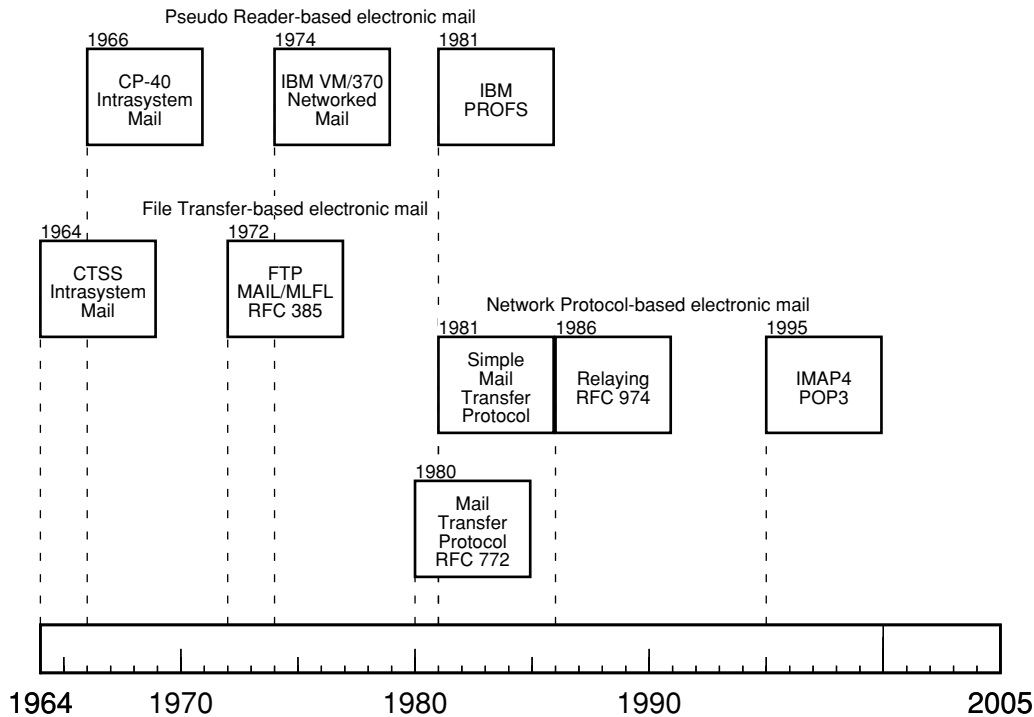

Figure 3: Four decades of evolution in electronic messaging.

electronic mail systems of CTSS and Multics. They developed many features, forms of which have been incorporated into other systems.

IBM's PROFS

IBM released PROFS in 1981 (Gardner, 1987). It was a commercialization of earlier internal work on mail systems, based upon VM/370 and its predecessors. PROFS is notable for its mail delivery mechanism, which differs from most other mail systems in that it does not require privileges or special mechanisms.

In the mid-1960s, IBM's Cambridge Scientific Center worked on a variety of projects related to time sharing that led to the development of VM/370. The antecedents of VM/370, CP-40 and its successor, CP-67, provided a virtual machine environment where each user was provided with the illusion of a dedicated mainframe. CMS (Conversational Monitor System) provided an interactive user environment that ran on a user's individual virtual machine. Shortly after its introduction, CP-67 was enhanced with a facility that allowed users to exchange files between different virtual machines. Shortly thereafter, this facility was used to implement an electronic mail system.

The VNET (VM Network) facility extended the existing file exchange facility to enable the store-and-forward exchange of files between different users on different physical machines (Hendricks & Hartmann, 1979). This delivery mechanism became generally available with the release of RSCS in 1974. RSCS provided VM/370 users with the ability to transfer files between different VM systems in a network. Files could be transferred between systems, even on routings that required storage of the file at the intermediate node. RSCS was thus a natural foundation for a store-and-forward electronic mail network.

IBM, beginning in 1974, developed just such an application for internal use.

It is worth noting that for many years IBM maintained an internal, computerized implementation of a tear-tape messaging system, known as ITPS, within the company for the transmission of messages between IBM facilities. This system had a gateway that allowed electronic mail users to transmit messages to non-electronic mail users within the company, foreshadowing by at least a decade the day when Internet electronic mail under RFC 780 (Sluizer & Postel, 1980) would sprout gateways to systems not directly connected to the Internet.

Digital's Mail-11 Systems

The *Digital Network Architecture* is the set of specifications, developed by Digital for the DECnet series of networking products. Mail-11 is the unpublished specification that describes the handling of DECnet electronic mail.

Mail-11 was first released to users as part of RSTS/E for the PDP-11 in 1980. Mail-11 is designed to transmit text messages between nodes in a DECnet network. Mail-11 is not designed for the transmission of mail that contains attachments, although special provisions exist to transmit binary messages between cooperating nodes.

The Mail-11 implementation for the VAX/VMS (now OpenVMS) is actually implemented in two components: the mail receiver process, which does not require any system privileges for its operation, and a very limited mail-delivery component that has the privileges associated with the actual mail delivery into an individual user's mailbox.

An operational shortcoming is Mail-11's requirement that both the source and destination node be online at the time that the message is sent. There are no provisions for

store-and-forward processing. In a small, local, or dedicated network, the requirement for simultaneous connectivity is an occasional annoyance. In larger networks, with greater numbers of machines and which require indirect connections, it becomes more of a limitation.

Digital's All-in-1™ Office Automation

Mail-11 was not the only electronic mail system sold by Digital Equipment Corporation. All-in-1 was marketed in the office automation market, as an all-encompassing product, a market niche similar to IBM's PROFS.

All-in-1 was a popular office automation and electronic mail system from its introduction in 1982 until the late 1990s. Originally implemented on Digital Equipment Corporation's VAX systems running VAX/VMS, All-in-1 provided a variety of office automation tools. With the advent of the 64-bit Alpha processor, All-in-1 became available on OpenVMS/Alpha.

All-in-1 mail could be connected to outside electronic mail systems including those based on SMTP and other mail systems using gateways. All-in-1 was a pioneer in the use of attachments to electronic mail messages, predating the widespread adoption of the MIME extensions to the SMTP standard.

uunet

uunet was originally a network of UNIX™ systems running the standard UNIX uucp (unix-to-unix copy) utility to connect on a demand or scheduled basis between different systems. Mail routings in this network were explicitly enumerated. The inverse path was used for replies.

The primary users of uunet were machines that could not justify a full-time network connection, but needed a way to connect to the larger world. In some environments, such as university campuses and communities, uucp was used as a way to connect small systems to larger university systems on a regular basis for the exchange of electronic mail and news. The larger systems were often connected via leased lines to ARPAnet, CSNET, or NSFnet.

With time, uucp provided support for RFC 822-style addresses by the use of a so-called "smart host," a host defined to have better knowledge of the routing environment. In effect, this implements the same default routing options available when using the RFC 821/822 electronic mail infrastructure, which often uses a default mail route for systems unable to resolve addresses or connections to the outside world.

CSNET

Funded by the U.S. National Science Foundation in 1980, CSNET was a separate network from ARPAnet. CSNET was originally implemented using a Mail Transfer Agent known as MMDF (Multi-channel Message Distribution Facility) operating over dial-up circuits. Originally designed and implemented with uucp-style explicit routing in destination addresses, CSNET adopted RFC-822-compliant addressing in 1985.

CSNET as a separate network disappeared into the overall Internet for several reasons. Some of these reasons were technical, based upon the migration to IP. Other reasons were political and administrative. Originally, CSNET was conceived as a way to provide an electronic mail

capability to computer science departments not connected to the ARPAnet. ARPAnet had a variety of restrictions originating from its status as a U.S. government-funded enterprise. Until 1995, connection to ARPAnet required an actively funded contract from the U.S. Department of Defense. CSNET, as originally conceived and implemented, was outside the ARPAnet restrictions.

The cessation of direct government funding for the ARPAnet, and the transition to a commercial carrier-owned infrastructure, removed the administrative reasons behind a separate CSNET.

FidoNet

FidoNet was implemented for motivations similar to those for uunet, but was personal system-centric rather than UNIX-centric. The structure of FidoNet is unashamedly hierarchical. By contrast, the structure of uunet was flat, with every node being theoretically equal and thus requiring explicitly enumerated routes.

FidoNet was designed as a minimal-structure messaging network, without an omnipresent name resolution mechanism. The FidoNet address unambiguously determined the routing for a message from its sender to its recipient. There is no need for external routing information.

In 1984, Tom Jennings originated FidoNet as a way of providing communications between microcomputer users via intermittent connection voice-grade telephone lines. The addresses are assigned in the form of <zone>:<net>/<node>.<point>.

In 1986, a gateway between FidoNet and the Internet was established. Several machines are listed in the Internet DNS as mail gateways for addresses in the fidonet.org zone. These gateways receive messages using RFC 821 on the Internet side and map addresses of the form p<point>.f<node>.n<net>.z<zone>.fidonet.org into their equivalent FidoNet addresses, and vice versa.

In many developed areas, the advent of relatively inexpensive broadband (digital subscriber line (DSL), or cable) connections has consigned Fidonet to history. However, in areas where broadband service is not available or not affordable, FidoNet and similar systems remain viable mechanisms for electronic messaging. In 2004, FidoNet still had more than 10,000 active members.

FidoNet contains a number of design elements intended to optimize the network for personal computers communicating on an irregular basis to exchange electronic mail and discussion group messages.

BITNET

In 1981, a number of university sites, led by the City University of New York, formed an electronic mail network called BITNET, based upon the RSCS facility in IBM's VM/370. BITNET also had a number of non-VM/370 nodes that implemented communications using RSCS-compatible protocols. Similar to PROFS, BITNET had, as its underlying structure, the virtual card readers and related components provided by IBM's RSCS on mainframes.

BITNET was primarily a mail transport network. Later, BITNET adopted the IP protocols developed for the ARPAnet and disappeared as a distinctive entity.

The Internet

A short review of the principles underlying the Internet is an important backdrop to the evolution of electronic mail (a full description of the evolution of the Internet can be found elsewhere in this *Handbook*).

- The Internet is a network of networks.
- Each network is composed of computer systems running a multitude of different operating systems on a wide variety of architectures.
- The computer systems are separately owned and managed. They are located over a widely diverse geographical area.
- The communications links constituting the network, or indeed the ones providing connectivity between two nodes on the network, cannot be presumed to be operational at any given moment in time.

Big Three

Internet RFCs number in the thousands. Even allowing for the convention that a revision of an RFC is assigned a new number, there are still literally hundreds of protocols. RFC stands for *Request for Comment*. This reflects the nature of the Internet Standards process, now organized by the Internet Engineering Task Force. Although the process has become more formal over the years, the fundamentals remain unchanged in concept. A proposal defining a particular function over the Internet will be written by an individual or small group, with some degree of input from the community. The draft will then be made available to the interested community, which will then comment on it, hence the name. RFCs may cover specifications, best current practices, or other matters.

Although there are thousands of extant RFCs, only a limited number are directly involved in the transmission and reception of electronic mail.

TELNET. Every network has to start somewhere, and the history of the global Internet is appropriately humble. The initial goal of ARPAnet was to provide resource sharing, primarily time sharing, for researchers throughout the ARPA-funded research community. In 1969, the global Internet's progenitor, ARPAnet, went online, with the initial connection established by way of network processors between two host computers, one each at UCLA and SRI. This first network session was referred to as a "virtual terminal session," the progenitor of the protocol now known as *TELNET*.

stelnet (a program implementing the TELNET protocol using SSL as an underlying technology to provide authentication and encryption) and *SSH* (secure shell) provide the secure implementations of a network terminal protocol. The exposure of unencrypted usernames and passwords has made *stelnet* and *ssh*, both of which have provisions for encryption, the protocols of choice for terminal communications.

TELNET itself still survives, for use in simple situations, and over otherwise encrypted network links.

FTP. For the first several years, electronic mail on the ARPAnet was dealt with as a special case of the File Transfer Protocol (FTP). Electronic mail was delivered to a special location on the destination system, and the destination system was responsible for its processing from that point. It is worthy of note that this design concept, effectively discarded with the advent of SMTP, a dedicated mail transfer protocol, resurfaced as a design pattern for implementations of higher integrity electronic mail systems.

A complete description of FTP can be found elsewhere in this *Handbook*.

SMTP. Originally referred to as MTP (Mail Transfer Protocol) and renamed as SMTP (Simple Mail Transfer Protocol) with the publication of RFC 788 (Postel, 1981) in November 1981, SMTP defines a dedicated protocol for the interchange of electronic mail on the Internet. The focus of MTP/SMTP is to provide for an interchange mechanism in internetting mail between different networks. It was not originally seen as the ultimate mail transport protocol.

A detailed description of SMTP is contained elsewhere in this *Handbook*.

Communications Infrastructure

Originally, both the FTP-based electronic mail provisions and the first few versions of the purpose-designed mail transfer protocol presumed connectivity between the originating host and the receiving host. However, the Internet community was far from unchanging. At the very moment that SMTP was being written, the underlying network was transitioning from a network composed of relatively few large hosts connected via a highly reliable network infrastructure to a more hierarchical structure. This structure embraced computing resources beyond the large-scale hosts that originally were part of ARPAnet. The changeover to IP allowed large numbers of smaller systems to connect through campus local area networks to ARPAnet.

The large-scale hosts that were already connected to ARPAnet became gateways and trusted intermediaries. SMTP was ideally positioned to adopt a new role within the Internet community, that of a protocol for "internetting" electronic mail from senders to recipients with provisions for intermediate relaying. This transitioned electronic mail from a point-to-point transfer mechanism to a store-and-forward message-switching architecture. In a store-and-forward architecture, messages travel from the originating system through an arbitrary number of intermediate nodes to the receiving system. This is an exact parallel to the tear-tape message-switching infrastructure used with punched paper tape. It is also analogous conceptually to the underlying structure of Internet packet switching, albeit using variable length packets over a vastly dilated time scale.

INTERNET ELECTRONIC MAIL GENERAL ARCHITECTURE

Today, most implementations of electronic mail adhere to the RFC 2821/2822 standards. Even where closed systems

Figure 4: RFC 2821/2822, SMTP electronic mail architecture.

use different mechanisms, these RFCs establish the conventions by which mail is exchanged between systems. RFC 2821/2822, released in 2001, is a consolidation of all the enhancements and clarifications since the release of RFC 821/822 in 1982. The basic architecture of an RFC 2821 mail system is shown in Figure 4.

Conceptually, the RFC 2821 electronic mail system is an abstraction of the system by which a letter goes from the sender to the recipient, just as RFC 2822 defines the format and meaning of the address fields of the message.

Unlike the CCITT X.400 standard, which explicitly specified a model of how addresses related to organizations and how organizations were structured, RFC 2822 makes no such assumptions.

In principal, the address fields are composed of two elements separated by an @. The left-hand side identifies an entity to receive a particular message. The right-hand side corresponds to one or more systems, translatable to an IP address or addresses, either direct to one or more hosts (using a DNS A-record in the DNS) or to one or more mail exchangers (using a DNS MX-record). See Figure 5.

In actuality, the seeming black-and-white difference between a mail recipient on the left-hand side of an address and the host name on the right-hand side is blurred by the presence of gateways, forwarders, and aliases, any one (or all of which) can rewrite all or part of the addresses associated with a message.

Often, this rewriting can take place in several unconnected phases. The first hop of the journey may be covered within the sender's organization by an overall policy requiring all SMTP mail to be routed through one of several outgoing gateways. In some cases, this will be static. In other cases, the rewriting is done by intercepting the SMTP connection request of the sending system. This process may be repeated multiple times, depending upon the structure of the sending organization's or

Figure 5: Electronic mail address components.

their Internet service provider's network, until the message reaches a mail exchanger that is permitted to establish outgoing SMTP connections to the recipient domain's mail exchangers. The message will then be received by one of the receiving organization's externally accessible mail exchangers. From this point, the process is inverted until the message reaches its recipient. At any stage in this process, on the sending or receiving side, either side of the address may be rewritten.

As an example, consider processing of electronic mail when many recipients in university communities had multiple aliases, one each for uunet, CSNET, ARPAnet, and BITNET. One reason for the different addresses might be message content. Until 1995, commercial content was not within the acceptable use policy of the ARPAnet. So, a user would, depending upon the message, address the mail to

- johnsmith@harvard.edu
- johnsmith@harvard.csnet
- johnsmith@harvard.bitnet
- johnsmith@harvard.uucp

Although each of these addresses would go from the same sender to the same recipient, the transport paths of the messages would differ. Many mail gateways had rewriting rules, mechanisms to syntactically rewrite addresses to explicitly route messages through specific gateways based upon the destination address.

Rewriting of electronic mail addresses occurs for many reasons. In some cases, such as a gateway, it is used to reformulate addresses from one convention's syntax to the differing syntax requirements of a different network or protocol. In other cases, it is used to convert addresses from an internal form to an external form. Rewriting may add or remove information for addresses, depending upon context. For example, as shown in Figure 6, a message may start with a sender address that contains an internal node name, which may be rewritten by a firewall/gateway to remove the internal node name. The recipient's firewall/gateway may similarly add internal information to the recipient address as the message is routed to its final destination.

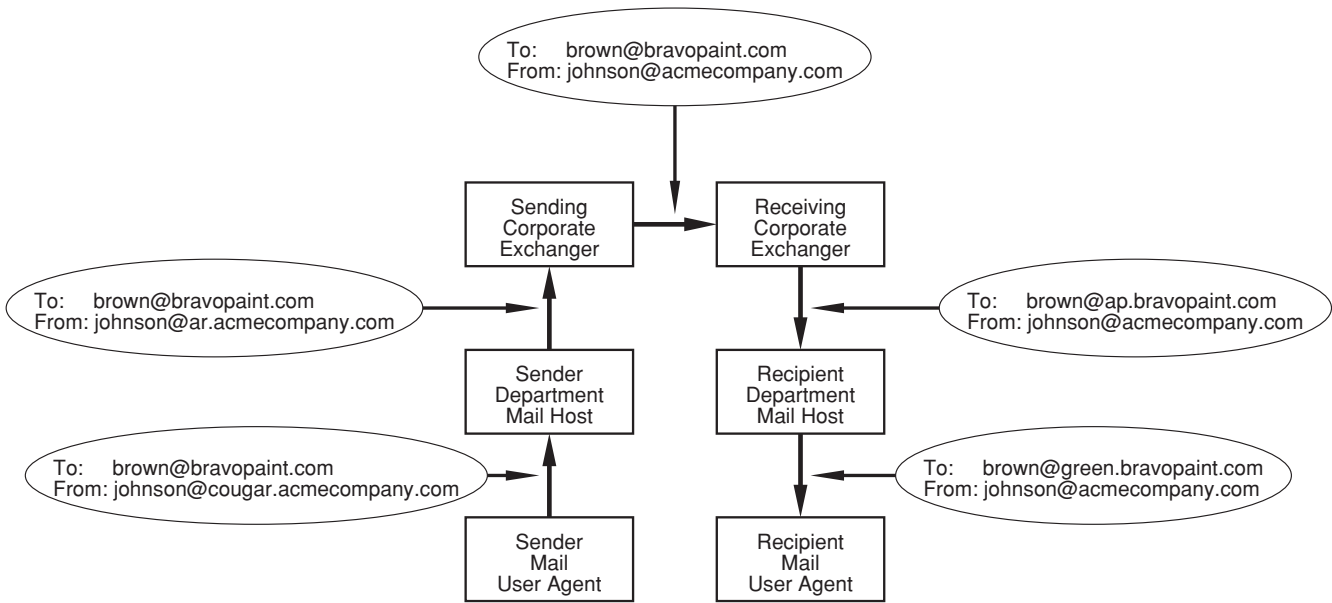

Figure 6: Rewriting of electronic mail addresses.

The actual routing of SMTP mail on ARPAnet and its descendant, the global Internet, is totally divorced from the addressing of the network and the hierarchy of carriers. There are hierarchies in some components, notably in the naming structure of DNS, but these are hierarchies of nomenclature, not structure. The IP address space is flat and featureless, without any inherent structural hierarchy.

In standard SMTP mail, there is a hierarchy of mail exchangers used to relay messages toward their ultimate destination, but it is a ranking of topology and capability, not a direct map of the network. For each different destination node, there is potentially a different set of mail

relays; conversely, the same relay may occupy different relative positions in different relay paths specified in the DNS (Figure 7).

Applicable RFCs

A protocol, such as SMTP, may go through a long progression of RFC numbers as the specification is refined based upon implementation experience. A version of a program may (or may not) be compatible with another program written to an earlier RFC for the same protocol. Compatibility will depend upon the extent and character of the difference, as well as the degree to which the issue was foreseen by the developer.

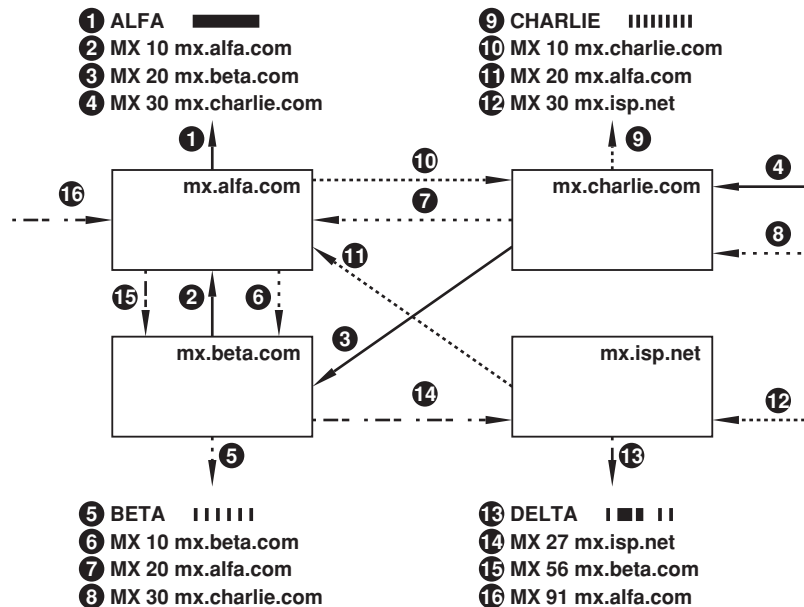

Figure 7: Mail exchangers may occupy different positions in the hierarchy.

Original

RFC 772, entitled “Mail Transfer Protocol” for ARPAnet electronic mail was purpose-designed and written by Suzanne Sluizer and Jon Postel in September 1980. From that origin, the Mail Transfer Protocol has been revised to deal with a number of issues, including hierarchical addresses and relaying.

Standards often piggyback on more fundamental standards by specifying the contents of an element within the bounds of the established definition. *MIME*, the “Multipurpose Internet Mail Extensions,” which regulates the inclusion of attachments of various types within the bodies of electronic mail messages otherwise described by RFC 822 and its successors, is just one such example.

In an ideal world, the areas covered by related standards would be orthogonal, with no influences from one line of specifications to a related line. The real world, however, is far from perfect. Although many specifications take great pains to be upwardly compatible, this is far from a guarantee.

Present Day

SMTP is generally considered to be governed by RFCs 2821 and 2822, which describe the transport protocol for and the addressing of messages, respectively. Although RFC 2821 and 2822 govern the addressing and transport of electronic mail, they are not the only specifications that affect electronic mail. Other RFCs, for example, those for complex message types, referred to as *MIME*, and the User Agent specific protocols POP3 and IMAP4 are also part of the electronic mail infrastructure. See Table 1 for a summary.

SMTP makes limited presumptions about network services at or below the level of TCP. Therefore, there are implementations of SMTP with underlying protocols other than TCP/IP.

Dependencies

SMTP makes some presumptions about the underlying network environment. These assumptions ensure the correct operation of the protocol. On the level of the connection between the sender and recipient, the connections are presumed to be sequenced and error-free, 7-bit transparent connections.

It may seem to be an anachronism, but when the specifications were written, not all computers on the network used a consistent 8-bit version of ASCII. In the name of interchange, SMTP presumes that the connection between the two nodes is restricted to a subset of the 7-bit character set. The *MIME* extensions to SMTP define the means

by which arbitrary 8-bit bytes can be encoded, which enables the handling of a wide range of data types beyond basic text mail.

Changes in the presumed network transport layer have limited effects. SMTP implementations are little affected by the difference in address sizes between IPv4 (32-bit addresses) and IPv6 (128-bit addresses). Outside of extremely limited issues, differences in the transport are irrelevant to an SMTP implementation.

DNS (Domain Name System)

Name resolution is the other component of the supporting infrastructure for mail transmission. Originally, each node on the ARPAnet used a local copy of what is still known as the “Hosts” file. By the early 1980s, the expansion and overall dynamic activity on ARPAnet made this approach problematical.

The original DNS specification (RFC 883, Mockapetris, 1983) was developed to provide a robust, flexible mechanism to resolve host names to IP addresses. The expansion of the ARPAnet to the wider community brought into question the presumption that electronic mail could always be directly sent from sending system to receiving system.

In an example of coevolution, a mail-relaying mechanism described in RFC 974 (Partridge, 1986) proposed changes to the DNS and to the processing of electronic mail governed by SMTP. These changes implemented a relay mechanism, through the creation of a new DNS record, the *MX*-record (Mail Exchanger). *MX*-records identify network nodes that act as a relay for a destination or group of destinations.

As a result, it became possible to describe internetwork gateways as a form of relay, obviating the need for special purpose code in every mailer to deal with the existence of other networks. For example, relaying mail to hosts connected to CSNET no longer required special provisions in mail systems, simply one or more *MX*-records identifying the CSNET gateways.

Nonhostile Environment

RFC 2821/2822 has a quaint presumption from an earlier time, that of an essentially benign operating environment. The underlying standard predates the modern Internet, to a time when the networked community was smaller, the message volumes were smaller, and moral suasion was a viable strategy to ensure adherence to network norms.

The most widely used implementation of RFC 821/822 (now RFC 2821/2822), a UNIX program known as *sendmail*, has been exploited to compromise many systems.

Table 1 Common RFCs Applicable to Internet Electronic Mail

RFCs	Category	Subject Area
2045–2049	Extended content	Multipurpose Internet Mail Extensions (<i>MIME</i>)
2821	Message transfer	Simple Mail Transfer Protocol
2822	Message contents	Internet message format
1939	User Agent protocol	Post Office Protocol, Version 3 (<i>POP3</i>)
1730	User Agent protocol	Internet Message Access Protocol (<i>IMAP</i>)

The 1988 Morris Worm exposed areas where sendmail did not take adequate measures to ensure its own integrity against malicious clients. Subsequently, sendmail has been found to be particularly vulnerable to such exploits and has generated a total of 36 warnings from the CERT (CERT.ORG) since 1990.

Mail Handlers

Electronic mail passes through many hands on the journey from sender to recipient. The end points of the system frequently are not part of the actual electronic mail infrastructure governed by RFC 2821/2822. Often, the first and last steps of the journey are provided by programs operating according to other protocols (e.g., POP3, IMAP4), whose roles are focused more on the end point origination and reception of messages than on the routing of messages through the network as a whole.

In today's Internet, where there are large volumes of spam, it is not unusual to see filters designed to eliminate such material at various stages in message routing. Often, the sheer economies of scale will mean there is at least some filtering at the firewall or gateway level to an internal network. There may also be additional levels of filtering at the Mail Host, or Mail User Agent level.

Mail User Agents

A Mail User Agent, to adopt the terminology used in various Internet RFCs, is a program that directly interacts with the user in the generation or reception of electronic mail. Mail User Agents often use the Post Office and Internet Message Access protocols to communicate with the message store located on the Mail Host.

Mail User Agents also represent a vulnerability. In the past few years, attacks targeting the display mechanism have increased in popularity. These attacks, which have often targeted personal computers, particularly systems running Microsoft's Outlook software, target Outlook's capabilities to execute code and HTML pages attached to documents.

IMAP4. IMAP4 (Internet Message Access Protocol, Version 4) is defined in RFC 1730 (Crispin, 1994). IMAP4 is a protocol designed for the communications between mail hosts and mail user agents.

POP3. POP3 (Post Office Protocol, Version 3) is defined by RFC 1939 (Myers & Rose, 1996). POP3 is a protocol for accessing a user's mail message store stored on a system other than the system that the user is using.

Toolkits/Utilities

Electronic messaging protocols, and SMTP in particular, are well suited for roles in applications more complex than straightforward electronic mail. In particular, SMTP's relaying and queuing make an excellent vehicle for conveying information through networks to remote locations, whether organizationally or geographically.

As an example, many file retrieval systems and information systems have been built upon a base consisting of a pseudouser and an application that processes messages received by that user.

Web browsers, such as Netscape and Internet Explorer, generally provide an electronic mail client, both to process mailto: URLs and as part of the integrated browsing experience.

An electronic mail client typically uses a mix of protocols, often using IMAP4 or POP3 for retrieving messages and manipulating the user's mailbox, and SMTP for sending outbound messages. Some implementations include both immediate and delayed transmission, which permits a mobile user the luxury of responding to electronic mail while not connected or connected via a low-bandwidth connection and sends all outgoing mail at a chosen point in the future.

Mail Transfer Agents

Often, at an ISP, there are a series of systems tasked to the management of in-transit electronic mail. These systems fall into two categories, relays and gateways.

Relays

An SMTP relay is a staging point for messages, analogous to the queue at a tear-tape shop. In most situations, the queue for an individual customer system at a relay will be of modest size. Often, there is more than a single layer of relays, providing geographic or organization depth to the resilience of the network for delivering electronic mail.

Consider a typical corporate environment for a company of medium size, for example 3,500 employees spread over several installations. To further illuminate the issues, suppose that a local or regional ISP serves some of the company's offices.

Structurally, the simplest electronic mail implementation would be a single large system to which every user connected to read their electronic mail. This approach does work, but ensuring accessibility and availability can be difficult and expensive. In that case, there would be a large system at a corporate-wide data center, and employees would use user agents or Web access via an intranet to access their mail. Between sites, a Virtual Private Network (VPN) using encrypted tunnels would provide the appearance of a single, company-wide network. One advantage of such an environment is the ease of dealing with a single system to manage in the context of records and archiving, a regulatory requirement in some organizations and industries.

A more distributed architecture would have multiple mail hosts, perhaps hierarchically organized along geographical or business unit lines. The implementation issue of user electronic mail addresses is independent of the routing of individual messages; after all, the addresses can be rewritten as well as routed.

Even a unified, company-wide mail host needs mail relays. Despite the best of intentions, network links will fail and usability of individual hosts will be disrupted. The simplest of electric devices fail; the humble plug or socket will, at some point, fail.

These failures can be within the company, in which case a mail relay at the corporate firewall can store mail for later forwarding, or at the ISP, where mail can be queued awaiting the repair of a damaged cable.

Thus, the best practices for an overall electronic mail architecture include the incorporation of multiple levels of relays to ensure robust queuing of messages in the event of the inevitable host and/or network interruptions.

Gateways

Gateways are responsible for providing connections for mail transmission between dissimilar networks. Generally, the networks employ different protocols, requiring a gateway to translate between the two protocols. Gateways are not directly involved with the queuing and storage of messages, acting merely as a translator between two networks.

In one sense, the corporate firewalls that separate an intranet from the Internet can be considered gateways. But in this sense, a gateway isolates two different and incompatible addressing schemes for the different networks. The addressing schemes could be any combination of network addresses, or mail addresses, or both.

Undefined Issues

Despite the volume of specifications that govern routing, content, and other interactions with electronic mail, there are many areas where issues are undefined.

This is not necessarily a design shortcoming. As in the case of the relationship between SMTP and MIME, the underlying specification (SMTP) has sufficient flexibility to allow the additional specification (MIME) to define the inclusion of nontext attachments in a compatible fashion.

Message Relay

Message relay is one of the most important facilities in the modern Internet. Without message relay, message transport would not be the robust mechanism we use everyday.

Message relay also means that a message may seem to come from a node that does not correspond to its sender address. The relaying node may belong to the sending organization, the receiving organization, an organization that is a correspondent of either (related organizations may mutually provide relays for each other for redundancy), or an ISP.

Address Content

The contents of message address lines may arbitrarily be within the specifications laid out in RFC 2822. An address could, at the receiving system, be an individual, a mailing list, a daemon, or some combination.

Other Networks

SMTP can and has been implemented using underlying infrastructure other than that provided by TCP/IP. So long as the alternative network transport is capable of providing the “reliable data stream channel” envisaged by SMTP, the implementation can be exact. In some cases, even protocols that do not completely conform to the model envisaged by SMTP can also be employed. For example, SMTP permits lines up to 998 characters in length. However, SMTP also acknowledges that many implementations have difficulties dealing with messages that contain lines longer than 78 characters. The MIME standards (RFC 2045–2049) specifically state that lines in encoded

attachments should be 76 characters long, to deal with this particular concern.

Extensibility

Electronic mail has been, and continues to be, used as a carrier for a wide variety of content. The ability of electronic mail to transmit content between a sender and a recipient, without the need for both to be present, or indeed connected at the same time, is a powerful mechanism.

Foundation extensions such as MIME (RFC 2045–2049) provide a context that allows Internet electronic mail to become a transport for a wide variety of content.

In some cases, the content is binary, such as PEM (Privacy Enhanced Mail, RFC 1421–1423) or PGP (Pretty Good Privacy). In other cases, the content may be executable or multimedia files.

MIME

MIME (RFC 2045–2049) is a set of standards that provide for extending the simple text-message content presumption of SMTP into a vehicle for more complex data. The complexity may simply be a matter of longer lines, such as those generated by many word processing programs when word wrapping paragraphs, or extensive binary files.

PGP

Phil Zimmermann developed PGP in 1991. The idea behind PGP is to provide a mechanism to transmit secure messages between individuals without the need for a tree of digital certificates. As an example of the use of nested standards, as described earlier in this chapter, PGP messages are formatted or packaged using the MIME standard. PGP and PEM both provide technological solutions to confirm the authenticity of a message and to prevent a sender from disowning or repudiating a message.

PEM

Privacy Enhanced Mail is a set of standards for signed, private electronic mail, based upon a hierarchy of digital certificates. The problem with the deployment of PEM has been the difficulty of managing large numbers of digital certificates.

INFRASTRUCTURE SECURITY

Electronic mail has been both boon and bane. Electronic messaging has reduced the delays in business communication from days or weeks to seconds or minutes, while simultaneously reducing costs of transmission and delivery to mere fractions of a cent.

The Internet mail system makes presumptions about its operating environment. To be fair, RFC 2821 and its predecessors cannot be held responsible for all of the shortcomings, perceived or real in the overall Internet.

However, it is a fact that electronic mail, in the RFC 2821 model, does not have any form of inherently robust control over the integrity or authenticity of electronic mail. Individual mail server implementations are free to implement controls or limitations on mail relay, size, or content, but this is not standardized.

Some SMTP server implementations limit, or can be configured to limit, mail processing in a variety of ways, including

- size limits,
- limits on relaying (only within certain IP address ranges; typically the local network),
- requiring secure supplemental authentication (connecting with secure verifications of identity and encrypted connections, such as those provided by SSL),
- content checks,
- addressing limits, and
- refusing messages from machines listed on so-called “Black Hole” lists (a “Black Hole” list typically lists names and/or IP addresses of systems who have been associated with spam or open relays).

Unwanted Commercial Messages

In turn, this tremendous reduction in cost has given rise to a plague of unsolicited commercial electronic mail, generally referred to as spam. The volume of these unsolicited messages can be hundreds or thousands of messages per day per user, every day. The phenomenon of spam deserves far more extensive treatment than a section in a chapter, but some facts are worth noting:

- The scale of Internet connectivity is unprecedented. Never before in human history has it been possible for an individual to produce and send hundreds of thousands of messages per day to individual recipients at minimal cost. Even a relatively small Internet connection (tens of thousands of bits per second of bandwidth) is sufficient to send thousands of messages a day. Broadband connections only increase the scale of the problem.
- The low cost of Internet connectivity is unprecedented. Many users in the United States can obtain broadband connectivity for less than US\$ 60.00/month. This means that even infinitesimal success rates for spam remain economically viable.
- The ready availability of inexpensive computing hardware makes it economical to produce large volumes of messages, including mass customized messages. Even the most inexpensive personal computer has the computational speed and mass storage to generate hundreds of thousands, if not millions, of messages per day.

Inevitably, spammers and antispammers are engaged in a technological arms race. The first wave of the spam epidemic was dealt with by simply filtering the originator addresses associated with unwanted commercial electronic mail.

A popular tactic for spam is to come through a relay, in the hope that message vetting will be less stringent from a known relay. Nothing should be further from the truth. Vetting provisions to detect and eliminate spam should not be based upon the node that relays the message.

Some commentators lump all solicited and semisolicited messages into one category. This practice is, in this author’s opinion, not fair to all members of the network community. The large volume of barely, or totally, unsolicited electronic mail, typically relating to get-rich-quick

schemes, dating, cut-rate pharmaceuticals, enhancement of various body parts, and the like, is one particularly offensive stratum. Almost invariably, the individuals sending these messages use forged addresses, misleading subject lines and, in many cases, other falsified headers. These combined measures make it increasingly difficult to separate legitimate messages from unsolicited messages of dubious legality.

External, semisolicited messages are another aspect of the problem. These messages are legitimate and appropriate, but from an individual’s perspective, ill timed. Vendor newsletters, sales announcements, and electronic copies of statements are appropriate content, but the sheer volume can be overwhelming. Companies should provide mechanisms for customers to control the scale and frequency of such communications. Companies should also restrain the tendency to include large attachments with such files, instead using electronic mail to notify customers of the availability of information located on, for example, the Web site.

However, even if we were to magically eliminate this entire class of messages, problems remain. The ease of electronic messaging has spawned a tendency toward overuse. Even within organizations, the volume of legitimate messages can overwhelm recipients. This is particularly so when many individuals adopt the conservative measure of including large numbers of coworkers as addressees in messages of limited importance or relevance. This effect is not limited to larger organizations. It takes only a few individuals within an organization, each forwarding copies of messages to each of their coworkers, to bring productive work to a total standstill.

Regulatory requirements in some industries and countries also have an effect. Securities and Exchange Commission Rule 17a-4 in the United States, covering the financial and securities industry, requires the archiving of all electronic messages entering an organization, creating a mass of low-value material, all of which must be archived for years.

Archiving and compliance requirements may also be the determining factors in where messages are received. A centralized message store may be desirable from the compliance perspective.

Accountability

Ensuring that messages were sent or received remains a problem with Internet electronic mail. Many corporations have policies requiring that electronic mail go through certain gateways for vetting and archiving, both incoming and outgoing. The ability to send a message outside of the monitored channels, possibly with forged headers, is an ongoing problem.

Without resorting to PEM or PGP, and secure mechanisms for access to the systems generating electronic mail, it is not possible to prevent header forgery and the resulting lack of accountability.

Authenticity

Authenticity is a more serious problem. Since the use of the telegraph, authenticity has been an ongoing issue, with the reliability of a message hinging on the difficulty

of generating a false message and the costs or difficulties in sending it. However, there have been legal challenges to the authenticity of electronic messages since the beginning, hence the adoption of wire fraud statute, 18 USC §1343, in 1952.

The dramatic decrease in access costs and the resulting ubiquity of access have made forgery a straightforward activity well within the abilities of many adolescents. The present solution is often to use PGP with digital signatures. Unfortunately, the awkwardness of such solutions has prevented their adoption on a widespread basis.

It is to be hoped that the lowering costs of digital certificates, together with advances in managing certificate trees, will lead to increased ease of use.

SUMMARY

Electronic mail has dramatically changed from its beginnings in 1964 as a mechanism for communicating short messages between users of a single computer system. Today, electronic mail is used to move huge volumes of data over globe-spanning networks.

The mechanisms for processing electronic mail from its point of origin to its destination have evolved and continue to evolve. Far from being a tree of evolution, with each branch diverging from a common ancestor at MIT in 1964/1965, electronic mail evolution has been and continues to be a tapestry, with each thread interweaving and influencing the others.

Electronic mail will likely continue to evolve in the future, as requirements and needs change for the noninteractive transmission of files and documents. Security concerns, particularly the need to ensure privacy and authenticity while retaining ease of use, are the greatest issues for the future.

ACKNOWLEDGMENTS

I thank the numerous people who generously took the time to speak with me about their roles and recollections of events. I thank Susan Sluizer, Craig Partridge, Paul Mockapetris, Peter Capek, John Covert, and others. I also

thank Fern Hertzberg for her assistance in organizing and copyediting this chapter.

GLOSSARY

All-in-1 Digital Equipment Corporation's integrated office automation and electronic mail system, originally released in 1982.

ARPAnet A research packet-switching network funded by the Advanced Research Projects Agency of the U.S. Department of Defense. ARPAnet's first link became operational in 1969. The ARPAnet was officially de-commissioned in 1995 and transitioned into a commercially funded network.

CCITT (Comité Consultatif International de Télégraphique et Téléphonique) The Paris-based international standards body within the ITU (International Telecommunications Union) that develops international telegraphic and telecommunications standards. In March 1993, CCITT was reorganized as ITU Telecommunication Standardization Sector (ITU-T).

CTSS One of the first time sharing systems, the Compatible Time Sharing System was developed at the Massachusetts Institute of Technology in 1961–1963, based on a modified IBM 7094 system.

DECnet Digital Equipment Corporation's proprietary set of network protocols originally developed in the late 1970s for networking computer systems. DECnet was, from its initial origin, a peer-to-peer network, contrasted with IBM's SNA, which was hierarchical in philosophy.

DNS The domain name system is the Internet mechanism for resolving hierarchical node names to IP addresses. The protocol used by DNS is currently defined by RFCs 1034/1035.

IETF Established in 1986, the Internet Engineering Task Force is the branch of the Internet Architecture Board (IAB) responsible for coordinating the development of Internet standards.

Mail Exchanger A system that accepts mail in transit from one place to another in the SMTP (RFC 2821)

architecture. This categorization is not exclusive; a mail exchanger may also play any or all of the other roles described in the RFC, in virtually any combination.

Mail Host A system that is hosting a message store.

Mail Transfer Agent A computer system that transfers mail from a user to its destination. This term was defined in the SMTP series of RFCs.

Mail User Agent The program that users utilize to access their mail. It may be an application running directly on a mail host with a local file, or it may be a client/server application accessing a remotely located message store using POP, IMAP, or other protocol.

Message Store A storage mechanism for electronic messages. Messages may be organized in a series of files in a directory structure, as part of a database, or some other mechanism. Other than the requirements for storage and retrieval, the SMTP specifications do not make statements about the internal organization of the message store.

MIME (Multipurpose Internet Mail Extensions) The set of IETF RFCs governing the encapsulation of non-text data types within standard RFC 2822 messages.

Node Name The fully qualified Internet Domain Name System (DNS) name of a system.

OpenVMS HP's operating system for VAX, Alpha, and Itanium processors, originally developed by Digital Equipment Corporation as VAX/VMS in conjunction with the VAX processors, released in 1978. OpenVMS is fully described elsewhere in the *Handbook*.

PROFS An IBM office automation and electronic mail system, originally released in 1981.

Protocol The contents and sequence of the information exchanged between two system components cooperating on a single task.

RFC A Request for Comment is a proposed or generally accepted Internet standard; see <http://www.ietf.org/rfc> for a repository of RFCs.

RFC 2821 The Internet Engineering Task Force RFC describing the Simple Mail Transfer Protocol.

RFC 2822 The Internet Engineering Task Force RFC governing the internal format of mail messages.

SMS (Short Message Service) A service for transmitting short text messages, often used for transmitting text messages to mobile devices such as mobile telephones.

SMTP (Simple Mail Transfer Protocol) The IETF specified protocol for the transmission of electronic mail, current defined by RFC 2821/2822; descended from the Mail Transfer Protocol originally defined by RFC 772.

SNA IBM's Systems Network Architecture is a proprietary set of network protocols for communications between mainframes and associated systems.

VAX/VMS See OpenVMS.

X.400 The CCITT (now ITU-T) standard for "message handling services."

INTRODUCTION

PKI is an acronym for “public key infrastructure.” This chapter discusses what that means and the challenges associated with providing this functionality.

If Bob believes Alice’s public key is pub_A , and Alice knows the private key associated with pub_A , then Bob can use pub_A to encrypt a message for Alice, or Alice can use the associated private key to prove to Bob that she is Alice (i.e., she can *authenticate* to Bob). The purpose of a PKI is to provide a convenient and secure method for obtaining the public key associated with some principal.

The basic idea is to have a trusted authority known as a CA (certification authority) digitally sign a message known as a *certificate*, thereby vouching that a particular key goes with a particular name. If Alice has been certified by the CA, Bob knows the CA’s public key, Bob trusts that CA, and Bob receives Alice’s certificate, then he can validate the CA’s signature on that certificate and know Alice’s public key. In the chapter about digital certificates in this volume, some examples of certificate formats that have been deployed are discussed. In this chapter, we concentrate on the concepts and ignore the formats.

There is not universal agreement on the definition of a PKI, the minimal functionality that one must provide to be credibly called a PKI, nor the limits of functions that might be provided by a PKI. Besides providing a secure mapping between a name and a key, other functions of a PKI are to provide timely revocation of certificates (such as if a private key were stolen), to enable users to obtain their own private key, and to provide certification of attributes or privileges.

Authentication

Authentication is generally assumed to mean proving one’s identity, but like most words in the field, there is no universally agreed-upon definition. For instance, there might be a shared key for a group, and for purposes of access to some resource it might be enough to prove

knowledge of the shared key. Some might consider this authentication, although this would definitely not be proving an identity, because proving knowledge of a key shared by a set of individuals does not distinguish between individuals. It just proves that you are one of the individuals in the set.

For most cases, however, the PKI will link an identity’s name with a public key, and authentication will be done by proving knowledge of the associated private key.

Authorization

Authorization is the right to do something. A common method of specifying authorization is through an *access control list* associated with a resource, which specifies the identities authorized to access the resource, together with what access rights they have. For instance, for a file, some members might have read-only access, whereas others might have read and write access.

Usually authorization involves authentication because it is often convenient to specify authorization as a set of identity or rights pairs.

In contrast, another model of authorization is “credentials based,” where possession of a credential implies authorization. In the real world, this might be a door key or the combination to a safe. In the network security world, sometimes knowledge of a key is thought of as a credential. The key might not be associated with any named identity, but it might be used to assure someone that two messages originated from the same source. In that case, one might claim that authentication has taken place and that the identity is “the holder of that private key.”

We will discuss more issues associated with identity, authentication, and authorization later in this chapter.

Security without Public Key Cryptography

At first glance, security appears similar whether it is based on secret keys (symmetric keys) or public keys. Authentication, encryption, and integrity protection all

Figure 1: KDC knows one secret for each principal.

are possible. However, there are important functional differences.

One important aspect of public key cryptography is the ability to verify a signature without knowing the private value. In contrast, with secret key cryptography, the same secret that was used to generate the integrity check must be known by the verifier to verify the signature. This means that with secret keys, it is hard for Bob to prove to a third party that a message came from Alice. If only Bob and Alice know the secret, then if Alice sends a message to Bob using an integrity check based on their shared secret, Bob can know it came from Alice, but he cannot prove to anyone else that Alice generated the message because Bob could have created the same message. Also, with secret key cryptography, if Alice needs to send a message to multiple recipients and she has a different key she shares with each recipient, she has to generate an integrity check separately for each recipient, using the key she shares with that recipient. In contrast, with public key cryptography, Alice can sign the message using her private key and anyone can verify it using her public key.

Because it would be impractical to separately configure a key between every pair of entities that might want to communicate [an $O(n^2)$ solution], the usual solution is to use a key distribution center (KDC), as is done in Kerberos. The KDC stores a secret for each individual, and each individual only needs to store a single secret (the one the individual shares with the KDC). A diagram is shown in Figure 1.

If Alice wants to talk to Bob, she requests that the KDC introduce them. The KDC invents a new secret, K_{AB} , and prepares a message for Alice, encrypted with K_A (the secret the KDC shares with Alice), that tells her to use K_{AB} to talk to Bob. It also prepares a message for Bob, encrypted with K_B , that tells him to use K_{AB} to talk to Alice. See Figure 2 for an illustration.

Figure 2: Message flow before Alice and Bob can talk, which uses secret keys.

FUNCTIONAL COMPARISON BETWEEN PUBLIC KEY- AND SECRET KEY-BASED SYSTEMS

If Alice and Bob each know their own private key, they each know the CA's public key, and they each have a certificate from the CA, then they can talk by exchanging certificates, without needing to talk to a third party. See Figure 3.

The functional differences between a PKI-based solution (one based on public keys) and a KDC-based solution (one based on secret keys) are described in the next few sections.

Security

The KDC-based solution will be less secure. The KDC has a highly sensitive database (secrets for all its clients). In contrast, a CA does not need to know anyone's private keys. It only certifies public keys and therefore does not have access to any secrets (other than its own private key).

A KDC must be online because it is needed to facilitate all conversations. This makes it an attractive target for network-based attacks. In contrast, the CA does not need to be online. It signs certificates once, and the certificate can be made accessible on the network, but the CA does not need to be accessible.

Because the KDC must be available to facilitate conversations, it must be replicated (because having it be down would be intolerable). Each replica needs to be physically secured. In contrast, it would not be a problem if the CA were down for some period of time. New users might not be able to be certified, but communication between existing clients would not be hindered (except possibly for revocation, although a revocation server could be different from the CA and have a different key—see the section on revocation in this chapter). Physically securing the CA is easy because it need not be accessible to the network.

The KDC needs to be a complicated system, capable of simultaneously communicating via the network to many clients simultaneously. This makes it likely that it will have security vulnerabilities. In contrast, the CA is a simple system. All it needs to do is sign certificates, a much simpler problem than communicating via a network. Plus, the CA need not be online, so if physical security is enforced, even if the CA had security vulnerabilities, they would not be exploitable. On the other hand, a real security flaw for any system is the involved humans, so if the CA operator can

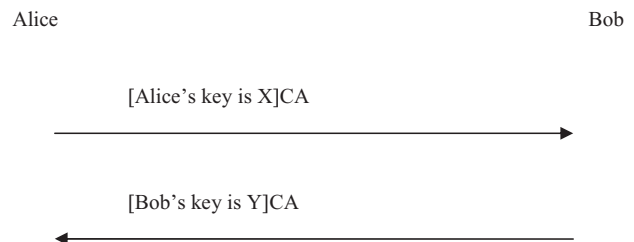

Figure 3: With certificates, Alice and Bob can immediately communicate.

be bribed or tricked or threatened, it would be possible to forge certificates.

Cost

The KDC solution will be more expensive, because the KDC is a complex, performance-sensitive, replicated system. A CA does not have these properties.

When Kerberos was designed, licensing of public key technology was prohibitively expensive, so the Kerberos designers needed to avoid public key technology. Once the RSA patent expired, a public key–based system became less expensive.

Performance

Public key cryptography is a lot slower than secret key cryptography. However, the performance of the mathematics is counteracted by the necessity, in KDC-based systems, of having additional round trips before connection setup in order to communicate with the KDC. Once a conversation is facilitated, whether with PKI or with KDC, a secret key is established between the parties, so performance is only an issue on conversation startup.

Interorganizational Communication

It is common for organizations to communicate with the outside world through a firewall. Because the KDC is the most security-sensitive box in the network, it is likely that the firewall administrator would want to block access to the KDC from outside the network. This would preclude setting up a conversation between parties in different organizations. In contrast, with a public key–based system, Alice and Bob can e-mail their certificates. Thus, a PKI-based system is more likely to work between organizations.

Issues with Public Key Infrastructure

Although on the surface a PKI-based system seems straightforward, there are many deeper issues, which we explore in the remainder of this chapter. If Alice knows her own private key, Bob knows the CA's public key, and Alice has a certificate signed by the CA that Bob trusts, then Bob can, for instance, send an encrypted message to Alice. However, how does Alice know her own private key? How does Bob know the CA's public key? How can Alice get securely certified? How can Bob obtain Alice's certificate?

PKI MODELS

In this section, we explore various ways of building the PKI. Who should be the initially trusted CAs? How does a principal obtain the CA's key? If Alice is not directly certified by a CA that Bob knows and trusts, how can Bob (or Alice) find a chain of certificates linking Alice's name with a CA that Bob trusts?

The public key(s) that Bob trusts a priori, and which are somehow securely known to Bob (e.g., by being installed on his system) are known as Bob's *trust anchors*.

Monopoly

In this model, the world chooses one organization, universally trusted by all countries, companies, organizations, and individuals, and configures that organization's public key into all software and all hardware. In other words, that key is everyone's trust anchor. Everyone obtains certificates from this one organization. This model is simple to understand and implement. However, there are problems:

- There is no such thing as a universally trusted organization.
- Even if everyone agreed to trust one organization, the entire security of the world would depend on that one organization never having an employee that could be tricked, bribed, or threatened into misusing the CA's private key.
- This model grants an eternal monopoly to one organization. Once widely deployed, it would be impractical to switch organizations if that organization started charging too much money or being careless about creating certificates, because it would mean reconfiguring everything and perhaps even changing hardware.
- The configured key can never be changed. If it ever was stolen, or if advances in cryptography warranted changing to a different algorithm or a different key size, it would be prohibitively expensive to change that key.

Oligarchy

In this model, instead of choosing a single organization, each piece of software (and perhaps hardware) comes preconfigured with several CA public keys. In some cases, users are allowed to edit that list. This eliminates the monopoly issue, but there are still problems:

- The default keys (the ones that come preconfigured) are those trusted by the software or hardware vendor, not necessarily the user.
- In the previous model, security depended on one organization never having a corruptible employee. Now there are more organizations, and a breach of an employee at any of those organizations will compromise the security of the world.
- Even if all the CAs in the default list are trustworthy, if the list is modifiable, a user can be tricked into using a platform with bad CA keys inserted. This can be because the user is using a platform in a public place (like at an Internet café) or because the user visited some site that presented a certificate signed by an unknown CA, the user was presented with a pop-up box with an obscure message about "unknown CA," and the user agreed to trust this CA forever.
- It would be impractical for even a sophisticated user to examine the list of configured CA keys to see if they are all legitimate. It is not enough to look at the organization names. It would be necessary to examine hashes of the keys.

Anarchy

In the previous models, there are no certificate chains. Alice must be directly certified by one of Bob's trust anchors. In this model, we allow chains of certificates.

In this model, users each configure their own trust anchors, based on who they have personally met, trust, and for whom they have securely received a public key. If Bob wants to find Alice's public key and Alice is not one of Bob's trust anchors, then Bob must somehow find an external source of certificates and search through them to try to find a path from one of his trust anchors to Alice's name.

This is the model used by PGP ("pretty good privacy"), a secure e-mail product. Often when there is a gathering of technical people, there is an event called a "PGP key signing party," in which people distribute their public keys and publicly announce their names and digests of their keys. Anyone who believes a person's identity and that the person has securely obtained his or her key can sign a certificate for that person. There are public databases of certificates to which anyone can contribute. Thus, if Bob wants Alice's key, and her key is not one of his trust anchors, he can search through a public database of certificates to see if he can find a path from one of his trust anchors to her name.

The problems with this model are these:

- This will not scale. If this was the model for Internet authentication, there are potentially billions of users, and if each signed, say, 10 certificates on average, the database of certificates would be on the order of 10s of billions. It would be unwieldy to search through such a database to try to find a mathematically valid sequence of certificates that would lead to Alice's name.
- Even if a path is found that mathematically works out (X1 is a trust anchor, X1 vouches for X2, X2 vouches for X3, X3 vouches for Alice), it does not mean that this path should be trusted. In a relatively small community of honest people, this scheme will seem to work, but once the community is infiltrated by people motivated to poison the database with incorrect information, there is no feasible way to securely find the key of someone several certificate hops away. Revocation is yet another issue. If someone's private key were stolen, how would they know everyone that needed to be notified?

Revocation is an interesting issue with this model. The designers of PGP suggest that to revoke your public key, you sign a revocation certificate (with the private key you want to revoke), stating "please stop using this public key for me because it has been compromised." If you knew all the certificate repositories in which anyone would be looking, you could then store the revocation certificate in each of them. That you would know all the repositories is a fairly major assumption. It also assumes that you can create such a revocation certificate (you need to know the compromised private key to create the certificate). In case the private key is on a smart card that got stolen, you would have needed to create the revocation certificate in advance, while you had control of the private key, and store it someplace for safekeeping so that it could be retrieved and distributed after the key was compromised.

As for all the users that might have your public key as one of their trust anchors, in order for revocation to work at all for them, they would have to periodically check the public certificate repositories to see if you have posted a revocation certificate.

Name-Based Trust

This is an important concept that says that instead of trust in a CA being a binary decision (the CA is either "trusted" or "not trusted"), a CA is trusted for certifying only certain name and key pairs. For this model, we assume a hierarchical name (such as a domain name server-style name). Each node in the namespace (say, "example.com") is represented by a CA, who is responsible for certifying names below it in the hierarchy. Thus, example.com might certify its child node "labs.example.com," which in turn might certify "alice.labs.example.com."

This trust policy is rather natural. The name by which an object is known implies who is trusted to certify its key. A person might be known by the name JohnDoe.Smalltown.Alaska.us, in which case it might be the town clerk of Smalltown, Alaska, USA, that would be trusted to certify their key. That person might also have an identity JD9975.RandomISP.com, in which case RandomISP would be trusted to certify the mapping between that identity and a key. Or, the person might be JohnD.Company.com, in which case Company would be trusted to certify the key of that identity. Or, the person might be agent99.freedomfighters.org, in which case freedomfighters.org would certify the mapping. It is in an organization's interest to take care to manage the key/name mappings of its members. These different identities may or may not use the same public key pair, and it is irrelevant that they might all map to the same human being. Each name is a different identity.

Top-Down, Name-Based

In this model, there is a root CA (representing the root of the namespace), each node in the namespace is represented by a CA, and each CA signs the key of each of its children. This model is scalable, and it is clear what path to take to lead to a node (follow the namespace). There are problems, however. The root must be configured to be everyone's trust anchor. If compromised, it can impersonate the world, because all certificate chains start with the root. It also gives the organization holding the root key a monopoly. We fix these problems in the next model.

Bottom-Up, Name-Based

We modify the previous model by also having each child in the namespace certify the parent. That way, the trust anchor need not be the root. With a tree, and links in both directions, one can start anywhere and navigate to anywhere else. The rule is that some principal in the namespace, probably a leaf node (say, AliceSmith.labs.Company.com) that wants the key of JohnD.Company.com, starts with its trust anchor (which could be anywhere, but the most elegant place is its own key). Starting at that place, the rule is that if you are already at an ancestor of the target name, then just follow the namespace down.

Figure 4: Name tree with bidirectional links.

Otherwise, go up as far as necessary to get to a least common ancestor (in this case it would be Company.com), and then go down from there. See Figure 4 for an example.

An additional important feature is the notion of a *cross link*. A cross link is where any node in the namespace can certify the key of any other node. Cross links are important for several reasons:

- They connect organizations before a global interconnected PKI exists.
- They bypass untrusted CAs higher in the hierarchy.

This might seem like it would lead to the anarchy model, but the rule is that only one cross link would be followed on any path. The rule is that one starts at the trust anchor, and if you are at an ancestor of the target, you go down. Otherwise, you look to see if there is a cross link from that point to an ancestor, in which case you follow it. If there is not, you go up a level and continue until you get either to the least common ancestor (in which case you go down) or to a cross link to an ancestor of the target (in which case you go down). See Figure 5 for an illustration.

The assumption is that PKIs would grow from the bottom. Each organization would grow its own PKI, and organizations would then link them together with cross links. Then, there would be a business case for providing root service. “We offer interorganizational certification. If you certify us, and let us certify you, you will have a path to the following n organizations that have already joined. This is how much we charge. This is how much liability we assume. This is how careful we are about checking before we certify keys.”

There could be multiple roots in parallel, and different organizations might use a different subset of the roots. If there were many roots, it might be hard to find a common root, and there might be pairs of organizations that did not have a connected chain of certificates to each other.

Figure 5: Name tree with bidirectional links and cross links.

The advantages of this model are these:

- To deploy public-key-based authentication and authorization within your organization, there is no need to get certificates from any outside organization.
- Certificate chain paths are easy to find.
- The policy is something that will make sense to people, without them needing to understand it, and be sufficiently flexible.
- Security of what are presumably the most security-sensitive operations, authentication between things in your own organization, is entirely in your hands. This is because chains of trust between two identities within your namespace never leave your namespace. Each of the certificates in the chain of certificates will have been issued by a CA within your organization.
- No single compromised key requires massive configuration.
- Configuration is minimal: a user’s own private key can be her only trust anchor, and starting with one’s own public key is the minimal configuration necessary.

Bridge Model

A model known as the bridge model had been adopted for the U.S. federal PKI. It is the same as the bottom-up model, except that the trust anchor is the root of the user’s organization. This is practical in organizations in which all the workstations are centrally managed, so that in case the organization’s root key changes, a central administrator can reconfigure all the machines.

To find a target’s public key, start at the root of your own organization (say fbi.gov), and, if you are at an ancestor of the target, go down from there to the target’s name. If not, then go up a level to what is called the “bridge CA,” and then go down from there.

USING PKI

Regardless of what model is used for the trust anchors and certificate paths, there is also the problem of gathering the relevant certificates. Suppose Bob needs to know Alice’s public key. There are various possibilities for gathering the chain:

- Alice could gather the chain and give them to Bob, for instance, in a real-time protocol, such as IPsec or SSL, or e-mail.
- Bob could gather the chain from some online certificate storage system.
- A helper node whose job it was to gather certificate chains could be queried, and it would gather the chain to be presented to Bob.
- The helper node might gather and verify the chain, and then sign an assertion that it has securely discovered that Alice’s public key = P.

What does it mean to have a chain by which Bob will know Alice’s public key? The chain must start with a trust anchor of Bob’s and terminate with Alice’s name. How

could Alice or the helper node know what Bob's trust anchors are? The real-time protocols such as IPsec and SSL provide a method for Bob to inform Alice of his trust anchors. In PEM (privacy enhanced email, RFC 1422), the model is assumed to be the monopoly model, with the single root trust anchor configured into everything.

In the case of a helper node gathering and verifying the chain and asserting Alice's key to Bob, the helper node is completely trusted by Bob, and the trust anchor for the chain, and the legal chains, would be determined by the helper node.

In the case of Bob finding the certificate chain, it is clear what model the X.509 community had in mind because of the terminology. To them, building a chain from the target name to a trust anchor is known as building in the "forward direction," whereas building from a trust anchor to the target name is known as building in the "reverse direction." However, building from the target name is more suited to the monopoly model or perhaps the oligarchy model with very few roots.

Certificate Revocation

If a private key is stolen, it is important that the certificate vouching for the mapping between the compromised public key and the name no longer be honored. Certificates have expiration dates, but because it is expensive to issue certificates, the certificate is generally valid for a relatively long time (such as a year). It is unacceptable for someone who has stolen a private key to be able to impersonate a valid principal until the certificate expires. Therefore, there needs to be some method for more timely revocation.

There are two models in the real world for revoking credit cards when a card is reported stolen. One model is where a list of all the revoked but unexpired credit card numbers is distributed to all merchants, a model that was common several years ago. Today, instead, credit card revocation is done by having the merchant check, on each transaction, about the revocation status of a particular card.

In the PKI world, the first model is implemented through use of a CRL (certificate revocation list), periodically issued and signed by the CA or by a public key that the CA certifies as authorized to sign the CRL. The CRL contains a list of unexpired, revoked certificates. It must be issued periodically even if nothing changes, because otherwise there is no way to know whether an old CRL (before the relevant certificate was posted) was substituted for the most recent CRL. The period with which it needs to be posted must be no longer than the maximum amount of time it is acceptable for revocation to take effect.

It is possible for the CRL to get very large. In this case, it would be expensive for every principal that must verify certificates to download the latest CRL every period. In this case, an optimization to the CRL mechanism can be used that is known as a "delta CRL." A delta CRL contains a reference to the last full CRL, and it only states the changes that have occurred since that last full CRL. So, in many cases, the delta CRL will have no information

(other than a pointer to the last full CRL). Only when the delta CRL starts to become large would it be necessary to issue a new full CRL, in which case the subsequent delta CRLs would be small again.

The other model for revocation is what is currently done in the credit card world. An online service accepts queries about specific certificates and responds with the revocation status of those certificates. Typically, this is done by the verifier.

CONCLUSION

PKI is very successfully deployed in the Web environment, but primarily in order for the server to authenticate to the client. Although some PKI-based email standards are in use, their wide adoption has been slow because of the difficulty in use of existing products. However, the basic concepts are sound, the advantages of having a widely deployed PKI are profound, and there is hope that sometime in the future PKI will be more widely deployed.

GLOSSARY

Authentication Showing proof of identity.

Authorization The right to access a resource or perform an action.

Certificate A signed assertion, usually the mapping between a name and a key.

Certification Authority A party that creates certificates.

KDC (Key Distribution Center) The server, in a secret key-based authentication system, that holds a key for every principal and allows secure introduction between principals.

PKI (Public Key Infrastructure) The databases, data structures, and protocols whereby public keys can be securely obtained.

Revocation Invalidation of a certificate.

S/MIME (secure multipurpose Internet mail extensions) is a versatile standard designed to increase Internet e-mail security by providing authentication, message integrity, message origin nonrepudiation, and confidentiality. S/MIME is widely available because it is implemented in most modern e-mail user applications. Now in its third version, it can be considered fairly mature. S/MIME usually relies on X.509 certificates for key exchange. It assumes a threat environment in which adversaries can read and modify e-mail in transit and senders may wish to repudiate their messages. There are also some optional enhanced security services for S/MIME that provide signed receipts, security labels that can be used for MLS, RBAC, or other purposes, and signing of certificates to prevent certain vulnerabilities with X.509 certificate exchange. S/MIME may be a sensible choice for improving the security of e-mail systems on the Internet and is easy for users to employ.

S/MIME is short for secure MIME. MIME, a widely used Internet e-mail standard is an acronym for multipurpose Internet mail extensions. From this, we can immediately see that S/MIME is designed to be a way to make Internet e-mail more secure (this is sometimes referred to as “message security;” the terms “e-mail” and “message” will be intermixed in this chapter). S/MIME began with version 1 in 1995 (Galvin, Murphy, Crocker, & Freed, 1995), and is currently in its third version.

Caveat Lector: It is extremely important to view S/MIME as a way to achieve more (or better) security, and not as a security panacea. We usually cannot guarantee total e-mail security through the use of S/MIME alone (and frankly, probably not by any combination of means); as always, we should be concerned with the fundamental principle of *defense in depth* when it comes to implementing security mechanisms in particular threat environments. In this chapter, the term

“security” is not meant to imply *total* security, but just *improved* security.

Version 3 of S/MIME, described in what is probably the most important S/MIME reference, RFC 2633 (RFC stands for Request for Comment), “S/MIME Version 3 Message Specification” (Ramsdell, 1999), provides a consistent way to send and receive S/MIME data via the ubiquitous Internet RFC 822 e-mail standard (Crocker, 1983). Standard Internet e-mail is often likened to sending a postcard through the mail: Anyone along the way can read the contents, the address is easily forged, and people along the way can alter the message on the postcard. The analogy is a good one, and S/MIME is an attempt to remedy these problems. It provides additional security services for e-mail in the areas of *authentication*, *message integrity*, and *nonrepudiation* (of the message’s origin). S/MIME can also increase message *privacy* via confidentiality obtained through encryption.

The rest of this chapter features a brief history and overview of MIME, an examination of the objectives and threat environment of S/MIME, a look at S/MIME usage, an examination of the mechanisms used by S/MIME to achieve its security objectives, a look at how S/MIME messages are created and interpreted, a tour of the newer enhanced security services for S/MIME (RFC 2634), and a look at some alternatives to S/MIME.

A BRIEF HISTORY OF MIME

The most current version of MIME is available as a set of four Requests for Comments (RFCs 2045, 2046, 2047, and 2048), which are the default standard (Freed & Borenstein, 1996a, 1996b; Freed, Klensin, & Postel 1996; Moore, 1996). This section is a brief overview of the basic features and structure of MIME and is not intended to take the place of a detailed examination of MIME.

MIME is designed to enhance the venerable RFC 822 e-mail standard (Crocker, 1983). The problem with RFC 822 is that it addresses only textual e-mail. Before MIME, if nontext content (audio, video, image, non-ASCII (American Standard Code for Information Interchange) binary files, non-ASCII character sets, etc.) were required, ad hoc methods were used. A typical problem is that RFC 822 limits the message body to “printable” 7-bit ASCII characters. In today’s world of rich character sets, many fonts, text sizes, and so forth, plain RFC 822 is often unsuitable. Before MIME, users would have to convert their data into 7-bit printable ASCII characters if they wanted to use the ubiquitous RFC 822 e-mail standard. For example, a program object file could be converted to printable hexadecimal characters (restricted to the characters 0 through 9 and A through F). This could be inefficient, and it certainly was not standardized because there were many schemes for doing such conversions.

MIME is a set of mechanisms designed to solve this problem. Basically, MIME consists of a set of predefined “Content-Types” that designate various types of data (e.g., audio, video, text, and image). A MIME encoded RFC 822 message has a message body that contains a special MIME header that gives a MIME version number and other data, and one or more “parts,” in which each part is assigned a particular “Content-Type” header field. A message can contain parts of various content types via the “multipart” Content-Type. MIME is so flexible that even applications can be encoded as Content-Types (i.e., executable content such as programs or PDF files).

MIME also has a special Content-Transfer-Encoding header field that can be used to specify auxiliary encoding(s) that might be required for the various mail transport systems through which the message passes (and that requires special encoding[s]). There are two additional header fields named Content-ID and Content-Description that allow more descriptive power (if desired) for message parts.

MIME was designed from its beginnings in 1992 to be extensible, and it currently has a huge number of Content-Types. A typical modern example is the use of sending e-mail in both plain ASCII text and HTML. This is commonly done so that recipients who lack the ability to view HTML can read the plain ASCII text portion, and recipients who have HTML capability can view an HTML version of the text message, which might take advantage of HTML’s variety of fonts, type size, colors, and so on.

Content types are further subdivided into subtypes. For example, a Content-Type of “image” is used for any one of the many available image formats. The specific image type is identified with a subtype. Suppose we are dealing with a JPEG image. We might see the following Content-Type and subtype: “image/jpeg.” This system is flexible, because the high-level Content-Type part allows a mail agent to determine that the type is “image,” even if the subtype is unknown to that agent. If types need to be mixed for some reason, then the “multipart” or “application” types can be used.

Parameters can also be added to content-subtypes and act as modifiers. An example might be the “charset” parameter that specifies a particular character set for text data. The names for all of these types and parameters are

not case sensitive, and the system is flexible enough that the only thing implementers need worry about are two different types that have the same name or parameters. An example of this for text would be the following:

```
Content-Type: text/plain; charset=us-ascii; format=flowed
Content-Transfer-Encoding: 7-bit
```

This tells us that we are dealing with Content-Type “text” with content-subtype “plain” with two parameters: “charset” and “format” which have particular values assigned. The Content-Transfer-Encoding tells us that we are dealing with 7-bit words.

The following might be an example for an image:

```
Content-Type: image/jpeg; name="filename.jpg"
Content-Transfer-Encoding: base64
```

This example shows a Content-Type of “image” with a content-subtype of “jpeg” and has the parameter “name” with a particular value (in this case, the file name). The Content-Transfer-Encoding tells us that we are dealing with base64 encoding.

There is a lot more to MIME than this brief overview, and the interested reader or implementer should read the source documents cited earlier (RFCs 2045, 2046, 2047, and 2048) for more and definitive information.

S/MIME OBJECTIVES AND THREAT ENVIRONMENT

There are four major objectives for standard S/MIME: *authentication*, *message integrity*, *nonrepudiation*, and *message privacy*. In a real sense, these objectives also define the *threat environment* for which S/MIME was designed: an environment in which adversaries can read and modify messages. This threat environment is a fair assumption for the Internet and other systems that use RFC 822 type messaging.

Authentication

Authentication means that the recipient of a message can be assured that the message’s identification of the sender is the actual identity of the sender, and not a spoofed, forged, or otherwise obscured version of the actual sender. This is an important and desirable property due to the ease with which RFC 822 e-mail headers can be forged. With good authentication, we can be reasonably assured that the sender is who or what it purports to be.

Message Integrity

Message integrity means that the recipient can be assured that the message received was not modified in transit. Messages can be modified by insertion of false information, deletion of information, or other trickery designed to cause security problems. This is an important property for anyone who wishes to be assured that e-mail is not tampered with in transit.

Nonrepudiation

Nonrepudiation means that the sender cannot deny sending a message (or the contents of a message). For example, if an unscrupulous person sent an order to their stockbroker via e-mail to sell 100 shares of stock and that stock later went up in price, it would be to the seller's advantage to repudiate the message to make more money. In other words, the seller would tell the broker that the message ordering the selling of the stock never occurred (or a message to sell less stock occurred, etc.). This is obviously an important property to have for financial systems, military systems, and other interests.

Message Privacy

Message privacy means that agents along the route from the sender to the receiver taken by the message cannot read the contents of the message. Going back to the postcard analogy, message privacy is, in a sense, an "envelope," (and in fact the term "enveloped-data" is used by S/MIME to refer to encrypted data along with its encrypted key). It is important to note that message privacy does not mean that the sender and receiver of the message cannot be identified but only that the contents of the message cannot be identified. This means that S/MIME offers no protection against traffic analysis.

Note that S/MIME is not specifically concerned with the high-level security property of *availability*. It makes no guarantee that a message will be delivered or that resources will be available for sending or receiving messages. Users of S/MIME should be cautioned that if there is a need for availability in a system, S/MIME is probably not a solution.

S/MIME provides authentication, message integrity, and nonrepudiation via digital signatures and provides message privacy through the use of encryption.

S/MIME USAGE

S/MIME is mainly used by *mail user agents* (MUAs)—in other words, standard RFC 822 Internet e-mail with MIME capable MUAs. S/MIME adds security services when sending messages and serves as an *interpretation* of the added cryptographic mechanisms for messages at the receiving end. Technically, S/MIME is not restricted to e-mail and any MIME transport mechanism (e.g., HTTP) can take advantage of S/MIME. RFC 2633 (Ramsdell, Ed. 1999) also mentions the following in section 1: "Further, S/MIME can be used in automated message transfer agents that use cryptographic security services that do not require any human intervention, such as the signing of software-generated documents and the encryption of FAX messages sent over the Internet." S/MIME takes advantage of the object-based features of MIME by creating MIME body types that serve S/MIME purposes. There are two basic body types: one used for digital signatures, and the other for encryption.

S/MIME allows secure messages to be exchanged in mixed transport systems (i.e., technically, *multi-level secure*, or MLS systems; in actuality, e-mail that has secure and nonsecure MIME parts). This means that (for example) a system that sends encrypted S/MIME messages

might not be able to read (interpret) S/MIME messages it receives. Because of this, the various S/MIME RFCs make a distinction between *receiving* and *sending* agents (collectively known as *S/MIME agents*; note that a receiving agent can also be a sending agent, and vice versa). Another consideration is that heterogeneous MUAs might be used (in fact, for e-mail via the Internet, this is almost a certainty) and because of this the S/MIME standard recommends using a strategy of "be liberal in what you receive and conservative in what you send" (Ramsdell, 1999). For example, with the many cryptographic hash algorithms, encryption algorithms, and so forth, it is important that a MUA be able to handle on receipt as wide a variety of algorithms as possible, while retaining the ability to use a restricted set of algorithms for sending.

In practice, the average Internet e-mail user will use an X.509 public key infrastructure (PKI) to exchange certificates with other S/MIME e-mail users. Once valid certificates are exchanged (and the exchange can be done using S/MIME), the resultant S/MIME operations should be transparent to the users, who need only select the S/MIME options they want. For example, assuming a modern MUA, and once certificates are exchanged, if a user wished to send digitally signed or encrypted e-mail, the MUA would only require that those respective options be selected. For receipt of digitally signed mail, most modern MUAs will notify the user that the mail is digitally signed and automatically verify (or give a warning about) the digital signature. Encrypted mail will automatically be decrypted without any user intervention. Given that it is literally that simple, it is hard to understand why more users do not use S/MIME to digitally sign or encrypt important e-mail. One often-cited reason for not using S/MIME is that it is heavily reliant on PKI, and PKI has not become as widespread as its proponents have hoped.

S/MIME MECHANISMS

The two basic S/MIME mechanisms required are digital signatures and encryption. S/MIME uses the Public Key Cryptography Standard #7 (PKCS#7) cryptographic message syntax (CMS) for these purposes, and because every MIME body part must have a type, S/MIME uses the "application/pkcs7-mime" MIME type.

When digital signatures are used by S/MIME, multipart MIME is usually used (although another option is covered later). There are two options: the "multipart/signed" and the "application/pkcs7-signature" MIME types. This is more fully described in RFC 1847 (Galvin, Murphy, Crocker, & Freed, 1995).

Cryptographic Message Syntax Support

CMS offers a wide range of options and flexibility. As described in RFC 3369 (Housley, 2002), it is designed "to digitally sign, digest, authenticate, or encrypt arbitrary message content." It is a derivation of version 1.5 of PKCS #7 described in RFC 2315 (Kaliski, 1998), which was designed for privacy enhanced mail (described in RFCs 1421, 1422, and 1423).

CMS was designed to provide support for various types of content. Protocols and applications using CMS are

expected to negotiate a set of common algorithms that are appropriate for their threat environment. This gives great flexibility, because new algorithms can be added more easily to CMS as they become available and as the state-of-the-art evolves.

In theory, there are five CMS content types that S/MIME can use: signed-data, enveloped-data, digested-data, encrypted-data, and authenticated-data. A brief description of each type follows. For more detailed information, see Housley (2002).

- **signed-data:** This type of content contains zero or more instances of digital signatures. It is a fairly standard digital signature method whereby a message digest (cryptographic hash) of the content is created, the message digest is then signed by encrypting it using the signer's private key, the signature information is collected into one "value" (object), and then a "SignedData" value is created that contains the message digest algorithm information (identification and parameters) as well as the content. The recipient independently computes a message digest in the same way that the sender did, and then uses the sender's public key to decrypt the signature and verify that the two message digests match.
- **enveloped-data:** This is simply encrypted content, as well as an encryption key. It is constructed by randomly generating a content encryption key (i.e., a session key) and encrypting the content encryption key for each recipient (there are various techniques, but one method is to encrypt using the recipient's public key, in which case only the recipient's private key can decrypt the content key). These data are collected together into a "RecipientInfo" value, the content is then encrypted using the content encryption key, and all of these are collected together to form an EnvelopedData value that can be considered an "envelope." A recipient opens the "envelope" by decrypting the content key and then decrypting the content.
- **digested-data:** This is simply a message digest (cryptographic hash) of the content. The digest is added to the content to create a "DigestedData" value. The recipient verifies the message digest by independently computing the message digest and comparing the two.
- **encrypted-data:** This is simply encrypted content but differs from enveloped data in that it does not contain a content key. Key management must be done by some other, unspecified, method (X.509 certificates are typical for S/MIME).
- **authenticated-data:** This is a method to verify content integrity. This type consists of any other type of content, a message authentication code (MAC; a digest or cryptographic hash), and an encrypted authentication key (more than one key is allowed if there is more than one recipient). The idea is that the MAC and encrypted authentication key are enough to verify the integrity of the content.

Because CMS offers much flexibility, it is an obvious choice for S/MIME. The last three CMS content types are mentioned only for completeness, since S/MIME only uses the SignedData and EnvelopedData content types.

Backward Compatibility

There are many backward compatibility issues because S/MIME is in its third version. For a few examples, S/MIME Version 3 must support the SHA-1 cryptographic hash algorithm for backward compatibility. The MD5 message digest algorithm is recommended for backward compatibility but is not mandatory. S/MIME Version 3 should support the RSA public key system (PKCS-1) for compatibility with Version 2 digital signatures. For a complete list of all of the backward compatibility issues for Version 3 of S/MIME, see RFC 2633 (Ramsdell, 1999), section 2.

Diffie–Hellman Key Exchange

S/MIME must also support Diffie–Hellman (DH) key exchange. Because symmetric cryptography is always based on a shared secret between the sender and recipient of a message and because in some cases such a shared secret does not exist *ab initio*, DH is used for dynamically and securely constructing a shared secret key in the S/MIME threat environment. Of course, other methods exist and can be used, such as RSA. It is important to note that for algorithms such as DH and other cryptographic protocols, when the RFCs specify *random* numbers, truly random numbers must be used, and not pseudorandoms.

There are known problems with DH and S/MIME version 3, and these are addressed in RFC 2785 (Zuccherato, 2000). Basically, DH as used with S/MIME version 3 is vulnerable to the "small subgroup" attack. For a description of the attack, as well as potential remedies, see Zuccherato (2000).

X.509 Certificates

These play a major part in S/MIME. A full discussion of X.509 is beyond the scope of this chapter and is discussed elsewhere in this handbook. This chapter is restricted to discussing the role of X.509 with S/MIME.

For most use of S/MIME, X.509 certificates play a major role. For example, the typical Internet e-mail user will make use of the X.509 PKI to take advantage of the security features of S/MIME. In particular, X.509 works to disseminate the public keys used for both digital signatures and the exchange of symmetric keys for bulk encryption of message data. (Symmetric key encryption algorithms such as the Data Encryption Standard (DES) and its variants or the Advanced Encryption Standard (AES) are typically used for "bulk" encryption instead of using public key algorithms, because the latter are too inefficient for bulk encryption; however, public key systems are necessary for digital signatures and for encrypting symmetric algorithm "session keys," which are both small in size.)

Briefly, an X.509 certificate contains a public key along with some other data (such as a certificate expiration date and identification information about the certificate authority and user). Certificate authorities (CAs) are trusted third parties (TTPs) that create the certificates and sign them by encrypting them with the TTP's private key. MUAs typically come preloaded with certificates for CAs, but if they do not, there are X.509 methods for obtaining (or not, as the case may be) a certificate for a CA.

Because this chapter is not about X.509, the simplifying assumption is that both the sender and receiver MUAs use the same CA, and both have that CA's certificate (this is a reasonable assumption given that popular CA certificates come preloaded into most modern MUAs).

There are basically two X.509 certificate exchange cases to consider. Either the sender of an S/MIME message does not have the recipient's X.509 certificate or the recipient does not have the sender's X.509 certificate.

The sender lacks the recipient's certificate: This is a common situation when users first try to use S/MIME with one another. If the sender lacks the recipient's certificate, it probably means the sender lacks the recipient's public key. This means the sender cannot use encryption because that requires the recipient's public key to encrypt a content key. The sender can remedy this situation by sending an e-mail with the sender's certificate attached. This can be done with a special certificate transfer mechanism (covered later) or by simply sending a signed message (which, with most modern MUAs will cause the sender's certificate to be attached to the e-mail). When the recipient gets the e-mail, the certificate will be available and, with most modern MUAs, will automatically be entered into the recipient's certificate database (it is important to realize that some organizational-specific MUAs and also Web-based MUAs do not have S/MIME support at the time of writing). The recipient can then verify the signature by decrypting the certificate using the CA's public key, thus obtaining the sender's public key. At this point, the recipient only needs to reply to the e-mail with either a signed or encrypted message, which will contain the recipient's certificate (with most modern MUAs), and then the sender will then be able to decrypt that certificate to obtain the recipient's public key. Because of the lack of standardization among MUAs though, it is important that S/MIME compliance be tested before one relies on it.

The recipient lacks the sender's certificate: This is also a common situation, but it is not a particular problem with S/MIME. If the sender has the recipient's certificate (and thus public key), the sender can send digitally signed or encrypted mail to the recipient on request, which will automatically include the sender's certificate. If the sender does not have the recipient's certificate, a special certificate only message can be sent to the recipient to provide the sender's certificate. Of course, there are other methods to exchange certificates, such as sending diskettes through the regular mail or hand delivering them.

Once the sender and recipient have each other's public key, it becomes possible for each to digitally sign messages (so that the other can authenticate them) or to encrypt messages using a symmetric cryptographic algorithm session key (content key) that is exchanged by encrypting it with the recipient's public key so that it can only be decrypted with the recipient's private key. This is generally all transparent to the user.

Other Options

S/MIME has many options that are negotiable between sender and recipient. Some examples are the choice of symmetric algorithm, the choice of message digest (cryptographic hash function), key size, and so forth. The way the negotiation is done is fairly simple. Capability lists for

each entity are created from information in previous communications. In addition, it is possible to use other methods (such as out-of-band communication). All options for a client need not be listed, and in general, options are listed in preference order. For example, a particular client might wish to use RC5 as a block cipher, specify a particular key length, the number of rounds, and the block size. RFC 2633 (Ramsdell, 1999), section 2.7.1 (for example), gives the rules for deciding how to negotiate the capabilities for the receiver. This flexibility is a major feature of S/MIME, especially with the rapidity with which cryptographic technology changes.

Multiple Recipients

Multiple recipients are allowed with S/MIME. The utility and convenience of sending one message to multiple recipients should be obvious, but in practice it poses an interesting security problem. RFC 2633 (Ramsdell, 1999) 2.7.3 warns about the following cryptographic vulnerability when using this capability:

If a sending agent is composing an encrypted message to a group of recipients where the encryption capabilities of some of the recipients do not overlap, the sending agent is forced to send more than one message. It should be noted that if the sending agent chooses to send a message encrypted with a strong algorithm and then send the same message encrypted with a weak algorithm, someone watching the communications channel may be able to learn the contents of the strongly-encrypted message simply by decrypting the weakly-encrypted message.

An attack based on this potential vulnerability is fairly straightforward. The attacker simply cracks the message with the weakest encryption (presumably this is feasible). At this point, the attacker has the plaintext of the message and can perform a known-plaintext attack on the other recipients and perhaps derive the symmetric session (content) keys used. Even so, this type of known-plaintext attack is not a particularly worrisome threat because content keys should be changed often (in fact, once for each S/MIME transmission). However, assuming it can be done (a big assumption!), it allows the attacker to see the text of the most "highly" encrypted message. In effect, this is a "weak link in the chain" problem. If this problem is a serious consideration, why bother to use strong encryption when a weak algorithm will allow an attacker to feasibly decrypt the message in the first place? This is also a concern for "secure mailing lists," which are covered later.

CREATION AND INTERPRETATION OF S/MIME MESSAGES

All or any subparts of a MIME message may be secured with S/MIME, but it is important to note that the RFC 822 headers are not part of MIME and therefore are not necessarily secured by S/MIME in any way. This means that it is not possible to use S/MIME to hide the sender or recipient IDs. In any event, the parts that are to be secured are done

so by making them *canonical MIME entities*. This allows the CMS to produce a *CMS object* that is then “wrapped” in MIME with the appropriate transfer encoding. It is that simple.

On receipt, the reverse happens: the security services for the appropriate S/MIME type are invoked which results in a MIME entity that is presumably passed on to a MIME capable user agent for further processing (such as decoding and presentation to the user).

The purpose of converting each MIME entity into a canonical form is so that it can be unambiguously (and uniquely) interpreted by the MUA that receives it (and the MUA's environment). Therefore, canonicalization is mandatory for enveloping (encrypting) and signing. Canonicalization details depend on the specific MIME type. This is more of a MIME issue than an S/MIME issue.

The “application/pkcs7-mime type” is used for CMS EnvelopedData and SignedData types. There are several types of application/pkcs7-mime objects, which gives great flexibility (and the potential for confusion if the MUAs are not in agreement).

Filename Extensions

When agents use S/MIME types, they should use specific filename extensions for particular types of S/MIME objects. Treating S/MIME objects as files is useful for several reasons. The objects can be handled as files and stored on disk. Also, for gateways that do not recognize S/MIME entities, treating an S/MIME object as a file causes the gateway to operate in a default manner (i.e., treat the entities as a generic attachment) that allows it to transition smoothly through the gateway. It also allows certain receivers to decide on the specific mechanism to use to handle that file (S/MIME) type, but note that this practice is *not* how standard S/MIME should work (the MIME types should be the determining criteria). Three filename extensions are used.

1. *Application/pkcs7-mime* This type is used for SignedData and EnvelopedData and uses the “.p7m” file extension.
2. *Application/pkcs7-mime* This type is used for “degenerate” SignedData “certs-only” messages (messages whose only function is to exchange an X.509 certificate) and uses the “.p7c” file extension.
3. *Application/pkcs7-signature* This type is used for digital signatures and uses the “.p7s” file extension.

Enveloped-Only Messages

An enveloped-only message is one that is encrypted along with its content (session) key but is not signed and is used for confidentiality and privacy. RFC 2633 warns (in section 3.2.2) that such messages do not guarantee message integrity because they are not signed (it is possible for an adversary to replace the encrypted data in such a way that it appears authentic).

The MIME entity is processed into a CMS object of type EnvelopedData. A copy of the content-encryption key (i.e., the session key) is also encrypted. The object is then turned into an application/pkcs7-mime entity. The

“enveloped-data” parameter is used along with the “.p7m” file extension. RFC 2633 gives the following sample message.

```
Content-Type: application/pkcs7-mime; smime-type=
  enveloped-data; name=smime.p7m
Content-Transfer-Encoding: base64
Content-Disposition: attachment; filename=smime.p7m
rfvbnj756tbBgHyHhHUujhJhJH77n8HHGT9HG4VQpfy
  F467GhIGfHfYT6
7n8HHGghyHhHUujhJh4VQpfyF467GhIGfHfYGTfVbnj
  T6jH7756tbB9H
f8HHGTfVhJhJH776tbB9HG4VQbnj7567GhIGfHfYT6g
  hyHhHUujpfyF4
0GhIGfHfQbnj756YT64V
```

Signed-Only Messages

There are two types of signed-only messages: application/pkcs7-mime with SignedData, and multipart/signed. The latter is the preferred method because the receiver can always view the cleartext MIME data (e.g., ASCII text) of a multipart/signed message, even if they are not S/MIME capable (granted, the signature portion itself will probably look like gibberish).

application/pkcs7-mime with SignedData: The MIME entity is processed into a CMS object of type SignedData and is turned into an application/pkcs7-mime entity. It uses the signed-data parameter with a file extension of “.p7m”. RFC 2633 gives the following sample message (note that the actual signed message is not understandable to an S/MIME incapable MUA):

```
Content-Type: application/pkcs7-mime; smime-type=
  signed-data; name=smime.p7m
Content-Transfer-Encoding: base64
Content-Disposition: attachment; filename=smime.p7m
567GhIGfHfYT6ghyHhHUujpfyF4f8HHGTfVhJhJH776t
  bB9HG4VQbnj7
77n8HHGT9HG4VQpfyF467GhIGfHfYT6rfvbnj756tbBg
  hyHhHUujhJhJH
HUujhJh4VQpfyF467GhIGfHfYGTfVbnjT6jH7756tbB9
  H7n8HHGghyHh
6YT64V0GhIGfHfQbnj75
```

Signing Using the Multipart/Signed Format: This is also known as “clear signing” because it will be viewable by recipients who have no S/MIME capability. It is broken down into two parts: the first contains the entity that is signed and the second contains the actual CMS “detached” signature SignedData object. The “application/pkcs7-signature” MIME type is used and the “micalg” parameter denotes the message digest algorithm used. RFC 2633 gives the following sample message (note that the signed message itself is understandable even to an S/MIME incapable MUA):

```
Content-Type: multipart/signed; protocol=“application/
  pkcs7-signature”; micalg=sha1; boundary=boundary42
--boundary42
```

```

Content-Type: text/plain
This is a clear-signed message.
--boundary42
Content-Type: application/pkcs7-signature; name=
smime.p7s
Content-Transfer-Encoding: base64
Content-Disposition: attachment; filename=smime.p7s
ghyHhHUujhJhjH77n8HHGTrfvbnj756tbB9HG4VQpfy
F467GhIGfHfYT6
4VQpfyF467GhIGfHfYT6jH77n8HHGghyHhHUujhJh

6ghyHhHUujpfyF4
7GhIGfHfYT64VQbnj756
--boundary42-

```

Signing and Encrypting

Both signing and encrypting a message are straightforward: the signed-only and encrypted-only formats are nested. The message can be signed first and then encrypted, or the opposite can be done. When signing first, the signatories are hidden by the encryption. When encrypting first, the signatories are not obscured by the encryption and can be verified without decrypting the message (this may be useful in some environments). RFC 2633 mentions the following security ramifications for the various methods.

A recipient of a message that is encrypted and then signed can validate that the encrypted block was unaltered, but cannot determine any relationship between the signer and the unencrypted contents of the message. A recipient of a message that is signed-then-encrypted can assume that the signed message itself has not been altered, but that a careful attacker may have changed the unauthenticated portions of the encrypted message.

Certificates-Only Message

Certificates-only messages exist to allow exchanging X.509 certificates or certificate revocation lists. The certificates are turned into a CMS SignedData object and enclosed in an application/pkcs7-mime MIME entity with the certs-only parameter and the “.p7c” file extension.

ENHANCED SECURITY SERVICES FOR S/MIME (RFC 2634)

RFC 2634, titled “Enhanced Security Services for S/MIME” (Hoffman, 1999) describes four optional security enhancements for S/MIME. The four services are signed receipts, security labels, secure mailing lists, and signing certificates. Signed receipts, security labels, and secure mailing lists are useful for business and finance applications (among others). Signing certificates are used when certificates are transmitted with signed messages. The section is a cursory look at the enhanced security services (for more details, see RFC 2634).

Triple Wrapping

A system called *triple wrapping* is used for the security enhancements and is worth noting. Triple wrapping means that a message is signed, then encrypted, and then signed again (not necessarily by the original signers). The “inside” (first) signature is used for integrity, origin non-repudiation, and binding security attributes to the content. Security attributes can be used for things such as access control. The second wrapping, the encrypted body, provides confidentiality, including hiding the inside signature. The “outside” (last) signature is used for authentication and integrity for information processed “hop-by-hop” where each “hop” is an intermediate entity such as a mail list agent. The attributes of the outside signature can be used for access control and routing decisions.

Signed Receipts

Signed receipts are an attempt to emulate the same physical concept with normal mail. A receipt is bound to the original message though a digital signature, so it may be used only for signed messages. If a recipient returns a signed receipt, then it provides proof to the sender that the message was delivered and that the recipient could verify the digital signature.

Security Labels

A security label is a set of information that helps define the sensitivity of the content. This information can be used to check if a user is authorized to access the S/MIME content (protect by encryption). Security labels can also be used for routing, can be used for an MLS hierarchy (e.g., “unclassified,” “confidential,” “secret”), and can be used for role-based access control (RBAC) so that one or more roles can be bound to the content.

Secure Mailing Lists

Mailing lists are handy and well known. When using S/MIME, it can become difficult to use a mailing list because recipients may have different encryption requirements. For a large number of recipients this can be a time-consuming task. *Mail list agents* (MLAs) can take a single message and do all of the recipient specific encryption processing. The MLA appears to the originator as a single message recipient, but it redistributes the message to all of the mailing list members automatically, thus reducing the management burden on the list administrator.

Secure mailing lists also have a feature to prevent mail loops. A mail loop happens when a mailing list is a member of another mailing list, and vice versa. In such a case, a message will bounce back and forth between the lists and create a cascade of messages. MLAs prevent mail loops by using an attribute of the outer signature of a triple wrapped message. If the MLA encounters its own unique identifier, it knows that a loop exists and will not send the message again.

Note that with secure mailing lists, the “weak link in the chain” effect mentioned earlier can happen.

Signing Certificates

There are several attacks against the signature verification process in S/MIME that are done by replacing the certificate(s) that are used for signature verification. A SigningCertificate attribute is designed to help protect against these attacks.

Security Issues With the Enhancements

The enhancements open up a whole area of security issues. It is important that the user understand what these are, because improper or naïve use could cause some horrific security problems. A full explication of this is given in section 6 of RFC 2634 and should be required reading for anyone using the enhancements.

ALTERNATIVES TO S/MIME

There are alternatives to S/MIME. One criticism of S/MIME is that it is reliant on the X.509 architecture and therefore TTPs (to some, this is not a criticism but a feature). Because the alternatives are covered in other chapters, they will not be discussed in any detail here. Some of them are using the digital signature standard (DSS), PGP, IPsec, SSL, Kerberos, and SSH (alone or in combination). Many of these can be used in conjunction with S/MIME.

One more alternative should be mentioned. That is to use standard RFC 822 e-mail with a “grow your own” solution. Unless you are an information system security researcher or an experienced developer, this could be difficult, expensive, and have a particularly dangerous outcome. Some of the issues that have to be dealt with are the key exchange problem, digital signatures, encryption, cipher suite compatibility, management and infrastructure issues, public key infrastructure issues, random and pseudorandom number generation, implementation details, and so forth.

Of course, there is one other option: avoid using e-mail for all sensitive transmissions.

CONCLUSIONS

We have seen that S/MIME is designed to be a way to make e-mail more secure. It is important not to lose sight of the fact that “more secure” does not mean “perfectly secure”—it is probable that S/MIME contains some serious flaws that will be discovered in the future (this is typical of virtual every security protocol). For example, one criticism of S/MIME (really, a criticism of existing security services) is that encrypted S/MIME messages can interfere with virus scanners (the kind that operate at the mail gateway); clearly unless the virus scanner possesses the key used for an encrypted message, it cannot reliably scan a message for a virus or other malware.

However, S/MIME often can be used to improve security, especially considering that most e-mail traffic is neither signed nor encrypted. S/MIME offers a relatively easy solution for users to get these services. It is also standardized, consistent, and present in most modern MUAs. Considering that RFC 822 e-mail specifies no security at all, S/MIME is a viable choice for adding authentication, message integrity, nonrepudiation, and increasing privacy via providing confidentiality through encryption. In addition,

the S/MIME enhanced security services offers signed receipts, security labels (particularly important for MLS and RBAC), secure mailing lists, and signing of certificates to prevent certificate vulnerabilities. Although there are alternatives to S/MIME, given that it is implemented in most modern MUAs and is a well-established standard (being in its third version at the time of writing), it is a sensible choice for those looking to improve the security of their e-mail systems.

GLOSSARY

Certificate Authority (CA) Usually for X.509. A trusted third party used for the exchange of public keys (among other things).

Cryptographic Message Syntax (CMS) For a more detailed explanation, see the section with the same name in this chapter.

Diffie-Hellman key exchange protocol A method of creating a shared secret (a key) between two communicating entities with the goal that an eavesdropper can not deduce the key.

Mail List Agent (MLA) Software that handles distribution of e-mail from senders to a list of multiple recipients.

Mail User Agent (MUA) Typically the software used to read and send mail by a user.

Message Authentication Code (MAC) A type of cryptographic hash, or message digest.

Multipurpose Internet Mail Extensions (MIME) For a more detailed explanation, please see the section with the same name in this chapter.

Multi-Level Security (MLS) Security that uses a lattice structure to partially order a hierarchy of security labels/levels.

Public Key Cryptography Standard (PKCS) Retrieved January 5, 2004, from <http://www.rsasecurity.com/rsalabs/pkcs/>

Public Key Infrastructure (PKI) A system based on one or more trusted third parties that is designed to manage, store, disseminate, and revoke public keys. Typically X.509 for S/MIME.

Role-Based Access Control (RBAC) A system of access control based on labeled “roles” that contain privileges, where users associated with particular roles may exercise those privileges. Control.

Secure/Multipurpose Internet Mail Extensions (S/MIME) See this chapter.

Trusted Third Party (TTP) A third-party entity that is trusted by its users. Useful in situations where users may not trust one another.

INTRODUCTION

A fascinating story from the early 1990s Internet boom is the development of PGP, or “Pretty Good Privacy.” PGP is a program for encrypting and digitally signing data and is most frequently used for e-mail. In fact, PGP may be the most well-known e-mail encryption software in existence with over 8 million users worldwide (PGP Corporation, n.d.). PGP’s notoriety is largely due to the legal issues surrounding its creation, rather than for its technical merits.

PGP is one of the few examples of software created in blatant disregard of patent and export laws to evolve into a legitimate commercial product. Illegal software of this nature is sometimes referred to as *guerillaware* and might include peer-to-peer file sharing networks like Kazaa or DVD copying software such as DeCSS. The legal battles faced by PGP’s creator, Phil Zimmermann, illustrate several policy barriers to developing cryptographic products that existed in the 1990s—namely, patent and export restrictions. Technically, PGP offers lessons of how performance, usability, and compatibility can affect adoption of a cryptographic product.

This chapter introduces PGP’s applications and underlying cryptographic components in the first section. The second section presents a short history of PGP. The third section describes several PGP implementations and alternative secure e-mail models, followed by a section that analyzes several problems of PGP and suggests lessons that might be learned. The final section speculates future directions of PGP and e-mail security in general.

Basics of PGP

E-mail is a common fixture in most U.S. households, despite having inherent privacy and authenticity issues. Broadly speaking, PGP is an e-mail encryption program that can address some e-mail security concerns. More accurately, PGP is a public-key cryptographic suite, providing encryption, digital signatures, key generation, and key management functionality. Although PGP may be used to encrypt and sign arbitrary data and is often used for disk encryption, it is primarily used for e-mail encryption. For

convenience, this chapter specifically discusses e-mail and may use the phrase “unencrypted e-mail” in cases where “unencrypted data” or “disk” might apply.

Anyone who can tap the network may intercept and read unencrypted traffic. Although tapping wires or corrupting network routers are not simple tasks, unencrypted wireless access points that are vulnerable to eavesdropping are becoming common. Snoops may intercept traffic sent through insecure access points and archive it for later analysis. This lack of privacy is inherent in most e-mail and instant messaging applications.

E-mail also lacks secure mechanisms to ensure message authenticity and integrity. As most spam recipients know, it is a trivial matter to send a message with an arbitrary “From:” header. Without cryptographic protection, it is easy to forge both message origins and contents. The lack of e-mail authentication is becoming more of a problem as viruses and worms cull e-mail addresses from infected hosts’ address books or as “phishing” attacks forge official-looking e-mail in an attempt to steal login details.

How can you ensure that your message wasn’t intercepted or modified in transit? How can you tell if a coworker really sent you a message with an attachment? How can you tell if a message really originated from an online stock broker or an auction site? PGP address all of these problems using public-key cryptography.

PGP guarantees e-mail privacy by encrypting messages with the recipient’s public key. This encrypted e-mail can only be read by the holder of the corresponding private key, namely the intended receiver. PGP provides e-mail authenticity and integrity through digital signatures. Users can sign message contents and headers prior to encryption. This allows users to verify that signatures on message contents and headers correspond to the received plaintext message.

This abstract view of encryption and signatures ignores the problem of key distribution. How does the sender acquire the receiver’s public key to encrypt? How does the receiver acquire the sender’s public key to verify signatures? Essentially, how does any user know that any public key is authentic?

Most cryptographic systems rely on a public key infrastructure (PKI) to store and distribute public keys. All users in the system will implicitly trust some part of the PKI, usually a certain certificate authority (CA). All trust in the system is implicitly derived from trust in the CA. In practice, most PKIs are hierarchical and have one centralized authority that all users implicitly trust. One innovation of PGP is that it may either use a centralized PKI or a “web of trust” model, which is discussed in the following section.

Technology Highlights

The previous section takes a high-level approach to cryptographic primitives and omits details about specific algorithms or practical constraints. Encryption and signature algorithms were only used abstractly, without any consideration of how they applied to PGP. This section discusses some of PGP’s technological features.

One of PGP’s most distinctive contributions is the “web of trust” PKI model. Rather than relying on a centralized hierarchy of Certificate Authorities, any user in a PGP web of trust may issue a certificate binding an identity to a public key. For example, a user Alice may issue a certificate stating, “I believe that Bob’s key is k . Signed, Alice.” This operation is often referred to as “signing a key,” for example, “Alice signs Bob’s key.” Although technically inaccurate, this phrase is useful in describing links in the web of trust.

For example, suppose a third user, Carol, already trusts Alice and receives Bob’s public key. With Alice’s certificate, Carol may reason, “I trust Alice. This certificate says Alice trusts k is Bob’s key. Therefore, I will trust that k is Bob’s key.” Thus, certificates are transitive. Each user may have a policy to decide how much trust to put in a particular certificate. This process is illustrated in Figure 1.

The transitive property of certificates allows users in a web of trust to “recommend” public keys to other users. PGP’s web of trust model also allows users to assign varying degrees of trust to different certificates. This model offers more flexibility than traditional, hierarchical PKIs, where all certificates are issued by trusted certificate authorities (CAs). In a web of trust, all users in a web of trust can effectively act as their own CA but must then decide whom they trust and to what degree.

Modern social networking services such as Friendster or Orkut capture the spirit of a web of trust PKI. The idea is that a close-knit group of people would sign each other’s keys. Eventually, connections between different groups would allow two strangers to establish trust in each

other through a network of mutual friends. PGP users are not limited to a web of trust. In practice, centralized key servers, such as `pgp.mit.edu`, may store and distribute keys and coexist with a web of trust.

Another key feature of PGP is its standardized formats for encrypted messages, signatures, certificates, and public keys. A standardized message format allowed PGP to be integrated into a variety of mail clients and allowed a flexible public key infrastructure. PGP’s message formats have evolved through several RFCs (requests for information; Internet Engineering Task Force, 1996). Much of the same functionality is also available in S/MIME’s (secure multipurpose Internet mail extension) cryptographic message formats (Kaliski, 2003).

Theoretically, all of PGP’s operations could be carried out using solely public key algorithms. However, public key operations are still too computationally intensive for most applications. Standardized public key primitives also typically have a maximum block size, which complicates operations on variable length or streaming data. As a practical optimization, PGP uses both public key encryption and symmetric encryption algorithms.

To encrypt a message, PGP will first generate a random *session key* to be used by a symmetric algorithm. As the name suggests, session keys are used for a single communication session and stored for a long term. Session keys should be indistinguishable from randomness and so are typically generated using a cryptographic pseudo-random generator or dedicated random number generation hardware.

The plaintext message will be encrypted under the session key using a symmetric algorithm. The session key is then encrypted using a public key encryption algorithm. Note that the session key is being treated both as a key and as a message. The ciphertext output from both operations is sent to the message recipient, who is able to decrypt the session key and recover the message plaintext.

A second performance and implementation issue arises in creating message signatures. Most practical signature algorithms have a maximum block size and are relatively costly operations. Rather than signing each block of a message, PGP will sign a *message digest* of the entire message. A message digest is a short string that is easy to compute from an arbitrary length string, such that it is difficult to find two messages that collide to the same digest. In practice, a cryptographic hash function such as MD5 or SHA-1 is used as a digest function. (However, weaknesses recently discovered in both MD5 and SHA-1 may make SHA-256 the de facto standard cryptographic hash function.)

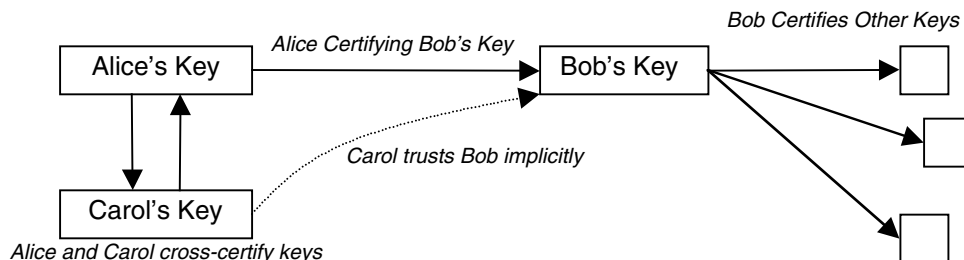

Figure 1: A “web of trust” between Alice, Bob, and Carol.

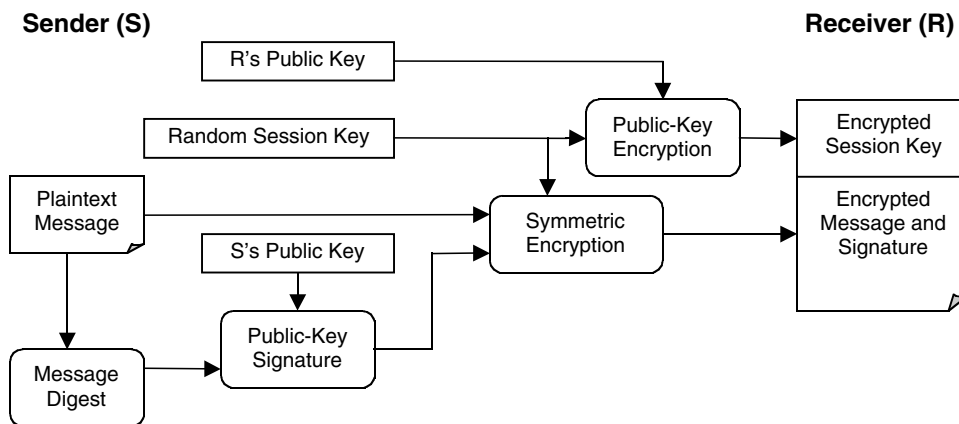

Figure 2: Dataflow diagram of PGP sign-and-encrypt process.

Typically, PGP users will first sign a message and encrypt both the message and the signature. This embeds an authentication and integrity check within the encrypted message that the recipient can verify. Figure 2 illustrates the entire sign-and-encrypt process.

Supported Algorithms and Key Recommendations

PGP supports the following public key encryption, signature, and key exchange algorithms:

- RSA
- El Gamal
- DSA
- Diffie–Hellman
- Elliptic curve public key algorithms.

PGP supports the following symmetric encryption algorithms:

- AES
- CAST
- Triple-DES
- IDEA
- Twofish.

PGP supports the following message digest algorithms:

- SHA-1
- MD5
- RIPEMD.

A common PGP configuration is to use RSA/IDEA/MD5 for public key, symmetric encryption, and message digest algorithms. Rather than for technical merits, this configuration was chosen specifically to avoid using the U.S. federal government’s Data Encryption Standard (DES) and Secure Hash Algorithm (SHA-1) standards. Both of these standards, as well as DES’s successor AES, are publicly available and patent-free (AES Homepage, n.d.).

RSA keys may be of various lengths, including 512, 1024, and 2048 bits. RSA keys of size 1024 are believed to be secure for all practical purposes. However, recent developments would allow a large organization to break a 1024-bit RSA public key in one year with \$10–50 million dollars worth of hardware (Kaliski, 2003). RSA 2048-bit keys are still believed to be secure against powerful adversaries for the foreseeable future (Lenstra & Verheul, 2003). With these considerations, a patent-free, standardized PGP configuration with sufficient public key size is RSA-2048/AES/SHA-1, although there are no known breaks in RSA/IDEA/MD5 or any other supported configuration is insecure.

HISTORY OF PGP

Origins of PGP

The development of PGP may be traced to the convergence of three key technological threads starting in the late 1970s and continuing through the early 1990s. The first was the maturation of the field of public key cryptography. The second was the advent of personal computers, particularly among hobbyist enthusiasts. Third was the rise in network communications. For the first time, a sizable number of computer enthusiasts and college students were connecting to the Internet and bulletin board systems with personal computers powerful enough to support public key cryptography. Appropriately, public key cryptography seems to have both private and public origins. Some of the earliest pioneers were Ralph Merkle, Whitfield Diffie, and Martin Hellman, who laid the foundation of modern public key cryptography circa 1974 (Diffie & Hellman, 1976; Merkle, 1978). Of particular importance was the Diffie–Hellman key exchange protocol based on the hardness of the discrete logarithm problem. Their work was among the first “public” public key cryptography results.

These early developments inspired the creation of the RSA public key cryptosystem by Ronald Rivest, Adi Shamir, and Len Adleman (1978) around 1976–1977. RSA’s security is based on the hardness of factoring large numbers, which is a famous outstanding mathematical problem.

It is likely that at least the intelligence communities in the United States and United Kingdom developed their own classified, “private” public key cryptographic primitives. In fact, documents declassified in the late 1990s reveal that in 1970, British researcher James Ellis outlined the possibilities for public key encryption (Ellis, 1970). Similar documents revealed that another British researcher, Clifford Cocks (1973), developed a classified RSA variant in 1973.

One of RSA’s strongest advantages was the fact that the same public keys could both encrypt and sign documents. RSA could also be executed, albeit slowly, on the emerging personal computer market. In fact, RSA was practical enough to be a viable commercial product.

In 1983, the U.S. Patent Office granted a patent for RSA to the Massachusetts Institute of Technology (MIT; U.S. Patent No. 4,405,829, 1983). Although this patent expired in 2000, it would become an integral part of PGP’s history. MIT granted full licensing rights of RSA to Rivest, Shamir, and Adleman, who founded a company to develop commercial cryptographic and security products called RSA Data Security. Today this company is known as RSA Security.

In 1986, RSA Security released a program for encrypting e-mail with RSA called MailSafe. One problem with MailSafe was that its users could only send secure e-mail to other MailSafe users. As a result, MailSafe never developed a large user base and represented a small fraction of RSA Security’s revenue.

One person who did acquire a copy of MailSafe was an independent computer scientist named Phil Zimmermann. At the time, Zimmermann had a strong interest in both cryptography and privacy rights. He had been considering developing his own implementation of RSA for the IBM PC. Although Zimmermann did and still does profit from the sale of PGP, he was also motivated by the idea that individual privacy is sacrosanct. In his own words, Zimmermann (2003, n.p.) comments on the reasons he wrote PGP: “PGP empowers people to take their own privacy into their own hands. There has been a growing social need for it. That’s why I wrote it.”

Zimmermann worked on RSA implementation until 1990. At this point, Zimmermann contacted RSA Security and requested a “free license” to use the patent-protected RSA algorithm. RSA Security denied his request, although they offered to sell Zimmermann a license. Zimmermann declined but nonetheless continued work on PGP. Because Zimmermann had no license to use RSA, releasing his software would violate U.S. patent laws.

A major catalyst in the eventual release of PGP was the U.S. Senate. The Comprehensive Counter-Terrorism Act of 1991 (S. 266 and H.R. 731, 1991), contained a clause in Section 2201 stating that electronic communication service operators and manufacturers of equipment were legally obligated to “ensure that communications systems permit the government to obtain the plain text contents of voice, data and other communications when appropriately authorized by law.”

Broadly translated, an implementation of an encryption algorithm constituted “electronic communications service equipment.” Essentially, S. 266 required that any software or hardware implementations of encryption

algorithms contain “backdoors” allowing government to read any encrypted messages. Strong cryptography, unless approved by the government, would be illegal.

Rather, the government supported key escrow. Users would register their private keys with a government organization. Those keys would be available to law enforcement and intelligence organizations that obtained a subpoena. Although government support for cryptographic key escrow is essentially dead, security concerns could spur renewed interest in key escrow.

For example, the new U.S. Transport Security Agency (TSA) forbids the use of any non-TSA-approved luggage locks. Authorized TSA baggage screeners may unlock TSA-approved locks. Ironically, many people locked their luggage to protect against theft by the very same baggage handlers who now have a master key (Travel Sentry, n.d.).

Bill S. 266 spurred privacy rights organizations and software makers into action. This legislation came at a time when online communication was rapidly growing and when both individuals and corporations had legitimate interests in secure communications. The bill could have burdened software and hardware manufacturers with significant new costs. With strong lobbying from the Electronic Frontier Foundation (EFF) and RSA Security, the offending language that required government access to plaintext messages was quickly removed.

The appearance of S. 266 hastened Zimmermann’s work on PGP until finally a stable version 1.0 was ready. PGP version 1.0 supported RSA and a weak symmetric algorithm called “Bass-O-Matic,” which is discussed later in the chapter. In 1991, Zimmermann circulated the program to a few friends and colleagues. Someone eventually posted the PGP to Usenet. Internet sites around the globe promptly mirrored their own copies of PGP. The Pandora’s Box of PGP was open.

Patent Infringement

PGP version 1.0 lacked one key component: a license to use the RSA algorithm. Although Phil Zimmermann requested a free license, RSA Security never offered nor granted one. PGP did offer some of the same functionality as RSA Security’s MailSafe but represented little competitive threat. MailSafe accounted for a minute fraction of RSA Security’s revenue. Most of their income came from licensing cryptographic patents.

RSA Security’s failure to defend their RSA patent vigorously would set a dangerous precedent. Why would anyone pay a license fee when PGP was using RSA for free? Losing its RSA patent revenue stream represented the true threat to RSA Security’s livelihood.

As a response, RSA Security conducted a campaign to eliminate the distribution of PGP. They threatened legal action against major online services, such as CompuServe and America Online, who did not remove copies of PGP from their systems. Universities and the EFF removed PGP from their own sites out of fear of litigation.

Although RSA Security successfully defended their RSA patent, their actions energized PGP enthusiasts. Every action to suppress the distribution of PGP inspired individual privacy advocates and cryptographic rights “cypherpunks” to mirror and distribute illegal copies of

PGP around the globe. A core group of users began to develop and PGP became a centerpiece in the debate over cryptographic rights and patent laws. As more people used PGP, technical problems emerged. Zimmermann never intended to release PGP 1.0 to the public. His code contained at least one fatal flaw. Not trusting the government's own DES encryption algorithm, Zimmermann cobbled together his own symmetric encryption algorithm called Bass-O-Matic (the name pays homage to a classic comedy sketch involving a fish blender). A cryptographer named Eli Biham quickly broke Bass-O-Matic and exposed severe security flaws. With more private individuals relying on PGP for secure communications, Zimmermann realized that he could not ignore patent issues and that PGP needed a thorough code review.

Phil Zimmermann and a group of international volunteers continued to develop PGP over the next 2 years, by adding features, fixing bugs, and making several major improvements. Notably, the International Data Encryption Algorithm (IDEA; Lai & Massey, 1990) replaced Bass-O-Matic as PGP's symmetric algorithm of choice. Volunteers also internationalized PGP by translating it into several languages and adding support for international character sets. By 1993, PGP version 2.3 had stabilized into a more or less robust product.

At this point, there was growing pressure from PGP users to settle its outstanding patent infringement issues. Particularly, potential business customers wanted to legitimize PGP. With its legality in question, corporate users could not risk using PGP without fear of litigation. PGP had few users outside a core following of privacy and cryptography buffs. Unless mainstream users could use it, PGP would remain relegated to the underground.

Rather than negotiate directly with RSA Security to obtain a license, Zimmermann decided to solicit companies that already held RSA licenses. Eventually, Zimmermann found a European suitor named ViaCrypt willing to sell PGP as a commercial product. ViaCrypt released ViaCrypt PGP version 2.4 in late 1993. This move may have hurt PGP's overall position. Zimmermann's "selling out" PGP to a company alienated some dedicated users and volunteer developers. Few users were willing to pay for a commercial product that they had always used for free. Worse, despite acquiring a license via ViaCrypt, corporate users remained skeptical about the legality of PGP.

Meanwhile, RSA Security had warmed to allowing free noncommercial RSA licenses. Granting noncommercial licenses encouraged research and peer review of RSA implementations. Following PGP's initial release, RSA Security released a reference implementation of RSA called RSAREF. Soon, products such as Mark Riordan's Internet Privacy Enhanced E-mail (RIPEM) were built on top of RSAREF and the new Privacy Enhanced E-Mail (PEM) standard (Internet Engineering Task Force, 1993). RIPEM was a free, patent-licensed and standardized alternative to PGP.

RSAREF contained two poison pills targeted at PGP. First, its programming interface did not allow access to functions specifically needed by PGP. Second, parties that previously violated RSA Security patents were denied a noncommercial RSAREF license. Regardless, RSA Security did offer a compromise to accommodate PGP. They

would grant noncommercial licenses to a new version of PGP only if it were made intentionally incompatible with older "guerillaware" versions of PGP. Versions 2.3 and prior would not be able to communicate with later versions. This incompatibility was intended to avoid granting "amnesty" to users of patent-violating PGP versions. Zimmermann refused this offer.

During this time, a group of researchers at MIT had been building a legitimate version of PGP on top of RSAREF. They discovered that RSAREF version 2.0's new programming interface was sufficient to implement PGP. With the help of Zimmermann, MIT was prepared to release a PGP version 2.5 in early 1994. MIT PGP version 2.5 appeared to abide by the RSAREF license agreement. It would be difficult to argue that MIT was violating the very same patent it had originally granted RSA Security the rights to use.

RSA Security did object to PGP 2.5's backward compatibility, however, because it would allow illegal versions of PGP to communicate with legitimate versions. MIT and RSA Security reached a compromise. Rather than releasing version 2.5, MIT would release version 2.6 which had one new "feature": on September 1, 1994, version 2.6 would cease to be compatible with prior versions. This would offer an incentive for non-licensed users to upgrade, without immediately locking them out. Zimmermann agreed to this compromise because it gave prior users time to upgrade to a new version. For all intents and purposes, PGP's patent issues had finally been resolved. Yet Phil Zimmermann's legal troubles persisted.

Export Licenses

MIT PGP version 2.6 was the first version of PGP free of license issues. Although ViaCrypt PGP 2.4 appeared to be legal, version 2.6 was released with the express approval of RSA Security. Corporate customers could use PGP without fear of litigation.

Yet another legal issue loomed. Soon after its release, version 2.6 was quickly distributed to FTP (file transfer protocol) servers around the globe. This was strictly forbidden by U.S. export laws. In fact, all prior versions of PGP had also been illegally exported.

It was illegal to export encryption technology with key lengths greater than 40 bits without government approval; despite the fact that 40-bit keys were thought to be insecure. Typically, this led to having two versions of a product: a domestic version with 64- to 128-bit keys and an international version with weak, 40-bit keys. PGP's symmetric algorithm, IDEA, used 128-bit keys. Although IDEA was developed outside the United States, the export of PGP resulted in a federal investigation of Zimmermann.

At the time, U.S. export laws produced some complicated restrictions on cryptography. Encryption software was considered "munitions." Exporting code fell into the same legal class as exporting warheads or missile guidance systems. Although this categorization might seem severe, it does highlight the importance of cryptography with regard to national defense.

Because of freedom of speech guarantees, however, printed material did not fall under this restriction. A book was not considered an "encrypting device" like software

source code. This idiosyncrasy in the law made it illegal to export encryption source code over a network or on a floppy disk but legal to print the identical source code in a book. Exporting a book containing the entire source code of PGP in machine-readable fonts was perfectly legal. This is exactly what Zimmermann (1995) did.

Foreign buyers quickly scanned Zimmermann's book and distributed the resulting source code. This exposed weaknesses in the government's case. How could someone be charged with exporting "munitions" that could be bought in a bookstore? Zimmermann's case also highlighted the outdated restriction on keys greater than 40 bits.

In early 1996, the federal case was dropped against Zimmermann with no charges being filed. Later that year, Zimmermann addressed the U.S. Congress on reforming cryptographic export laws. Over the next 4 years, the Electronic Frontier Foundation (n.d.), cryptographic researchers such as Ron Rivest, and several industry groups lobbied Congress for export law reform. In January 2000, cryptographic export laws were significantly loosened, allowing free export of cryptography except to state sponsors of terrorism.

PGP VARIANTS AND ALTERNATIVES

PGP Corporation and OpenPGP

Several versions of PGP are available today. PGP Corporation sells a variety of PGP products, namely, PGP Personal and PGP Universal, which are briefly discussed later in this section. Phil Zimmermann originally founded PGP Incorporated, which merged with ViaCrypt, in 1996. In 1997, Network Associates Incorporated acquired PGP Inc. In 2002, a newly formed PGP Corporation purchased all PGP products and intellectual property from Network Associates. Phil Zimmermann currently acts as a special advisor and consultant to PGP Corporation (n.d.).

Zimmermann also acts as the chairman for the OpenPGP alliance, which developed and advocates the OpenPGP standard (Internet Engineering Task Force, 1993). OpenPGP is a nonproprietary, secure e-mail standard. It defines formats for encrypted messages, signatures, and public key certificates. OpenPGP is similar in many respects to S/MIME, the Secure Multipurpose Internet Mail Extensions, developed by RSA Security (Internet Engineering Task Force, 1999). S/MIME is discussed briefly later in this section.

OpenPGP supports the RSA, Diffie–Hellman, DSA, and El Gamal public key algorithms. OpenPGP also supports the AES, CAST, 3DES, IDEA, and Twofish symmetric encryption algorithms and the SHA-1, MD5, RIPEMD-160, and MD2 hash algorithms. The standard has reserved fields for experimental and emerging cryptosystems, such as elliptic curve cryptography. Future developments in OpenPGP may add support for mobile devices or compatibility with S/MIME.

PGP Corporation's PGP Personal offers secure messaging and storage for home use. PGP Personal is a commercial product and offers full OpenPGP compatibility, although a freeware version is available for download. Version 9.0 Beta is the latest release as of early 2005. PGP Personal may be considered the legitimate heir of PGP and

may even be purchased directly from Phil Zimmermann (2003).

MIT PGP Freeware and PGPi

An alternative OpenPGP-compliant implementation is MIT's PGP Freeware version 6.5.8 (MIT Distribution Center for PGP Freeware, n.d.). On September 20, 2000, the RSA patent expired and the algorithm became free for public use. Patents on Diffie–Hellman key exchange and other early work by Hellman, Merkle, and Pohlig have also subsequently expired.

The expiration of RSA's patent essentially grants amnesty for guerillaware versions of PGP. Most prominent of these PGP variants are internationalized versions developed by volunteers around the world, such as by the PGPi project (PGP International, n.d.). One unofficial international version of PGP, version 2.6.3i, has been translated into more than 25 languages and ported to several platforms. Currently, there are efforts to translate and port PGP freeware versions 6.0 and higher.

GnuPG

Another free, near-compliant OpenPGP alternative is the GNU Privacy Guard, or GPG. As with all software under the GNU Public License (GPL), GPG depends on no proprietary code. Because of the GPL, GPG cannot use any patented encryption algorithms, most notably the IDEA symmetric encryption algorithm.

An advantage to having several OpenPGP-compliant alternatives, such as GPG, is that attacks and software bugs affect smaller portions of the market. For example, a weakness discovered in the OpenPGP format that potentially leaked private keys did not affect GPG (Klima & Rosa, 2001).

S/MIME

An alternative secure messaging service similar to OpenPGP is S/MIME. S/MIME was originally developed by RSA Security and submitted to the Internet Engineering Task Force (1998, 1999) as a new standard. Most major e-mail clients, including Microsoft Outlook and Mozilla e-mail, have adopted S/MIME.

S/MIME and OpenPGP offer much of the same functionality. Unfortunately, the two standards are currently incompatible, although many commercial implementations do support both standards. Adding to the confusion is the existence of an OpenPGP precursor called PGP/MIME, which is also incompatible to S/MIME. The OpenPGP and S/MIME working groups have supposedly been meeting to discuss unifying the two standards. As of 2004, it is unclear whether the OpenPGP and S/MIME working groups will merge the two standards any time soon.

Server-Side and Web-Based Secure E-Mail

A facetious rule of thumb in designing security products is that every keystroke needed to use the product cuts the market in half. By this rule, the most successful products should be the ones that require the least user interaction, which appears to hold in practice. Millions of

Web browsers connect to Web sites securely using secure socket layer (SSL). This requires negligible interaction from the user. Many academic and corporate institutions have replaced Telnet, which communicated in plain text, with the Secure Shell, or SSH. For all intents and purposes, the user experience of SSH is identical to Telnet.

PGP Corporation has apparently adopted the strategy of transparent security. Their recent PGP Universal product moves the burden of signing and encrypting e-mail from the desktop to the server. Users compose and send e-mail as they would regularly and let a common e-mail server act as a security proxy.

Although this model caters to the corporate market, it could be adopted to Web-based e-mail clients. In fact, this is essentially the model used by Hushmail (<http://www.hushmail.com>), Ziplip (<http://www.ziplip.com>), and other Web-based services. The Web-based approach addresses several of the usability issues discussed later.

Although implementation details may vary among services, they typically have similar models. Upon registering with a Web-based secure e-mail site, users will generate a public key pair that may either be stored by their browser or on the server side. Users may then connect to a Web site through an SSL connection and compose messages in their browser, similar to Hotmail or Yahoo Mail. The difference is that when sending messages, the user may sign and encrypt messages using the online service. Potentially, a Web-based service could also act as a portal to a PKI, allowing users to locate other recipients' public keys quickly.

Denial of service could be one effective attack against a centralized, server-side secure e-mail system. Because cryptographic operations are computationally expensive, flooding a server with many messages to encrypt, sign, or verify could create a performance bottleneck. Significantly degrading quality of service can frustrate users to the point where they fall back to plaintext e-mail. Of course, attackers could conduct this type of denial of service attack against servers in a centralized PKI. One advantage of PGP's web of trust model is that there is no single point of failure.

PGP PROBLEMS AND LESSONS

PGP is a useful case study in developing cryptographic software. It is an early example of the impact of laws and legislation on software development. In recent years, cases such as the Digital Millennium Copyright Act (DMCA) and conflicts over peer-to-peer file-sharing networks illustrate the interaction of laws and software. PGP is also an excellent example of the pitfall of forking in open source software development and of the effect of Metcalfe's law inherent in many security products. Finally, PGP brings to question the feasibility of developing widely used, user-level encryption software.

Changing Law for Changing Technology

PGP was an early example of how the existence of software can act as a catalyst for legal reform. At the time of its initial development, U.S. export laws were outdated and limited exported encryption to 40-bit keys. When the

law was written, 40-bit keys offered a reasonable level of security. As technology progressed, the law did not keep up. Simply by existing, PGP exposed the need for new approaches in public policy dealing with technology. For example, the notion that it was illegal to export PGP on disk, but legal to export it as a book obviously satisfies no one (Zimmerman, 1995).

In 2004, we are seeing a similar phenomenon in peer-to-peer networks. Intellectual property laws are becoming more difficult to enforce as technology allows more simple and anonymous dissemination of copyrighted material. Similar to how PGP spurred export law reform, the widespread use of peer-to-peer networks may spur intellectual property law reform.

The Need for Industry Standards

Regardless of legality, a second obstacle to PGP's adoption was the proliferation of several incompatible variants. Part of the problem was the forced backward incompatibility of MIT PGP version 2.6, which was part of the compromise with RSA Security to acquire a non-commercial license. The effect of this incompatible fork in development was to fracture the market for PGP. Official versions, international versions, and guerillaware versions could not always communicate freely with each other. Although OpenPGP addresses this problem, the damage appears to have been done. Most major e-mail clients support S/MIME, notably Microsoft Outlook and Mozilla. These clients do not support OpenPGP by default. A lesson is that software creators need to assert control over their "brand." It would have been better for Phil Zimmermann to dissuade incompatible versions from calling themselves "PGP," although this would have been inimical to the free-wheeling spirit of PGP's creation.

When it was released in 1997, the OpenPGP brand and standard were already several years too late. Fragmenting the market was particularly bad for a secure e-mail product. Like telephones, instant messaging clients, or other network communication systems, the utility of PGP depended on the number of people using it. If few people used PGP, there was little incentive to install it.

Bob Metcalfe, who was one of the creators of Ethernet, first elucidated the notion that a network's utility is the square of the number of users. In fact, Metcalfe's law applies to all public key cryptographic systems. Only people with public keys registered in the PKI may communicate with each other. One exception is Identity-Based Encryption, discussed later.

"Why Johnny Can't Encrypt"

Obstacles to adopting PGP apply to most user level, public key cryptographic products. Learning to use public key encryption can be daunting. Users must start by understanding the privacy and authentication security threats in e-mail. They must also understand enough of the fundamentals of public key cryptography to generate public keys, locate other users' public keys, and register public keys with a PKI or sign keys in a web of trust.

The terminology used to describe public key operations is not intuitive for a layperson. In the real world, we do

not have “public” and “private” physical keys, nor do we sign documents with keys. Perhaps a clever user interface could hide many of the technical details. Unfortunately, the PGP interface was developed for computer hobbyists and experts, which has fared poorly with nonexperts.

Two researchers at Carnegie Mellon University conducted a usability study on PGP 5.0’s graphical user interface titled, “Why Johnny Can’t Encrypt” (Whitten & Tygar, 1999). Several college students were given a brief tutorial in using PGP and provided technical assistance via e-mail. The students were then asked to perform several tasks, including creating a public key, signing a document and encrypting a message with someone else’s public key. Some excerpts from the results are less than reassuring:

Three of the twelve test participants accidentally emailed the secret to the team members without encryption . . . One participant forgot her pass phrase during the course of the test session and had to generate a new key pair . . . Among the eleven participants who figured out how to encrypt, failure to understand the public key model was widespread. Seven participants used only their own public keys to encrypt email to the team members.

In Ron Rivest’s “Network and Computer Security” course at MIT, students are assigned to read “Why Johnny Can’t Encrypt” and then send a PGP-signed and encrypted message to the course staff. Anecdotally, students take an average of 90 minutes to generate a public key pair, locate the course staff’s public key, sign, and encrypt the message. If it takes a computer science student enrolled in a graduate network security course at MIT 90 minutes to use PGP, there is little hope for widespread adoption.

FUTURE DIRECTIONS AND CONCLUSION

The need for secure e-mail has increased dramatically in recent years. E-mail is the primary infection vector for worms and viruses. Malicious software and spammers frequently forge e-mail headers or hijack outgoing address books. Thieves frequently forge e-mail from online stockbrokers or auction sites to steal account information. These attacks all exploit the lack of e-mail authentication, which could be addressed using digital signatures.

E-mail privacy is another concern. Web sites frequently send confirmation passwords or sensitive information in plaintext through e-mail. Cellular telephones, personal digital assistants (PDAs) and laptops commonly send e-mail over wireless networks. All these technologies create more opportunities for attackers to spy on plaintext messages.

Regardless of these risks, there still has not been a large consumer demand for secure e-mail. Most users lack the concern, time, or savvy to use e-mail encryption, despite being supported by many e-mail clients such as Microsoft Outlook or Mozilla e-mail. Today, a small fraction of e-mail sent on the Internet is encrypted.

One public key cryptosystem that may lower the barrier to user adoption is identity-based encryption (IBE). Originally envisioned by Adi Shamir (1984), IBE is an alternative approach to generating public keys. Rather than requiring that receivers generate their public key first, senders can simply use the intended recipient’s e-mail address as the public key. To clarify, the plaintext e-mail address *is* the public key. Upon receiving an identity-based encrypted message, the receiver will contact a trusted third-party server to fetch a decryption key. This third-party server need not be universally accessible and may reside behind a corporate firewall.

In 2001, researchers Dan Boneh and Matt Franklin (2001) designed a practical identity-based encryption scheme. A start-up called Voltage Security (2003) started selling IBE security products based on Boneh and Franklin’s scheme. An advantage of IBE secure e-mail is that receivers do not have to be previously registered in the system. A sender may send a message to any e-mail address, giving impetus to the recipient to register with the system. Thus, an IBE system may not have the same network adoption problem as PGP or other security products.

Security concerns in mobile and pervasive computing devices such as cellular telephones, PDAs, or radio-frequency identification (RFID) tags, could be a major driver for widespread public key infrastructure deployment. In the cellular telephone market, the first generation of text messaging-based spam and viruses has already emerged. For example, in 2001 a virus struck Japanese cellular telephones, forcing them to dial the Japanese equivalent of 911 emergency services (Delio, 2001).

Because of these concerns, cell phones and mobile devices may be an emerging market for a standardized secure messaging format, such as OpenPGP. PGP Corporation already offers a lightweight product called PGP Mobile for Palm and Windows CE devices. There is also an effort within the OpenPGP alliance to accommodate smart cards and mobile and handheld devices.

A standardized PGP messaging format suitable for cellular telephones could be integrated into the Liberty Alliance’s (2004) federated network identity management services. Liberty Alliance members include several large cellular phone manufacturers who could provide the critical mass of users necessary for a successful system. Cellular phone makers have a history of using proprietary encryption formats that have been broken (Goldberg & Briceno, 1998; Wagner, Schneier, & Kelsey, 1997). Open cryptographic standards would go far in bolstering the security reputation of cellular manufacturers.

In conclusion, PGP illustrates many of the problems involved in developing an abstract algorithm like RSA into a robust, practical product. Performance, legal issues, usability, and market conditions all influenced the course of PGP’s development. The lessons from PGP may prove useful in developing other security or cryptographic applications in the future.

Despite its faults and the hurdles in its development, PGP is being used in critical applications and is literally saving lives. Patrick Ball, deputy director of the Science and Human Rights program at the American Association

for the Advancement of Science, describes how human rights workers in Guatemala used PGP to securely report human rights violations (Ball, Kobrak, & Spierer, 1999).

Human rights workers encrypted database records with the public keys of nongovernmental organizations, such as the Amnesty International. Activists arrested and threatened with torture could not be forced to reveal private keys to large encrypted databases because they did not know them. Based on these experiences, the Crypto Rights Foundation (2003) is developing a secure human rights communication system based on PGP called High-Fire.

Perhaps the single biggest motivator for typical users to adopt PGP or other secure e-mail products is the deluge of unsolicited "spam" e-mail being sent on the Internet. By mid-2003, unsolicited advertisements accounted for more than 45% of e-mail traffic ("Stopping Spam," 2003). Legal remedies such as the recent CAN-SPAM Act passed in the United States may not stem the tide of unsolicited e-mail, because it is an international problem (Controlling the Assault of Non-Solicited Pornography and Marketing (CAN SPAM) Act, 2003).

A technological solution may be the best defense. Using PGP or other secure e-mail and rejecting all unsigned e-mail is one approach. Although spammers could create public keys and sign messages, this would increase their per-message cost. The high computational cost of signatures would be a benefit, because mass e-mailers would need orders of magnitude more processing power. Ironically, every unsolicited e-mail message sent hawking free prescription drugs, cheap home loans, or other once-in-a-lifetime opportunities may contribute to secure e-mail's eventual success.

GLOSSARY

Advanced Encryption Standard (AES) U.S. government-approved symmetric block cipher; designed as a replacement for Data Encryption Standard (DES).

Certificate Authority (CA) A public key infrastructure component that distributes public key certificates.

Guerillaware Software created in violation of patent, copyright, or export laws.

Identity-based encryption (IBE) A public-key cryptosystem where identities are used as public keys, making a public key infrastructures unnecessary.

Message Digest Computes a short "fingerprint" from a long input message that is highly unlikely to collide with other messages' fingerprints. Typically implemented with a cryptographic hash function.

Public Key Infrastructure (PKI) An entity that stores and distributes public key certificates.

RSA A Public key cryptosystem created by Rivest, Shamir, and Adleman in 1978.

Secure/multipurpose internet mail extensions (S/MIME) A secure messaging standard.

Secure Sockets Layer (SSL) A suite of protocols frequently used by Web browsers to encrypt transactions.

Session Key A random symmetric encryption key generated for a single session.

"Signing a Key" Issuing a digitally signed certificate that binds an identity to a public key.

Web of Trust A PKI model in which any user may issue certificates for any other user.

INTRODUCTION

Electronic mail (e-mail) is one of the most popular network services nowadays. Most e-mail systems that send mail over the Internet use simple mail transfer protocol (SMTP) to send messages from one server to another. The messages can then be retrieved with an e-mail client using either post office protocol (POP) or Internet message access protocol (IMAP). SMTP is also generally used to send messages from a mail client to a mail server in “host-based” (or Unix-based) mail systems, where a simple `mbx` utility might be on the same system [or via Network File System (NFS) provided by Novell] for access without POP or IMAP.

This chapter describes the fundamentals of SMTP, elements of its client–server architecture (user agent, mail transfer agent, ports), request–response mechanism, commands, mail transfer phases, SMTP messages, multipurpose internet mail extensions (MIME) for non-ASCII (American Standard Code for Information Interchange) data, e-mail delivery cases, mail access protocols (POP3

and IMAP4), SMTP software, vulnerability and security issues, standards, associations, and organizations.

SMTP FUNDAMENTALS

SMTP is used as the common mechanism for transporting electronic mail among different hosts within the transmission control protocol/Internet protocol (TCP/IP) suite. It is an application layer protocol. Under SMTP, a client SMTP process opens a TCP connection to a server SMTP process on a remote host and attempts to send mail across the connection. The server SMTP listens for a TCP connection on a specific port (25), and the client SMTP process initiates a connection on that port (Cisco SMTP, 2005). When the TCP connection is successful, the two processes execute a simple request–response dialogue, defined by the SMTP protocol (see RFC 821 for details), in which the client process transmits the mail addresses of the originator and the recipient(s) for a message. When the server process accepts these mail addresses, the client process transmits the e-mail instant message. The message must contain a

message header and message text (“body”) formatted in accordance with RFC 822.

Mail that arrives via SMTP is forwarded to a remote server, or it is delivered to mailboxes on the local server. POP3 or IMAP allow users download mail that is stored on the local server. Most mail programs such as Eudora allow the client to specify both an SMTP server and a POP server. On UNIX-based systems, Sendmail is the most widely used SMTP server for e-mail. Sendmail includes a POP3 server and also comes in a version for Windows NT (“What is SMTP?”, 2005). The MIME protocol defines the way files are attached to SMTP messages. Microsoft Outlook and Netscape/Mozilla Communicator are the most popular mail-agent programs on Window-based systems.

The X.400 International Telecommunication Union standard (Tanenbaum, 2003) that defines transfer protocols for sending electronic mail between mail servers is used in Europe as an alternative to SMTP. Also, the message handling service (MHS) developed by Novell is used for electronic mail on Netware networks (“What is SMTP?”, 2005).

SMTP MODEL AND PROTOCOL

The SMTP model (RFC 821) supports both end-to-end (no intermediate message transfer agents [MTAs]) and store-and-forward mail delivery methods. The end-to-end method is used between organizations, and the store-and-forward method is chosen for operating within organizations that have TCP/IP and SMTP-based networks.

A SMTP client will contact the destination host’s SMTP server directly to deliver the mail. It will keep the mail item from being transmitted until it has been successfully copied to the recipient’s SMTP. This is different from the store-and-forward principle that is common in many other electronic mailing systems, where the mail item may pass through a number of intermediate hosts in the same network on its way to the destination and where successful transmission from the sender only indicates that the mail item has reached the first intermediate hop (“Simple Mail Transfer Protocol” [SMTP], 2004).

The RFC 821 standard defines a client–server protocol. The client SMTP is the one, which initiates the session (that is, the sending SMTP) and the server is the one that

responds (the receiving SMTP) to the session request. Because the client SMTP frequently acts as a server for a user-mailing program, however, it is often simpler to refer to the client as the sender-SMTP and to the server as the receiver-SMTP.

An SMTP-based process can transfer electronic mail to another process on the same network or to another network via a relay or gateway process accessible to both networks (Sheldon, 2001). An e-mail message may pass through a number of intermediate relay or gateway hosts on its path from a sender to a recipient. A simple model of the components of the SMTP system is shown in Figure 1.

Users deal with a user agent (UA). Popular user agents for UNIX include Berkeley Mail, Elm, MH, Pine, and Mutt. The user agents for Windows include Microsoft Outlook/Outlook Express and Netscape/Mozilla Communicator. The exchange of mail using TCP is performed by an MTA. The most common MTA for UNIX systems is Sendmail, and MTA for Windows is Microsoft Exchange 2000/2003. In addition to stable host-based e-mail servers, Microsoft Corporation has developed LDAP/Active-directory servers and B2B-servers that enhance mail-delivery practices. Users normally do not deal with the MTA. It is the responsibility of the system administrator to set up the local MTA. Users often have a choice, however, for their user agent (Stevens, 1993). The MTA maintains a mail queue so that it can schedule repeat delivery attempts in case a remote server is unable. Also the local MTA delivers mail to mailboxes, and the information can be downloaded by the UA (see Figure 1).

The RFC 821 standard specifies the SMTP protocol, which is a mechanism of communication between two MTAs across a single TCP connection. The RFC 822 standard specifies the format of the electronic mail message that is transmitted using the SMTP protocol (RFC 821) between the two MTAs. As a result of a user mail request, the sender-SMTP establishes a two-way connection with a receiver-SMTP. The receiver-SMTP can be either the ultimate destination or an intermediate one (known as a mail gateway). The sender-SMTP will generate commands, which are replied to by the receiver-SMTP (see Figure 1).

Both the SMTP client and server should have two basic components: UA and local MTA. There are few cases of sending electronic-mail messages across networks. In the

Figure 1: The basic simple mail transfer protocol (SMTP) model.

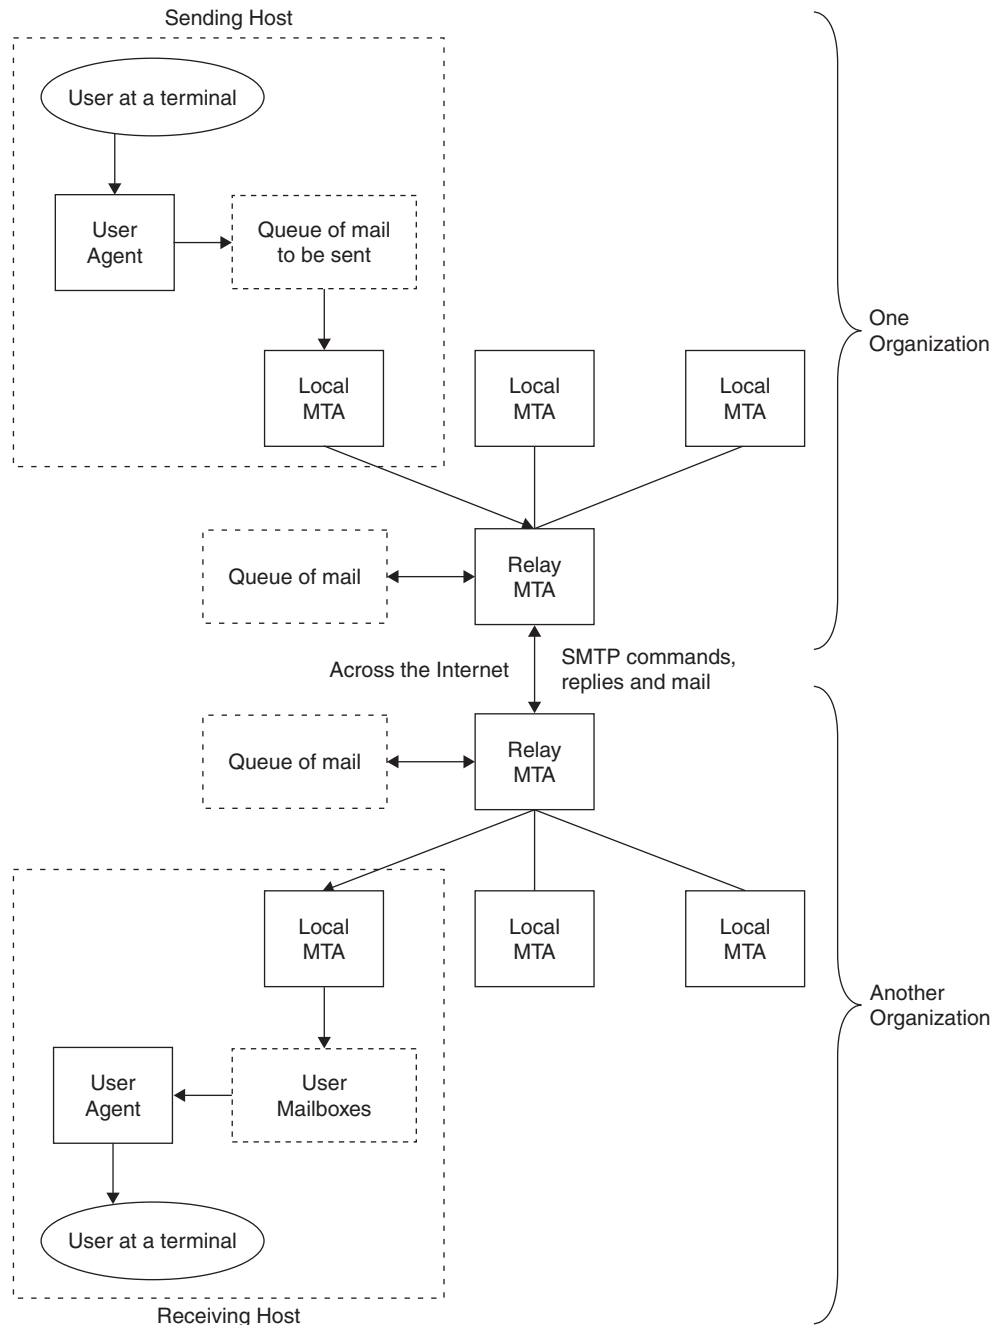

Figure 2: The simple mail transfer protocol (SMTP) model with relay mail transfer agents.

first case of communication between the sender and the receiver across the network (see Figure 1), the sender's UA prepares the message, creates the envelope, and puts message in the envelope. The MTA transfers the mail across the network to the TCP-port 25 of the receiver's MTA. In the second case of communication between the sending host (client) and the receiving host (server), *relaying* could be involved (see Figure 2). In addition to one MTA at the sender site and one at the receiving site, other MTAs, acting as client or server, can relay the electronic mail across the network.

The system of relays allows sites that do not use the TCP/IP protocol suite to send electronic mail to users on other sites that may or may not use the TCP/IP protocol

suite. This third scenario of communication between the sender and the receiver can be accomplished through the use of an e-mail gateway, which is a relay MTA that can receive electronic mail prepared by a protocol other than SMTP and transform it to the SMTP format before sending it. The e-mail gateway can also receive electronic mail in the SMTP format, change it to another format, and then send it to the MTA of the client that does not use the TCP/IP protocol suite (Forouzan, 2003). In various implementations, there is the capability to exchange mail between the TCP/IP SMTP mailing system and the locally used mailing systems. These applications are called mail gateways or mail bridges. Sending mail through a mail gateway may alter the end-to-end delivery

specification, because SMTP will only guarantee delivery to the mail-gateway host, not to the real destination host, which is located beyond the TCP/IP network. When a mail gateway is used, the SMTP end-to-end transmission is host-to-gateway, gateway-to-host, or gateway-to-gateway; the behavior beyond the gateway is not defined by SMTP.

USER AGENT

Introduced in RFC 821 and RFC 822, the SMTP defines user agent functionality, but not the implementation details. A survey of the SMTP implementations can be found in RFC 876. The UA is a program that is used to send and receive electronic mail. The most popular user agent programs for UNIX are Berkley Mail, Elm, MH, Mutt, Mush, and Zmail. Some UAs have an extra user interface (e.g., Eudora) that allows window-type interactions with the system. The user agents for Windows include Microsoft Outlook/Outlook Express and Netscape/Mozilla Communicator.

Sending e-Mail

Electronic mail is sent by a series of request-response transactions between a client and a server. An SMTP transaction consists of the envelope and message, which is composed of header (with `From:` and `To:` fields) and body (text after headers sent with the `DATA` command). The envelope is transmitted separately from the message itself using `MAIL FROM` and `RCPT TO` commands (see RFC 1123). A null line, that is, a line with nothing preceding the `<CRLF>` sequence, terminates the mail header. Some implementations (e.g., VM, which does not support zero-length records in files), however, may interpret this differently and accept a blank line as a terminator (SMTP, 2005). Everything after the null (or blank) line is the message body, which is a sequence of lines containing ASCII characters. The message body contains the actual information that can be read by the recipient.

Mail Header Format

The header includes a number of key words and values that define the sending date, sender's address, where replies should go, and some other information.

The header is a list of lines, of the form (SMTP, 2005):

```
field-name: field-value
```

Fields begin in column 1: Lines beginning with white space characters (SPACE or TAB) are continuation lines, which are unfolded to create a single line for each field in the canonical representation. Strings enclosed in ASCII quotation marks indicate single tokens within which special characters such as the colon are not significant. Many important field values (such as those for the "To" and "From" fields) are "mailboxes." The most common forms for these are the following:

- `jsmith@mail.it.rivier.edu`
- `John Smith <jsmith@mail.it.rivier.edu>`
- `"John Smith" <jsmith@mail.it.rivier.edu>`

The string "John Smith" is intended for human recipients and is the name of the mailbox owner. The string `jsmith@mail.it.rivier.edu` is the computer-readable address of the mailbox (the angle brackets are used to delimit the address but are not part of it). One can see that this form of addressing is closely related to the domain name system (DNS) concept (Internet Assigned Numbers Authority [IANA], 2005). In fact, the client SMTP uses the DNS to determine the IP address of the destination mailbox.

Some frequently used fields (key words) are the following:

- `to` Primary recipients of the message.
- `cc` Secondary ("carbon-copy") recipients of the message.
- `from` Identity of sender.
- `reply-to` The mailbox to which responses are to be sent. This field is added by the originator.
- `return-path` Address and route back to the originator. This field is added by the final transport system that delivers the mail.
- `Subject` Summary of the message. The user usually provides the summary.

Receiving e-Mail

The UA periodically checks the content of the mailboxes (see Figure 1). It informs the user about mail arrival by giving a special notice. When the user tries to read the mail, a list of arrived mail packages is displayed. Each line of the list contains a brief summary of the information about a particular package in the mailbox. The summary may include the sender mail address, the subject, and the time the mail was received or sent. By selecting any of the packages, the user can view its contents on the terminal display.

The SMTP Destination Address

The SMTP destination address (a mailbox address), in its general form `local-part@domain-name`, can take several forms (SMTP, 2005):

- `user@host`—For a direct destination on the same TCP/IP network.
- `user%remote-host@gateway-host`—For a user on a non-SMTP destination `remote-host`, via the mail gateway `gateway-host`.
- `@host-a,@host-b:user@host-c`—For a relayed message. This form contains explicit routing information. The message will first be delivered to `host-a`, who will resend (relay) the message to `host-b`. `Host-b` will then forward the message to the real destination `host-c`. Note that the message is stored on each of the intermediate hosts; therefore, there is no end-to-end delivery in this case. This address form is obsolete and should not be used (see RFC 1123).

Delayed Delivery

The SMTP protocol allows delayed delivery, and the message can be delayed at the sender site, the receiver site, or the intermediate servers (Forouzan, 2003).

In the case of delaying at the sender site, the client has to accommodate a spooling system, in which e-mail messages are stored before being sent. A message created by the user agent is delivered to the spool storage. The client mail transfer agent periodically (usually every 10 to 30 minutes) checks the spool to find the mail that can be sent. The mail will be sent only if the receiver is ready and the IP address of the server has been obtained through DNS. If a message cannot be delivered in the timeout period (usually about 3 to 5 days), the mail returns to the sender.

Upon receiving the message, the server-MTA stores it in the mailbox of the receiver (see Figure 1). In this case, the receiver can access the mailbox at any convenient time.

Finally, the SMTP standard procedures allow intermediate MTAs to serve as clients and servers. Both intermediate clients and servers can receive mail, store mail messages in their mailboxes and spools, and send them later to an appropriate destination.

Aliases

The SMTP mechanism allows one name, an alias, to represent several e-mail addresses (this feature is known as “one-to-many alias expansion”; Forouzan, 2003). Additionally, a single user can also be defined by several e-mail addresses (this is called “many-to-one alias expansion”). The system can handle these expansions by including an alias expansion facility (connected to the alias databases) at both the sender and receiver sites.

MAIL TRANSFER AGENT

MTAs transfer actual mail. The system must have the client MTA for sending e-mail and the server MTA for receiving mail (see Figure 1). The SMTP-related RFCs do not define a specific MTA. The UNIX-based MTA uses commonly the Sendmail utility. The most common MTA for Windows is Microsoft Exchange 2000/2003.

The “mta-name-type” and “address-type” parameters (e.g., `dnsc` and `rfc822` for the Internet mail, respectively) are defined for use in the SMTP delivery status notification document (see RFC1891). An identification of other mail systems can also be used. One of the identification methods has been described in “The COSINE and Internet X.500 Schema” (section 9.3.18) in the RFC1274 document. The mail system names listed here are used as the legal values in that schema under the “otherMailbox” attribute “mailboxType” type, which must be a PrintableString. The “Mapping between X.400 (1988)/ISO 10021 and RFC 822” is described in the section 4.2.2 of the RFC1327 document. The names listed here are used as the legal values in that schema under the “std-or-address” attribute “registered-dd-type” type, which must be a “key-string” (for details, see Mail Parameters, 2002).

SMTP Mail Transaction Flow

The SMTP protocol (RFC 821) defines how commands and responses must be sent by the MTAs. The client sends commands to the server, and the server responds with numeric reply codes and optional human-readable strings. There are a small number of commands (less than a

dozen) that the client can send to the server. An example of sending a simple one-line message and an interpretation of the SMTP connection can be found in Stevens (1993).

Although mail commands and replies are rigidly defined (see “Commands and Responses” later in this chapter), the exchange can easily be followed in Figure 3.

In this scenario (Comer, 1995; SMTP, 2005), the user `jsmith` at host `sun.it.rivier.edu` sends a note to users `darien`, `steve` and `bryan` at host `mail.unh.edu`. Here the lines sent by the server (receiver) are preceded by `S`, and the lines sent by the client (sender) preceded by `C`. Note that the message header is part of the data being transmitted. All exchanged messages (commands, replies, and data) are text lines, delimited by a `<CRLF>`. All replies have a numeric code at the beginning of the line.

The scenario includes the following steps (SMTP, 2005):

1. The client (sender-SMTP) establishes a TCP connection with the destination SMTP and then waits for the server to send a `220 Service ready` message or a `421 Service not available` message when the destination is temporarily unable to proceed.
2. The `HELO` command is sent, and the receiver is forced to identify himself by sending back its domain name. The client (sender-SMTP) can use this information to verify if it contacted the right destination SMTP. If the sender-SMTP supports SMTP service extensions as defined in the RFC 1651/1994, it may substitute an `EHLO` command in place of in RFC 1651. A receiver-SMTP, which does not support service extensions, will respond with a `500 Syntax error, command unrecognized` message. The client (sender-SMTP) should then retry with `HELO`, or if it cannot transmit the message without one or more service extensions, it should send a `QUIT` message. If a receiver-SMTP supports service extensions, it responds with a multiline `250 OK` messages that include a list of service extensions, which it supports.
3. The client (sender) now initiates the start of a mail transaction by sending a `MAIL` command to the receiver. This command contains the reverse-path, which can be used to report errors. Note that a path can be more than just the `user-mailbox@host-domain-name` pair. In addition, it can contain a list of routing hosts. Examples of this are when the mail passes a mail bridge or when the user provides explicit routing information in the destination address. If accepted, the server (receiver) replies with a `250 OK` message.
4. The second step of the actual mail exchange consists of providing the server SMTP with the destinations for the message (there can be more than one recipient). This is done by sending one or more `RCPT TO:<forward-path>` commands. Each of them will receive a `250 OK` reply if the destination is known to the server or a `550 No such user here` reply if it is not.
5. When all `RCPT` commands are sent, the client (sender) issues a `DATA` command to notify the server (receiver) that the message contents are following. The server replies with the `354 Start mail input, end with <CRLF>.<CRLF>` message.

```

S: 250 OK

C: QUIT
S: 221 mail.unh.edu Service closing transmission channel

```

Figure 3: An example of the interactive session between the client (C) and the server (S).

6. The client now sends the data line by line, ending with the sequence <CRLF>.<CRLF> line on which the receiver acknowledges with a 250 OK or an appropriate error message if anything went wrong.
7. The following actions (SMTP, 2005) are possible after that:
 - The sender has no more messages to send; he will end the connection with a QUIT command, which will be answered with a 221 Service closing transmission channel reply (see Figure 3).
 - The client (sender) has another message to send and simply goes back to Step 3 to send a new MAIL command.

In this description, only the most important commands that must be recognized in each SMTP implementation (see RFC821) have been mentioned. Other optional commands (the RFC 821 standard does not require them to be implemented everywhere) implement several important functions such as forwarding, relaying, mailing lists, and so on.

SMTP Commands

The commands formed with ASCII (text) are sent from the client to the server. The simple structure of the commands allows for building mail clients and servers on any platform. The list of commands and their description and formats are shown in Table 1. The command consists of

a key word followed by zero or more arguments. Five commands (HELO, MAIL FROM, RCPT TO, DATA, and QUIT) are mandatory, and every implementation must support them. The other three commands (RSET, VRFY, and NOOP) are often used and highly recommended. The next six programs (TURN, EXPN, HELP, SEND FROM, SOML FROM, and SAML FROM) are seldom used.

For a full list of commands, see the RFC 821 “Simple Mail Transfer Protocol” and RFC 1123 “Requirements for Internet Hosts—Application and Support.” For details of SMTP service extensions, see the RFC 1651 “SMTP Service Extensions,” RFC 1652 “SMTP Service Extension for 8bit-MIMEtransport,” RFC 1653 “SMTP Service Extension for Message Size Declaration,” and RFC 2554 “SMTP Service Extension for Authentication.”

The commands normally progress in a sequence (one at a time). The advanced pipelining feature introduced in the RFC 2920 document allows multiple commands to be sent to a server in a single operation of the TCP-send type.

Mail Service Types

The set of services desired from a mail server are sometimes characterized by the “hello” key word. The various mail service types are as follows (Mail Parameters, 2002):

- HELO for Simple Mail (see RFC821)
- EHLO for Mail Service Extensions (see RFC1869)
- LHLO for Local Mail (see RFC2033).

Table 1 Simple Mail Transfer Protocol (SMTP) Commands

Command	Description	Format	References
ATRN	Authenticated TURN		RFC2645
AUTH	Authentication		RFC2554
BDAT	Binary data		RFC3030
DATA	Data; used to send the actual message; all lines that follow the DATA command are treated as the e-mail message; the message is terminated by a line containing just a period	DATA Best wishes.	RFC821, RFC2821
EHLO	Extended Hello		RFC1869, RFC2821
ETRN	Extended TURN		RFC1985
EXPN	Expand; asks the receiving host to expand the mailing list sent as the arguments and to return the mailbox addresses of the recipients that comprise the list	EXPN: a b c	RFC821, RFC2821
HELO	Hello; used by the client to identify itself	HELO: sun.it.rivier.edu	RFC821, RFC2821
HELP	Help; requests the recipient to send information about the command sent as the argument	HELP: mail	RFC821, RFC2821
MAIL FROM	Mail; used by the client to identify the sender of the message; the argument is the e-mail address of the sender	MAIL FROM: jsmith@sun.it.rivier.edu	RFC821, RFC2821
NOOP	No operation; used by the client to check the status of the recipient; requires an answer from the recipient	NOOP	RFC821, RFC2821
QUIT	Quit; terminates the message	QUIT	RFC821, RFC2821
RCPT	Recipient; used by the client to identify the intended recipient of the message; if there are multiple recipients, the command is repeated	RCPT TO: steve@unh.edu	RFC821, RFC2821
RSET	Reset; aborts the current e-mail transaction; the stored information about the sender and recipient is deleted; the connection will be reset	RSET	RFC821, RFC2821
SAML	Send to the mailbox or terminal; specifies that the mail have to be delivered to the terminal or the mailbox of the recipient; the argument is the address of the sender	SAML FROM: jsmith@sun.it.rivier.edu	RFC821
SEND	Send; specifies that the mail is to be delivered to the terminal of the recipient and not the mailbox; if the recipient is not logged in, the mail is bounced back; the argument is the address of the sender	SEND FROM: jsmith@sun.it.rivier.edu	RFC821
SOML	Send to the mailbox or terminal; it specifies that the mail is to be delivered to the terminal or the mailbox of the recipient; the argument is the address of the sender.	SOML FROM: jsmith@sun.it.rivier.edu	RFC821
STARTTLS	Extended Hello with transport layer security		RFC3207
TURN	Turn; it lets the sender and the recipient switch positions whereby the sender becomes the recipient and vice versa (most SMTP implementations today do not support this feature; see RFC2821)	TURN	RFC821
VERFY	Verify; it verifies the address of the recipient, which is sent as the argument; the sender can request the receiver to confirm that a name identifies a valid recipient.	VERFY: steve@unh.edu	RFC821, RFC2821

Note: From "SMTP Specifications," 2005.

The EHLO key word has a numerical parameter SIZE for specifying the new format of e-mail messages (see RFC1870).

SMTP Service Extensions

SMTP (RFC821) specifies a set of commands or services for mail transfer. A general procedure for extending the set of services is defined in the STD11/RFC1869 document. The service extensions are identified by key words sent from the server to the client in response to the EHLO command (Mail Parameters, 2002). The set of service extensions are as follows:

- SEND—Send as mail (see RFC821)
- SOML—Send as mail or to terminal (see RFC821)
- SAML—Send as mail and to terminal (see RFC821)
- EXPN—Expand the mailing list (see RFC821)
- HELP—Supply helpful information (see RFC821)
- TURN—Turn the operation around (see RFC821)
- 8BITMIME—Use 8-bit data (see RFC1652)
- SIZE—Message size declaration (see RFC1870)
- CHUNKING—Chunking (see RFC3030)
- BINARYMIME—Binary MIME (see RFC3030)
- CHECKPOINT—Checkpoint/Restart (see RFC1845)
- PIPELINING—Command Pipelining (see RFC2920)
- DSN—Delivery Status Notification (see RFC1891)
- ETRN—Extended Turn (see RFC1985)
- ENHANCEDSTATUSCODES—Enhanced Status Codes (see RFC2034)
- STARTTLS—Start TLS (see RFC3207).

Some of these key words have parameters (for details, see Mail Parameters, 2002).

SMTP Responses

Responses are sent from the server to the client. A response is a three-digit code that may be followed by additional textual information. The meanings of the first digit are as follows:

- 2bc—positive completion reply; the requested command has been successfully completed and a new command can be started.
- 3bc—positive intermediate reply; the requested command has been accepted, but the server needs some more information before completion can occur.
- 4ab—transient negative completion reply; the requested command has been rejected, but the error condition is temporary, and the command can be sent again.
- 5ab—permanent negative completion reply; the requested command has been rejected, and the command cannot be sent again.

The second (b) and the third (c) digits provide further details about the responses. The list of typical reply codes and their description are shown in Table 2.

SMTP SERVER

The SMTP server sends and receives mail from other Internet hosts using the SMTP. The SMTP server processes all incoming and outgoing mail. Outgoing mail is spooled until the SMTP server can confirm it has arrived at its destination; incoming mail is spooled until users access it by using a POP3 or IMAP4 mail client. Spooling allows the transfer from client and server to occur in the background. The instructions on how to configure the SMTP server in the Windows NT environment and how to set options to provide security for the SMTP server are described in “How to Set SMTP Security Options” (2005).

ON-DEMAND MAIL RELAY

On-demand mail relay (ODMR), also known as authenticated TURN (ATRN), is an e-mail service that allows a user to connect to an Internet service provider (ISP), authenticate, and request e-mail using a dynamic IP address (instead of static IP addresses used in a “traditional” SMTP model) from any Internet connection (see RFC 2645). The initial client and server roles are short-lived, because the point is to allow the intermittently connected host to request mail held for it by a service provider. The customer initiates a connection to the provider, authenticates, and requests its mail. The roles of client and server then reverse, and the normal SMTP scenario proceeds. The provider has an ODMR process listening for connections on the ODMR port 366 (SMTP Specifications, 2005). On the server, this process implements the EHLO, AUTH, ATRN, and QUIT commands. Also, it has to be an SMTP client with access to the outgoing mail queues. An MTA normally has a mail client component, which processes the outgoing mail queues, attempting to send mail for particular domains, based on time or events, such as new mail being placed in the queue or receipt of an ETRN command by the SMTP server component. The ODMR service processes the outgoing queue on request. The ISP provider side has normal SMTP server responsibilities, including generation of delivery failure notices (SMTP Specifications, 2005).

MULTIPURPOSE INTERNET MAIL EXTENSIONS (MIME)

The RFC 821/STD 10 standard specifies that data sent via SMTP is 7-bit ASCII data, with the high-order bit cleared to zero. This is adequate in most instances for the transmission of English text messages but is inadequate for non-English text or nontextual data.

There are two approaches to overcoming these limitations. In the first approach, the MIME were defined in RFC 1521 and RFC 1522, which specify a mechanism for encoding text and binary data as 7-bit ASCII within the mail envelope defined by the RFC 822 standard. MIME is also described in SMTP (2005).

In the second approach, the SMTP service extensions (RFC 1651, RFC 1652, and RFC 1653) define a mechanism to extend the capabilities of SMTP beyond the limitations imposed by the RFC 821 standard. The RFC 1651 document introduces a standard for a receiver-SMTP to

Table 2 Simple Mail Transfer Protocol (SMTP) Reply Codes

Code	Description
Positive Completion Reply	
211	System status or system help reply
214	Help message
220	<i>Domain</i> service ready; ready to start TLS
221	<i>Domain</i> service closing transmission channel
250	OK, queuing for node <i>node</i> started; requested command completed
251	OK, no messages waiting for node <i>node</i> ; user not local, will forward to <i>forwardpath</i>
252	OK, pending messages for node <i>node</i> started; cannot VRFY user (e.g., information is not local) but will take message for this user and attempt delivery
253	OK, <i>messages</i> pending messages for node <i>node</i> started
Positive Intermediate Reply	
354	Start mail input; end with <CRLF>.<CRLF>
355	Octet-offset is the transaction offset
Transient Negative Completion Reply	
421	<i>Domain</i> service not available, closing transmission channel
432	A password transition is needed
450	Requested mail action not taken: mailbox unavailable; ATRN request refused
451	Requested action aborted: local error in processing; unable to process ATRN request now
452	Requested action not taken: insufficient system storage
453	You have no mail
454	TLS not available due to temporary reason; encryption required for requested authentication mechanism
458	Unable to queue messages for node <i>node</i>
459	Node <i>node</i> not allowed: <i>reason</i>
Permanent Negative Completion Reply	
500	Command not recognized: <i>command</i> ; Syntax error
501	Syntax error in parameters or arguments; no parameters allowed
502	Command not implemented
503	Bad sequence of commands
504	Command parameter temporarily not implemented
521	<i>Machine</i> does not accept mail
530	Must issue a STARTTLS command first; encryption required for requested authentication mechanism
534	Authentication mechanism is too weak
538	Encryption required for requested authentication mechanism
550	Requested action not taken (command is not executed): mailbox unavailable
551	User not local; please try <i>forwardpath</i>
552	Requested mail action aborted: exceeded storage allocation
553	Requested action not taken: mailbox name not allowed
554	Transaction failed

Note: From "SMTP Specifications," 2005.

inform a sender-SMTP, which service extensions it supports. New procedures modify the RFC 821 standard to allow a client SMTP agent to request that the server responds with a list of the service extensions that it supports at the start of an SMTP session. If the server SMTP does not support the RFC 1651, it will respond with an error and the client may either terminate the session or attempt to start a session according to the rules of the RFC 821 standard. If the server does support the RFC 1651, it may also respond with a list of the service extensions that it supports. A registry of services is maintained by the Internet Assigned Numbers Authority (IANA, 2005); the initial list defined in the RFC 1651 document contains those commands listed in RFC 1123 as optional for SMTP servers.

Specific extensions are defined in RFC 1652 and RFC 1653. A protocol for 8-bit text transmission (RFC 1652) allows an SMTP server to indicate that it can accept data consisting of 8-bit bytes. A server, which reports that this extension is available to a client, must leave the high-order bit of bytes received in an SMTP message unchanged if requested to do so by the client.

The MIME and SMTP service extension approaches are complementary. Following their procedures (RFC 1652), nontraditional SMTP agents can transmit messages, which are declared as consisting of 8-bit data rather than 7-bit data, when both the client and the server conform to the RFC 1651 or RFC 1652 options (or both). Whenever a client SMTP attempts to send 8-bit data to a server, which does not support this extension, the client

Table 3 Data Types and Subtypes in a Multipurpose Internet Mail Extensions (MIME) Content-Type Header Declaration

Type	Subtype	Description
Text	Plain	Unformatted 7-bit ASCII text; no transformation by MIME is needed
Multipart	Mixed	Body contains ordered parts of different data types
	Parallel	Body contains no-ordered parts of different data types
	Digest	Body contains ordered parts of different data types, but the default is message/RFC822
	Alternative	Parts are different versions of the same message
Message	RFC822	Body is an encapsulated message
	Partial	Body is a fragment of a bigger message
	External-Body	Body is a reference to another message
Image	JPEG	Image is in JPEG format
	GIF	Image is in GIF format
Video	MPEG	Video is in MPEG format
Audio	Basic	String channel encoding of voice at 8 KHz
Application	PostScript	Adobe PostScript
	Octet-stream	General binary data (eight-bit bytes)

GIF = Graphics Interchange Format; JPEG = Joint Photographic Experts Group; MPEG = Motion Picture Experts Group.

SMTP must either encode the message contents into a 7-bit representation compliant with the MIME standard or return a permanent error to the user.

The SMTP service extension has the limitation on maximum length of a line (only up to 1,000 characters as required by the RFC 821 standard). The service extension also limits the use of non-ASCII characters to message headers, which are prohibited by the RFC 822 regulations.

The RFC 1653 document introduces the protocol for message size declaration that allows a server to inform a client of the maximum size message it can accept. If both server and client support the message size declaration extension, the client may declare an estimated size of the message to be transferred, and the server will return an error if the message is too large. Each of these SMTP service extensions is a draft standard protocol and each has a status of elective.

The MIME protocols define five header lines that can be added to the original header section to define the transformation parameters: MIME-version, content-type, content-transfer-encoding, content-id, and content-description. Each header line is described in detail in the following sections.

MIME-Version

The header line `MIME-Version: 1.1` declares that the message was composed using the (current) version 1.1 of the MIME protocol.

Content-Type

The header line `Content-Type: <type/subtype; parameters>` defines the type of data used in the body of the message. The identifiers of the content type and the content subtype are separated by a slash. Depending on the subtype, the header may contain other parameters. The MIME standard allows seven basic content types of data, the valid subtypes for each, and transfer encodings,

which are listed in Table 3. Examples of the content-type headers can be found in Forouzan (2003).

Content-Transfer-Encoding

The `Content-Transfer-Encoding: <type>` header line defines the method to encode the messages into a bit-stream of 0s and 1s for transport. The five types of encoding are as follows:

- `7bit`—for NVT ASCII characters and short lines of less than 1,000 characters.
- `8bit`—for non-ASCII characters and short lines of less than 1,000 characters; the underlying SMTP protocol must be able to transfer 8-bit non-ASCII characters (this type is not recommended).
- `binary`—for non-ASCII characters with unlimited-length lines; this is 8-bit encoding. The underlying SMTP protocol must be able to transfer 8-bit non-ASCII characters (this type is not recommended).
- `base64`—for sending data made of bytes when the highest bit is not necessarily zero; 6-bit blocks of data are encoded into 8-bit printable ASCII characters (for details, see Forouzan, 2003; Stevens, 1993), which can then be sent as any type of character set supported by the underlying mail transfer mechanism.
- `quoted-printable`—for sending data that consist of mostly ASCII characters with a small non-ASCII portion; if a character is not ASCII, it is sent as three characters: the first character is the equal sign, and the next two are the hexadecimal representation of the byte.

Although the content type and encoding are independent, the RFC 1521 document recommends `quoted-printable` for text with non-ASCII data, and `base64` for image, audio, video, and octet-stream application data. This allows maximum interoperability with RFC 821 conformant MTAs (Stevens, 1993).

Content-Id

The header line `Content-Id: id=<content-id>` uniquely identifies the whole message in a multiple message environment.

Content-Description

The header line `Content-Description:<description>` defines whether the body is image, audio, or video.

Security Scheme for MIME

The S/MIME is a security scheme for the MIME protocol. It was developed by RSA Security and is an alternative to the pretty good privacy (PGP) encryption and digital signature scheme that uses public-key cryptography. The S/MIME scheme was standardized by IETF. According to "Report of the IAB Security Architecture Workshop" (RFC 2316), the designated security mechanism for adding secured sections to MIME-encapsulated e-mail is security/multipart, as described in "Security Multiparts for MIME: Multipart/Signed and Multipart/Encrypted" (RFC 1847).

The S/MIME is widely used by large companies that need to standardize e-mail security for both interorganization and intraorganization mail exchange (Internet Engineering Task Force [IETF] SMIME, 2005). It requires establishing a public-key infrastructure either in-house or by using any of the public certificate authorities (Sheldon, 2001).

MAIL TRANSMISSION TYPES

The SMTP (RFC821) and the Standard for the Format of Advanced Research Project Agency (ARPA) Internet Text Messages (RFC822) specify that a set of "Received" lines will be prepended to the headers of electronic mail messages as they are transported through the Internet (Mail Parameters, 2002). The received line may optionally include either or both a "via" phrase or a "with" phrase (or both). The legal value for the "via" phrase is intended to indicate the link or physical medium over which the message was transferred (e.g., the UUCP link type should be specified for the Unix-to-Unix Copy Program). The "with" phrase is intended to indicate the protocol or logical process that has been used to transfer the message (e.g., SMTP or ESMTP parameters are used respectively for SMTP [RFC821] or SMTP with service extensions [RFC1869] protocol types).

MAIL ACCESS MODES

To reach its final destination, an e-mail message should be handled by a mail server, the mail access protocol, and the mail client. A general concept of how these components work together is described in "Accessing Your Mail" (1997).

An Internet mail server (known as the mail transfer agent, described earlier) is the software responsible for transmitting and receiving e-mail across the Internet. The MTA software is run on a computer that has a connection to the Internet and is managed, monitored, and backed up by ISPs or a company's information services staff. Some

mail servers store mail only until the user retrieves it, whereas others store user mail permanently. An e-mail user typically uses a mail client program to interact with the mail server (Rose, 1993).

A mail client (known as the mail user agent, described earlier) is the software that a user employs to read, send, file, and otherwise process the electronic mail. Usually running on a user's desktop computer, the mail client also manages related e-mail data (address books, spelling dictionaries, and stationery). The mail client connects to a mail server to retrieve new mail. Some mail clients also use the mail server to store all e-mail (Rose, 1993).

The communication between the mail client and mail server is regulated by the mail access protocol, a standardized set of transmitted commands and responses sent over many different types of network connections. The protocol commands (created for managing access to the Internet e-mail only) depend on a design approach that can significantly affect the manner, modes, characteristics, and capabilities of the interaction between the mail client and mail server ("Accessing Your Mail", 1997). The SMTP Protocol handles the task of the actual sending of e-mail on the Internet.

A mail access protocol operates in three common modes that differ in where and how a user stores and processes his or her mail ("Accessing Your Mail," 1997):

- **Offline mode**—e-mail is downloaded from a temporary storage on the mail server to the user's computer. After download, the mail is deleted from the server.
- **Online mode**—user's e-mail, his or her inbox, and all filed mail remains permanently on the mail server. By connecting to the server and establishing an e-mail session, the user can download a temporary copy of his or her e-mail and read it, or send e-mail. Once the connection is finished, the copy is erased from user's computer, and only the original remains on the server.
- **Disconnected/resynchronization mode**—combines both offline and online modes. A copy of the user's e-mail is downloaded to his or her computer(s), and the original message remains on the mail server. The user can change a local copy of his or her e-mail on any computer, then resynchronize all copies, including the original e-mail message on the server and copies on additional computers.

All three modes offer multiplatform support. This includes support for existing platforms such as UNIX, Microsoft Windows, and Apple Macintosh, and future platforms such as Java Mail Service-based network computers. All three modes, including their advantages and disadvantages, are discussed in detail in "Accessing Your Mail" (1997).

MAIL ACCESS PROTOCOLS

POP3

POP is used on the Internet to retrieve e-mail from a mail server. There are two versions of POP. The first, known as POP2 (RFC 937), became a standard in the mid-1980s and requires SMTP to send messages. Nowadays it has a

status of “not recommended.” The newer version, POP3 (RFC 1725), can be used with or without SMTP.

POP was designed primarily to support the offline access mode (RFC 1939). Typically, e-mail arrives from the network and is placed in the user’s inbox on the server. POP is then used to transfer the mail from the user’s inbox on the server to the user’s computer. POP is designed so that mail client software can determine which messages have been previously downloaded from the server. The mail client can then download only new messages. POP also provides the ability to selectively delete messages from the server. It can be used by a mail client to perform basic resynchronization of the inbox on the server and on the user’s computers. The client can leave the most recent messages on the server after they have been downloaded. These messages can then be downloaded a second time to a second computer. Additionally, some POP implementations provide optional features, such as allowing users to download only headers at one session, to review the topics, and then download selected bodies and attachments in a subsequent session to minimize connection times over slow links (“Accessing Your Mail,” 1997).

POP servers are widely available both commercially and as freeware on a number of operating systems. Moreover, there are almost no interoperability issues between POP servers and mail clients, and users can use any POP mail client with any POP server. All ISPs support and use POP.

In the end-to-end application related to SMTP, the server must be available whenever a client (sender) transmits mail. If the SMTP server resides on an end-user PC or workstation, that computer must be running the server when the client is trying to send mail. For some operating systems (e.g., when a server program is activated on the VM SMTP service virtual machine or the MAIL program on DOS), the server becomes unavailable and unreachable by the SMTP client (SMTP, 2005). The mail-sending process will fail in these cases. Especially, it is important for single-user systems that the client has an accessible mailbox on various types of server (RFC 1725).

One of the simplest approaches to resolve this problem is to allow the end user to run a client program, which communicates with a server program on a host. This server program acts as both a sender and a receiver SMTP (SMTP, 2005). Here the end-user mailbox resides on the server, and the server system is capable of sending mail to other users.

In another approach, the SMTP server function has to be off-loaded from the end-user workstation, but not the SMTP client function. In this case, the user has a mailbox that resides on a server system, and he can send mail directly from the workstation. To collect mail from the mailbox, the user must connect to the mail server system.

The current post office protocol version 3 (RFC 1725) is a draft standard protocol, and its status is elective. POP3 extensions are described in RFC 2449. POP3 security options are introduced in RFC 2595. The RFC 1734 describes the optional AUTH command for indicating an authentication mechanism to the POP3 server, performing an authentication protocol exchange, and optionally negotiating a protection mechanism for subsequent protocol interactions (Sheldon, 2001).

IMAP4

IMAP is a protocol for retrieving e-mail messages (RFC 1064). The IMAP4 version is similar to POP3 but supports some additional features. For example, with IMAP4, the user can search through his or her e-mail messages for key words while the messages are still on the mail server. The user can then choose which messages to download to his or her machine.

IMAP uses SMTP as its transport mechanism. Following the simple analogy (Sheldon, 2001), IMAP servers are like post offices, whereas SMTP is like the postal carriers. IMAP uses TCP to take advantage of its reliable data delivery services, which are allocated on the TCP port 143. The latest IMAP version 4, revision 1 (IMAP4rev1) is defined in RFC 2060.

IMAP has many advanced features, such as the ability to address mail not by arrival number, but by using attributes (e.g., “Download the latest message from Smith”). This feature allows the mailbox to be structured more like a relational database system rather than a sequence of messages (Tanenbaum, 2003). Authentication mechanisms are described in RFC 1731. Security issues have been introduced in “IMAP4/POP Authorization for Simple Challenge/Response” (RFC 2195), “IMAP4 Login Referrals” (RFC 2221), and “IMAP4 Implementation and Best Practices” (RFC 2683).

SMTP SECURITY ISSUES

SMTP Vulnerabilities

The processes of retrieving e-mail from servers and managing data communication through the Internet are vulnerable to various attacks. A review of vulnerabilities can be found in “Vulnerability Tutorials” (2005) released by the Saint Corporation. The Common Vulnerabilities and Exposures (CVE) organization provides a list of standardized names for SMTP vulnerabilities and other information security exposures. All CVE references (CVE entries and CAN candidates) cited in this text can be found at the CVE Web site, provided in the references (CVE, 2005). Summaries of major SMTP vulnerability problems are given in Table 4.

A security audit of selected SMTP problems has been provided by the U.S. Computer Emergency Readiness Team (CERT) Coordination Center operated by Carnegie Mellon University, and E-Soft. Detailed information about vulnerability problems, possible actions of an attacker or spammer, recommendations for downloading updated versions of software, examples of code modification, and test results can be found on the CERT (2005) and Security Space (“SMTP Problems,” 2005) Web sites.

The vulnerability problems can be grouped into several general high-risk categories: buffer overflow; redirection attacks through the firewall; bounced “piping” attacks; and host-shell-gaining attacks (see Table 4).

The medium-to-high risk category includes denial-of-service attacks. Low-to-medium-risk categories include mail relaying on the remote SMTP server, mail-queue manipulation attacks; debug-mode-leak category; and crashing antivirus-software attack (“SMTP Problems,” 2005). Most SMTP-specific vulnerabilities occur from

Table 4 SMTP Vulnerability Problems (CVE, 2005)

CVE Name	Type of Vulnerability	Possible Attacker Intrusive Action
CVE-2004-309	Stack-based buffer overflow in the SMTP service support in vsmon.exe in Zone Labs ZoneAlarm before v. 4.5.538, ZoneLabs Integrity client v. 4.0.	It allows remote attackers to execute arbitrary code via a long RCPT TO argument.
CVE-2002-309	SMTP proxy in Symantec Enterprise Firewall v. 6.5.x includes the firewall's physical interface name and address in an SMTP exchange when NAT translation is made to an address other than the firewall.	It allows remote attackers to determine certain firewall configuration information.
CVE-2002-0055	SMTP service in Microsoft Windows 2000, Windows XP Professional, and Exchange 2000 to cause a DoS via a command with a malformed data transfer (BDAT) request.	An attacker may disrupt the SMTP service and, depending on the system configuration, potentially IIS and other Internet services as well. See also MS02-012.
CVE-2002-0054	SMTP service in Microsoft Windows 2000 and Internet Mail Connector (IMC) in Exchange Server 5.5 does not properly handle responses to NTLM authentication.	It allows remote attackers to perform mail relaying via an SMTP AUTH command using null session credentials.
CVE-2001-0894	Vulnerability in Postfix SMTP server that is configured to e-mail the postmaster: SMTP errors cause the session to terminate.	It allows remote attackers to cause a DoS (memory exhaustion) by generating a large number of SMTP errors, which forces the SMTP session log to grow too large.
CVE-2001-0692	Vulnerability in SMTP proxy in WatchGuard Firebox (2500 and 4500) v. 4.5-4.6.	A remote attacker may bypass firewall filtering via a base64 MIME encoded e-mail attachment whose boundary name ends in two dashes.
CVE-2001-0690	Format string vulnerability in Exim (v. 3.22-10 in Red Hat, v. 3.12 in Debian, and v. 3.16 in Conectiva) in batched SMTP mode.	It allows a remote attacker to execute arbitrary code via format strings in SMTP mail headers.
CVE-2001-0653	Local buffer overflow on Sendmail (v.8.11.x).	A local user may gain root privileges.
CVE-2001-0504	The authentication error on the remote SMTP server Microsoft Windows 2000. See also MS01-037.	An attacker may exploit this flaw to use the SMTP server as a spam relay.
CVE-2001-1203	Lotus Domino SMTP server (v. 4.63-5.08) is vulnerable to a DoS (central processing unit consumption) attack by forging an e-mail message with the sender as bounce@[127.0.0.1] (localhost).	It allows remote attackers to cause a DoS: the server enters a mail loop.
CVE-2000-1047	The Lotus Domino SMTP server (v.5.0.x) is vulnerable to buffer overflow when supplied a too long ENVID variable within a MAIL FROM command.	An attacker may use this flaw to prevent Domino services from working properly, or to execute arbitrary code on the host.
CVE-2000-1022	The mailguard feature in Cisco Secure PIX Firewall (v. 5.2(2) and earlier) does not properly restrict access to SMTP commands.	It allows remote attackers to execute restricted commands by sending a DATA command before sending the restricted commands.
CVE-2000-0507	The remote Idate SMTP server crashes when it is issued a HELO command with an argument longer than 1,200 characters.	vAn attacker may shut down the SMTP server.
CVE-2000-0488	Buffer overflow on the ITHouse mail server (v.1.04).	Remote attackers may execute arbitrary commands via a long RCPT TO mail command.
CVE-2000-0452	Buffer overflow in the remote Lotus SMTP server when the server is issued a too long argument to the MAIL FROM command.	An attacker may prevent the host from acting as a mail host and may execute arbitrary code on the system.
CVE-2000-0319	mail.local in the remote Sendmail server does not properly identify the .\n string, which indicates the message-text end.	A remote attacker may cause a DoS or corrupt mailboxes via a message line that is 2047 characters long and ends as .\n.

(Continued)

Table 4 (continued)

CVE Name	Type of Vulnerability	Possible Attacker Intrusive Action
CVE-2000-0075	Super Mail Transfer Package, later called MsgCore, has a memory leak.	Remote attackers may cause a DoS by repeating multiple HELO, MAIL FROM, RCPT TO, and DATA commands in the same session.
CVE-1999-0203	The remote Sendmail's SMTP server did not complain when issued the command (from piped program): MAIL FROM: testing	An attacker may send mail that will be bounced to a program that allows him to execute arbitrary commands on the host.
CVE-1999-0096	The remote Sendmail SMTP server seems to pipe mail sent to the "decode" alias to a program.	An attacker can use this "decode" flaw to overwrite arbitrary files on the remote server.
CAN-2003-0818	Multiple integer overflows in Microsoft ASN.1 library (MSASN1.DLL). See also MS04-007.	An attacker may execute arbitrary code on this host by sending a specially crafted ASN.1 encoded packet with improper lengths.
CAN-2003-0743	Exim MTA (v. 4.21) heap overflow.	An attacker may gain a shell on this host.
CAN-2003-0714	Exchange remote buffer overflow: SMTP service is vulnerable to a flaw in the XEXCH50 extended verb (command).	An attacker may completely crash Exchange 5.5 and execute arbitrary code on Exchange 2000. See also MS03-046.
CAN-2003-0681	Remote Sendmail servers (v. 8.12.9 and earlier) have prescan() overflow on a remote buffer.	An attacker may gain root privileges.
CAN-2003-0540	Remote Postfix (v. 1.1.12) daemon multiple vulnerabilities.	An attacker may remotely disable it, or use it as a DoS agent against arbitrary hosts.
CAN-2003-0264	SLMail (v. 5.1) SMTP server experiences various overflows.	A cracker might execute arbitrary commands on this host or to disable it remotely.
CAN-2003-0161	Sendmail (v. 8.12.8 and earlier) servers have buffer overflow due to type conversion.	An attacker may gain remotely root privileges.
CAN-2002-1337	Remote header buffer overflow on Sendmail servers (v. 8.12.7 and earlier).	A remote attacker may gain root privileges.
CAN-2001-0713	A user may supply a custom configuration file to remote Sendmail servers.	A local attacker may regain the extra dropped privileges and run commands as root.

Note: The CAN number indicates a candidate for inclusion in the Common Vulnerabilities and Exposures (CVE) list of standard names for security problems. It must be reviewed by the CVE editorial board before it can be added to CVE (CVE, 2005).

DoS = denial of service; MIME = multipurpose internet mail extensions; NAT = network address translation; SMTP = Simple mail transfer protocol.

misapplied or unapplied patches related to Sendmail installations or misconfigured Sendmail daemons on the SMTP servers (Campbell, Calvert, & Boswell, 2003).

ISPs restrict access to their outgoing mail servers to provide better service to their customers and prevent spam from being sent through their mail servers. There are several methods for establishing restrictions that could result in denying users' access to their outgoing mail server.

Originally (see RFC 821), e-mail servers (configured for SMTP relay) did not verify the claimed sender identity and would simply pass the mail on with whatever return address was specified. Bulk mailers have taken advantage of this to send huge volumes of mail with bogus return addresses. This results in slowing down servers.

To fix the problem, the origin of a spam e-mail should be identified. An e-mail message typically transports through a set of SMTP servers (including the sender's and receiver's servers) before reaching the destination host. Along this pass, messages get "stamped" by the intermediate SMTP servers. The stamps release tracking information that can be identified in the mail headers. Mismatches

between the IP addresses and the domain names in the header could unveil the real source of spam mail. The real domain names that correspond to the indicated IP addresses can be found out by executing a reverse DNS lookup. Modern mail programs have incorporated this functionality, which generates a Received: header line that includes the identity of the attacker (see examples in Campbell et al., 2003).

Antispoofing measures are under active development. Mail Abuse Prevention System (MAPS) and Open Relay Behavior-Modification System (ORBS) provide testing, reporting, and cataloging of e-mail servers configured for SMTP relay. These organizations maintain real-time blackhole lists (RBL) of mail servers with problematic histories. For protection and security purposes, companies may configure their SMTP servers and other e-mail service systems in such manner that any mail coming from RBL-blacklisted mail servers is automatically rejected (Campbell, 2003). Other initiatives for restricting the sender address spoofing include SPF, Hotmail domain cookies, and Microsoft's caller ID.

Also see "E-Mail Threats and Vulnerabilities".

SMTP Server Buffer Overflow Vulnerability

Sendmail contains a buffer overflow in code that parses e-mail addresses (CAN-2003-0161). When processing e-mail messages, sendmail creates tokens from address elements (user, host, domain). The code that performs this function (`prescan()` in `parseaddr.c`) contains logic to check that the tokens are not malformed or overly long. In certain cases, a variable in `prescan()` is set to the special control value `-1`, which may alter the program logic to skip the length checks. Using an e-mail message with a specially crafted address containing `0xFF`, an attacker could cause the length checks to be skipped and overwrite the saved instruction pointer on the stack. A remote attacker could execute arbitrary code or cause a denial of service on a vulnerable system. Upgraded versions of sendmail should be used for protection.

Another remote buffer overflow in sendmail was reported (CAN-2002-1337). This vulnerability may allow remote attackers to gain root privileges of the sendmail daemon. A properly patched sendmail server (version 8.12.8) will drop invalid headers, thus preventing downstream servers from receiving them.

A buffer overflow in the mail server was identified as vulnerability in the Lotus Domino family of servers (Lotus, 2005) that includes an SMTP server (see Table 4, CVE-2000-0452). It supports extensions, which allow for the use of delivery status notifications that provide information about the delivery status of an e-mail message to the sender. An e-mail client specifying an identifier for an outgoing message optionally uses the `ENVID` key word. This identifier is included in any delivery status notifications regarding that message. By sending a long argument to the `ENVID` key word, it is possible to cause a buffer overflow in the mail server. A remote attacker could exploit this condition to cause a denial of service or to execute arbitrary code. The `ENVID` vulnerability was discussed in the S.A.F.E.R. Security Bulletin (S.A.F.E.R., 2000).

Another buffer overflow condition exists in the code that implements the policy feature that can be used to set relaying rules. With this feature, an e-mail administrator can specify rules to determine when the server may be used for relaying mail from one remote site to another. This vulnerability in Lotus Domino (S.A.F.E.R., 2001) could also be used to cause a denial of service or to execute arbitrary commands.

A third vulnerability posted to Security Focus (Bugtraq, 2005) could allow an attacker to cause a denial-of-service in Lotus Domino by sending a long argument to the `RCPT TO`, `SAML FROM`, or `SOML FROM` commands.

Also see "Server-Side Security".

Mail Relaying SMTP Vulnerability

The SMTP that is used by a mail server to send, receive, or route e-mail across a network requires the `MAIL FROM` (sender) address and the `RCPT TO` (recipient) address to be specified. Normally, either the sender or the recipient address is in the server's domain. Some SMTP servers accept any sender or recipient address without checking whether at least one of them is in the server's domain. On such servers, it is possible to supply a fake sender address and an arbitrary recipient address, which greatly

facilitates the spread of spam. Even SMTP servers, which generally do not allow relaying, do allow it if the session originates from a host in the server's domain or from a host from which relaying is explicitly permitted. If the scan is performed from such a host, a false alarm may result. To resolve this issue, UNIX mail servers should be upgraded to the latest version of Sendmail, which does not allow relaying by default (Antirelay Parse, 2005).

Mail Relaying SMTP Vulnerability in Microsoft Windows 2000

A specific type of vulnerability in the default SMTP server running Microsoft Windows 2000 was discovered by Joao Gouveia ("Authentication Error," 2001). An SMTP implementation is provided with Microsoft Windows 2000, and it is installed by default. Microsoft Exchange Server also includes an SMTP service, but the component that performs SMTP authentication is different from the base SMTP Service in Windows 2000 and is not affected by the vulnerability. A flaw in the authentication process (CVE, 2001, No. 0504) used by the SMTP service that installs as part of Internet Information Services (IIS) could allow an unauthorized user to authenticate successfully to the service using incorrect credentials. An attacker can use this vulnerability to gain user-level privileges on the SMTP service, thereby enabling the attacker to use the service (e.g., to co-opt a server's resources for mass mailings) but not to administer it. The service can be used by an attacker to perform SMTP mail relaying. There have been cases in which threatening e-mails were relayed to prevent the recipient from being able to trace where they came from. This vulnerability affects only standalone machines (e.g., Web servers), not domain members or Microsoft Exchange mail servers running Windows 2000.

Customers who need SMTP services should apply the patch ("Patch Availability," 2005), which eliminates the vulnerability by ensuring that the SMTP service properly authenticates users before allowing them to levy requests on it. Also, proper firewalling could be used to prevent Internet users from exploiting the vulnerability. Recommendations for preventing the servers from relaying and spam can be found in Fugatt (2002, July 30).

Also see "Windows 2000 Security".

Encapsulated SMTP Address Vulnerability

The security vulnerability in Microsoft Exchange Server 5.5 (CVE, 2002, No. 0054) could allow an attacker to perform mail relaying via an Exchange server that is configured to act as a gateway for other Exchange sites, using the Internet Messaging Service.

The vulnerability lies in the way that site-to-site relaying is performed via SMTP. The SMTP service in Microsoft Windows 2000 and Internet Mail Connector in Exchange Server 5.5 does not properly handle responses to NTLM authentication, which allows remote attackers to perform mail relaying via an SMTP `AUTH` command using null session credentials. Encapsulated SMTP addresses could be used to send mail to any e-mail address. The method of configuring the Exchange Internet Mail Service (IMS) (called Internet Mail Connector in prior versions of

Exchange), is vulnerable to the attack. The IMS service provides encapsulated addresses, when used as a Site Connector, and uses a special form of addressing called “encapsulated SMTP,” which is used to encapsulate various message types into SMTP addresses. The Exchange supports three kinds of Site Connectors: an X.400 connector, the Exchange Site Connector, and the Exchange Internet Mail Service. A malicious user could address e-mails using this format and route mail through an Exchange Server, even if mail relaying has been disabled.

Any customer who has configured an IMS on an Internet-connected Exchange Server should consider installing the patch (“Patch Availability,” 2005) that eliminates the vulnerability.

Malformed Request Denial of Service

The SMTP service in Microsoft Windows 2000, Windows XP Professional, and Exchange 2000 is vulnerable to cause a denial of service via a command with a malformed data transfer (BDAT) request (CVE, 2002, No. 0055). By sending either a message with a corrupted time stamp or a malformed version of a particular SMTP command to the server, it is possible for a remote attacker to cause the mail service to crash and thus stop responding to legitimate requests.

Extended Verb Request Handling Flaw

IMS in Exchange Server 5.5 and Exchange 2000 do not require authentication before allowing a user to send a certain extended verb request. This vulnerability allows remote attackers to cause a denial of service (memory exhaustion) and to consume large amounts of memory by directly connecting to the SMTP service and possibly triggering a buffer overflow in Exchange 2000 (CVE, 2003, No. 0714). Command execution could be possible. The Microsoft Security Bulletin (2004, No. 03-046) recommends the patch to fix this vulnerability.

Reverse DNS Response Buffer Overflow

Microsoft Exchange does not check the length of the response from the DNS server before copying it into a fixed-length buffer (CVE, 2002, No. 0698). Therefore, a remote attacker who has control over a registered DNS server could cause a buffer overflow by creating a long, specially crafted reverse DNS entry and then issuing the EHLO command to Exchange. The overflow would crash the server or even allow the attacker to execute arbitrary commands. Microsoft Exchange 5.5 is affected by this vulnerability if the patch has not been installed. At the same time, Microsoft Exchange 2000 is not affected because it runs atop the native Windows 2000 SMTP service rather than the Internet Mail Connector. To fix the reverse DNS problem, the patch (“Patch Availability,” 2005) should be applied.

Firewall SMTP Filtering Vulnerability

During expanded internal regression testing by Cisco, it was discovered that the Cisco Secure PIX Firewall feature “mailguard”, which limits SMTP commands to a specified minimum set of commands, can be bypassed

(CISCO, 2001). The filtering command `fixup protocol smtp[portnum]`, which is enabled by default on the Cisco Secure PIX Firewall, can fail. All users of Cisco Secure PIX Firewalls with software that provide access to SMTP Mail services are at risk. To exploit this vulnerability, attackers can make connections to an SMTP mail server (protected by the PIX Firewall) and can circumvent the expected filtering of the `mailguard` feature. If the mail server is not properly secured, an attacker may collect information about existing e-mail accounts and aliases or can execute arbitrary code on the mail server. Cisco has offered free software upgrades for all affected customers (CISCO, 2001).

Spoofing

On the Internet, mail is usually delivered directly from the sending host to the receiving host. This inherent “open” design of SMTP allows a host computer, which needs to deliver a message to another computer(s), to make a connection (or multiple connections) to some other SMTP server and ask that server to relay the message(s) on its behalf. Gateways can be used to bridge firewalls.

By denying access to a sending machine with a firewall, many companies and ISPs have been blocking the receipt of unwanted mail from known sources. The “blocked” senders of junk mail may attempt to deliver it through another computer by requesting the computer to route that mail for them. Senders of unsolicited e-mail can also use this method to hide their real identity by manipulating the headers in the message and then sending the message through client’s system for delivery to its final destination. This “spoofing” action gives the appearance that the message originated from the relaying server. When a bulk mailer chooses a client’s computer to deliver unsolicited mail to thousands of other people (known as “spamming”), the client’s system immediately becomes busy delivering messages that did not originate with the client’s users.

The SMTP server may protect the client’s system against this type of abuse in two ways. First, the server allows administrators to configure the system to accept only mail originating from local users or destined for local users. Second, the server administrator can define systems from which the client never wants to receive mail. It blocks mail from known sources of spam mail (“Setting SMTP Security,” 2005).

Also see “Networks Attacks.”

Bounce Attack

In the case of anonymous file transfer protocol (FTP) services, the attacker can instruct the FTP server to send a file to the SMTP service being attacked on the victim’s system (see “FTP Security Considerations, RFC 2577). Using the FTP server to connect to the service on the attacked computer makes it difficult to track down the attacker (Campbell et al., 2003). Particularly, a client -attacker can upload a file that contains SMTP commands to an FTP server. Then, using an appropriate PORT command, the client instructs the attacked server to open a connection to a third computer’s SMTP port 25 and transfer the uploaded file containing SMTP commands to the third computer.

This action may allow the client-attacker to forge mail on the third computer without making a direct connection.

Restricting Access to an Outgoing Mail Server

The access to an outgoing mail server can be restricted by verifying that the computer is on the ISP's local network. When the user dials the modem and connects to the ISP, his computer is given an IP address that identifies him as being a part of that network. If the user has two ISPs and dials up to one and then connects to the other's mail server, it may prevent him or her from relaying mail because the computer is not identified as being on the local network for the provider. In this case, the user should try to use the SMTP server to dial up and connect to the Internet ("What Is SMTP Security?", 2005).

Another way to restrict access is to insist on a local domain return address. If users connect to the mail server for "domain.com," it may only allow them to send mail that is from "username@domain.com." Therefore, if they try to send mail from another account that has the return address of "username@anotherdomain.com," it may restrict them from relaying to another server ("What is SMTP Security?", 2005).

Mail Encryption

SMTP is not a secure protocol. Messages sent over the Internet are not secure unless some form of encryption is implemented. S/MIME is a widely used Internet e-mail standard. This and some other security topics (PGP, transport layer security [TLS], host-to-host encryption) are discussed in other chapters.

Also see "Encrypting E-Mail, PGP, S/MIME, TLS, and Virtual Private Networks (VPNs) Basics".

Bastille Hardening System

The Bastille Hardening System (Bastille Project, 2005) has been designed to "harden" or "tighten" UNIX-based operating systems. It currently supports the Red Hat Enterprise 3, Debian, Mandrake, SuSE, and TurboLinux Linux distributions along with HP-UX and Mac OS X. The Bastille Linux Hardening software [Version 2.1.2 is available from the Source Forge Web site (Bastille Linux Project, 2005)] enhances the security of a Linux box by configuring daemons, system settings, and firewalling. Written in Perl, the Bastille Linux intends to improve Linux-based computer security. Among others, it has a revised `sendmail` module dedicated to secure holes that were discovered previously (see Table 4). A review of other service modules (Remote Access, Pluggable Authentication, DNS, Apache, FTP, SecureInetd, File Permission, Patch Download, and Firewall Configuration IPChains) can be found in Raynal (2000).

POP AND IMAP VULNERABILITIES

POP was designed to support offline mail processing (Rose, 1993). The mail is deleted from the server and is handled offline (locally) on the client machine. In the implementation of this protocol on a UNIX system, the

server must run with root privileges; therefore, it can access mail folders and undertake some file manipulation on behalf of the user logging in. After login, these privileges are discarded. Vulnerability exists in the way the login transaction is handled in some implementations of these procedures (CERT, 2005). This vulnerability can be exploited to gain privileged access on the server. By preparing carefully crafted text to a system running a vulnerable version of the POP server, remote users may be able to cause a buffer overflow and execute arbitrary instructions with root privileges. They do not need access to an account on the system to do this. (Vulnerable POP versions are identified in CVE, 2001, No. 0443, and ("Vulnerability Tutorials," 2005).

POP servers allow non-UNIX users to access their mail on a machine without logging in. The servers give PC and Macintosh users a way to receive mail through another machine. When connecting to a POP server, the client transmits the users' `userid` and `password` in clear text. After authentication, users can access their mail. Each time the client reconnects to the POP server, the users' `userid` and `password` are transmitted. Some POP client programs check the server every few minutes to check for the arrival of new mail. These frequent checks increase the possibility of the machine, username, and password being discovered by a password sniffer "tuned" for POP mail systems.

This clear text password issue is resolved by using an optional command allowable for POP3 servers (RFC 1725). When the initial connection is made to a POP server, the server displays a time stamp in its banner. The client uses this time stamp to create an MD5 hash string that is shared between the server and client. The next time the client connects to the server (e.g., to check for new mail), it will issue the APOP command and the hash string. This method reduces the number of times that a user's `userid` and `password` are transmitted in clear text ("Vulnerability Tutorials," 2005). The current version of IMAP supports both online and offline operation, permitting manipulation of remote message folders. It provides access to multiple mailboxes (that can be allocated on multiple servers) and supports nested mailboxes as well as resynchronization with the server. The IMAP4 version also provides a user with the ability to create, delete, and rename mailboxes ("Vulnerability Tutorials," 2005).

The optional method, which is frequently used for IMAP4 (RFC 1734), provides another client's authentication mechanism (based on the AUTH command). This mechanism allows the client to specify authentication methods it knows about and to challenge the server to see whether it knows any of them as well ("Vulnerability Tutorials," 2005). If no authentication method can be agreed on, then the APOP command (RFC 1725) is used. Also, the latest Secure POP3 mail server (with APOP/IMAP4) can be installed.

Three other vulnerabilities have been discovered which affect different QPOP versions. The first is caused by the fact that the `euidl` command does not properly validate user input (CVE, 2000, No. 0442). This command could be used with a specially crafted e-mail message to gain shell access to the server with privileges of the mail group.

A valid account name and password would be required to exploit this vulnerability. The second vulnerability is a buffer overflow in the processing of the user's login name (CVE, 2001, No. 1046). By supplying a name longer than 63 characters, a remote attacker could crash the service or execute arbitrary commands. The third vulnerability (CVE, 2003, No. 0143) is in the `Qvsnprintf` function call, which is QPOP's own implementation of the `vsnprintf` function. A buffer overflow occurs as a result of a failure to add a terminating null byte, when creating long strings during subsequent calls to the `strcat` function, and allowing the execution of commands. Recommendations for resolving these issues can be found in ("Vulnerability Tutorials," 2005). Secure versions of POP3 (RFC 2449) and IMAP4 (RFC 2595) that use the public key encryption mechanism (Tanenbaum, 2003) are also available.

STANDARDS, ORGANIZATIONS, AND ASSOCIATIONS

Internet Assigned Numbers Authority

The IANA (2005) provides the central coordinating functions of the global Internet for the public needs. The IANA organization maintains a registry of the following services:

- Domain name services
- Database of indexes by Top-Level Domains code
- "Whois" service of domain name recognition
- IP address assignment services (for both IPv4 and IPv6)
- Protocol number assignment services

Internet Engineering Task Force Working Groups

Internet electronic mail was originally defined in the RFC821 standard as a part of the IETF project. Since August 1982, e-mail standards declared in this document were updated and revised by the IETF Detailed Revision/Update of Message Standards (DRUMS) Working Group. The group is also searching new directions in the electronic message communication through the Internet. The latest SMTP documents (including RFCs) can be found on the DRUMS Web site (IETF DRUMS, 2005).

The IETF Message Tracking Protocol (MSGTRK) Working Group is designing diagnostic protocols that a sender can use to request information from servers about the submission, transport, and delivery of a message, regardless of its status. The "Deliver by SMTP Service Extension" document (RFC 2852) specifies extensions to define message delivery time for making a decision to drop the message if it is not delivered within a specific time period. For diagnostic purposes, the "diagnostic-type" parameter (e.g., `smtp` for the Internet Mail) is defined for use in the SMTP delivery status notification (see RFC1891).

The IETF S/MIME Mail Security (SMIME) Working Group is developing S/MIME security standards. The latest S/MIME documents (including RFCs) can be found on the SMIME Web site (IETF SMIME, 2005).

Internet Mail Consortium

The Internet Mail Consortium Web site (IMC, 2005) publishes a complete list of electronic mail-related requests for comments documents (RFCs).

Mitre Corporation

The Mitre Corporation publishes a list of standardized names for all publicly known vulnerabilities and security exposures known as Common Vulnerabilities and Exposures (CVE, 2005).

CONCLUSION

SMTP is an application protocol from the TCP/IP protocol suite that enables the support of e-mail on the Internet. Mail is sent by a series of request-response transactions between a client and a server. The transactions pass the message, which is composed of header and body, and the envelope (SMTP source and destination addresses). The header contains the mail address(es), which consists of two parts: a local address (also known as a "user mailbox") and a domain name. Both SMTP client and SMTP server require a user agent (UA) and a mail transfer agent (MTA). The MTA function is transferring the mail across the Internet. The command-response mechanism is used by SMTP to transfer messages between an MTA client and an MTA server in three stages: connection establishment, mail transfer, and connection termination. The envelope is transmitted separately from the message itself using the `MAIL` and `RCPT` commands. MIME, which is an extension of SMTP, allows the transfer of non-ASCII (multimedia) messages. POP3 and the IMAP 4 together with SMTP are used to receive mail by a mail server and hold it for hosts. The SMTP's lack of security is a problem for businesses. The security in the SMTP transactions can be supported by S/MIME and other methods described in this chapter. Vulnerabilities of SMTP, POP, and IMAP servers (buffer overflow, mail relaying, spoofing, and other attacks) have been analyzed.

GLOSSARY

Body The text of an e-mail message. The body of a message follows the header information.

Bounce Attack An attack that uses a third party's FTP server to hide the true source of the attack from the victim.

Client Any application program used to retrieve information from a server. Internet clients include World Wide Web browsers, Usenet newsreaders, and e-mail programs.

Client-Server The relationship between two application programs. One program, the server, is responsible for servicing requests from the other program, the client.

Delivery Status Notification (DSN) An extended SMTP service that provides information about the delivery status of an e-mail message to the sender.

Disconnected-Resynchronization Mode A mail-access mode in which mail is synchronized between a server and a client computer. By synchronizing mail on the server, users can access their own mail from

any computer that has access to the server where the mail is stored.

Domain Name System (DNS) A behind-the-scenes Internet service that translates Internet domain names to their corresponding IP addresses, and vice versa.

E-Mail Client An application that runs on a personal computer or workstation and enables the sender to send, receive, and organize e-mail. It is called a client because e-mail systems are based on a client-server architecture. Mail is sent from many clients to a central server, which reroutes the mail to its intended destination.

Encapsulated Address This address provides a way to send the e-mail to a site acting as a gateway for another site while indicating the server to which the message eventually needs to be sent. An encapsulated address consists of an address within an address; the outer address directs the mail to the gateway, which uses the inner address to determine where to send the e-mail. Because the Exchange Internet Mail Service (IMS) uses SMTP as its e-mail protocol, mails sent to an IMS will use encapsulated SMTP as their addressing scheme.

Gateway Software that translates data from the standards of one system to the standards of another. For example, a gateway might exchange and convert Internet e-mail to X.400 e-mail.

Header Part of an e-mail message that precedes the body of the message and provides the message originator, date, and time.

Internet Message Access Protocol (IMAP) An Internet protocol used by mail clients for retrieving e-mail messages stored on servers. The latest version, IMAP4, is similar to POP3 but supports some additional features; for example, a user can search through his e-mail messages for key words while the messages are still on mail server. The user can then choose which messages to download to his or her computer. While IMAP-based applications can operate in offline mode, they typically operate in online or disconnected-resynchronization mode.

Mail Access Protocol A standardized set of commands and responses responsible for communication between the mail client and mail server.

Mailbox A file where e-mail messages are stored.

Mail Client The software used to read, file, send, and otherwise process e-mail, typically running on a user's desktop computer.

Mail Relaying A legitimate practice in which e-mail is routed to an intermediate mail server, which then delivers it to the recipient's mail server. For example, a company can have several servers and one of them is designated as a mail gateway to the Internet. Any e-mail sent to the company would arrive at the gateway server and then be relayed to the appropriate server for delivery to the recipient. Malicious users sometimes try to perform unauthorized mail relaying.

Mail Server A computer typically managed by an ISP or information services department that handles receipt and delivery of e-mail messages. It also may store mail for the user on a temporary or permanent basis.

Mail Transfer Agent (MTA) The software that is running on a mail server that relays and delivers mail.

Multipurpose Internet Mail Extensions (MIME) An Internet standard that provides the transfer of nontext information, such as sounds and graphics, and non-U.S. English (such as Cyrillic, Chinese, or Japanese) via e-mail.

Mail User Agent (MUA) The software (also known as the mail client) used to read, file, send, and process e-mail, typically running on a desktop computer.

On-Demand Mail Relay (ODMR) A restricted profile of SMTP described in RFC 2645.

Port In a software device, a port is a specific memory address that is mapped to a virtual networking cable. Ports allow multiple types of traffic to be transmitted to a single IP address. SMTP traditionally uses port 25 for e-mail communication.

Post Office Protocol (POP) A protocol used to retrieve e-mail from a mail server in offline mode. An e-mail client that implements the POP protocol downloads all new mail from a mail server, terminates the network connection, and processes all mail offline at the client computer. The current version, POP3 can be used with or without SMTP.

Server A host computer that provides resources to client computers.

Simple Mail Transfer Protocol (SMTP) A protocol widely used to exchange e-mail between e-mail servers on the Internet.

Spam Undesired junk e-mail or junk postings offering dubious business deals.

User Agent (UA) An SMTP component that prepares the message, creates the envelope, and puts the message in the envelope.

INTRODUCTION

When the Internet was created, security was left out of its TCP/IP standards. At the time, the crude state of security knowledge may have made this lack of security necessary, and the low frequency of attacks made this lack of security reasonable.

Today, however, security expertise is more mature. In addition, the broad presence of security threats on the Internet means that security today must be addressed deliberately and aggressively. In 2004, between 5% and 12% of all sampled traffic moving across ISP networks was malicious (Legard, 2004).

This article describes two ways to add standards-based security to the Internet.

- The first is for users to add standards-based security to individual dialogues, that is, to two-way conversations between pairs of communicating processes. Today, this can be done largely through the use of virtual private networks (VPNs) using the IPsec, SSL/TLS, and PPTP protocols. This “security overlay” approach is not as desirable as good general Internet security standards, but it solves many current user needs.
- The second approach is to add more security to central Internet standards. In addition to the “core three” standards (IP, TCP, and UDP), these central Internet standards include supervisory standards (such as ICMP, DNS, DHCP, SNMP, LDAP, and dynamic routing protocols), and application standards (such as SMTP, HTTP, and FTP). A major effort to retrofit existing Internet standards to add security is underway in the Internet Engineering Task Force under the “Danvers Doctrine,” but this effort is far from complete.

In this article, we will look at these two broad approaches, in the order just presented.

This article will not look at security for single network standards, including Ethernet, wireless LANs, ATM, Frame Relay, and the Public Switched Telephone Network. These individual LANs and WANs operate at the physical and data link layers. As Figure 1 shows, the Internet is a collection of individual LANs and WANs connected by routers. Under normal circumstances, attackers can only send data link layer commands to hosts on their own LAN or WAN. Consequently, for attacks occurring over the Internet, only internet, transport, and application layer attacks are possible. This article focuses on Internet security standards, so it will not discuss attacks on individual LANs and WANs.

This article focuses more specifically on TCP/IP internetworking, which is used on the Internet, rather than on IPX/SPX, SNA, and other forms of internetworking, which cannot be used on the Internet. More formally, this article focuses on security in TCP/IP standards at the internet, transport, and application layers.

SECURITY THREATS

Before looking at security in Internet standards, we need to consider major security threats and defenses. We will begin with types of attacks, because IETF Internet security efforts have focused on one type of attack, namely attacks on dialogues.

Penetration Attacks

One set of threats against which networks, must guard is attackers attempting to penetrate into networks and hosts by sending probe and break-in messages. These include:

- Hacking (when humans intentionally access systems without authorization or in excess of authorization).

Figure 1: The reason for focusing on internet layer (and higher) security.

- Attempting to conduct denial-of-service attacks against networks or hosts by crashing them or overloading them to the point of being useless to their legitimate users.
- Automated malware attacks using viruses, worms, spam, and other undesirable content.

Attacks on Dialogues

Second, when two parties communicate, they normally engage in a dialogue, in which multiple messages are sent in both directions between two hosts. These dialogues must be secure against attackers who may wish to read, delete, alter, add, or replay messages.

An IETF Focus on Dialogue Security

In general, dialogue security has been the main focus of Internet Engineering Task Force efforts to add security to Internet (TCP/IP) standards. Hacking, denial-of-service attacks, and malware attacks are sometimes addressed, but this is comparatively uncommon. Consequently, we will focus on dialogue security in our discussion.

DIALOGUE SECURITY

In dialogue security, there are three major goals: confidentiality, authentication, and integrity. Confidentiality is relatively easy to provide, and integrity normally appears as a by-product of authentication. Authentication is the most difficult protection to apply, so we will focus the most attention on it.

Confidentiality

Confidentiality means that eavesdroppers who intercept messages en route over the Internet cannot read them. Encryption for confidentiality is the chief tool against unauthorized reading en route.

Encryption is relatively easy to do well if the security developer stays with strong and proven encryption algorithm. In the past, this meant DES and 3DES. Today, this means the Advanced Encryption Standard (AES), which is strong and places a comparatively light processing and

memory burden on the communicating devices. AES has also been strongly tested and has survived many attempts to break it. If a security designer does not specify AES, it is incumbent on them to provide a very strong reason for this deviation from good practice.

Authentication and Integrity

Authentication means that the receiver of messages (called the verifier) can verify the identity of the sender (called the applicant or supplicant), in order to ensure that the sender is not an impostor. There are two forms of authentication.

- In *initial authentication*, one side proves its identity to the other side at or near the beginning of a dialogue.
- In *message-by-message authentication*, the sender continues to identify itself with every message, much as parties exchanging letters sign each letter. Message-by-message authentication is crucial to good security.

Integrity means that if a message has been captured and changed en route, then the receiver will be able to detect that a change has occurred. All forms of message-by-message authentication provide message integrity as a by-product. If a message is changed during transmission, either deliberately or through transmission errors, authentication will fail, and the receiver will discard the message.

Initial Authentication

As discussed later, when cryptographic protection systems begin to operate, they usually do initial mutual authentication. Virtual private network protocols, which add overlay protection on individual dialogues between hosts, tend to have well-developed initial authentication methods. All three major VPN standards—IPsec, SSL/TLS, and PPTP—have well-defined initial authentication stages.

However, when the IETF adds security to individual existing protocols, such as TCP, it usually implements message-by-message authentication but not initial authentication. Furthermore, it usually does this by

providing HMAC authentication, which is discussed later. HMAC requires the two parties to have a shared secret key. Protocols that use HMACs usually are silent on how to distribute these secret keys. While these keys can be distributed manually, this approach will not scale to large and complex networks.

One possibility for the future is to require protocols to use the Extensible Authentication Protocol (EAP) (RFC 2284, 1998), which uses public key authentication with digital certificates for at least one of the two parties. This would work well in many cases in which a server needs to work with multiple clients. Clients can use weaker authentication mechanisms if appropriate.

Message-by-Message Authentication

Although initial authentication is important, the most complex authentication issues revolve around message-by-message authentication. Consequently, we will focus more specifically on message-by-message authentication. There are two common message-by-message authentication methods: HMACs and digital signatures. Both are described in more detail in the article on Electronic and Digital Signatures. However, we need to discuss them briefly here.

Digital Signatures and Digital Certificates

As discussed in the article on Electronic and Digital Signatures, when security uses digital signatures, a bit string called a digital signature is added to each outgoing message. More specifically, the sender creates a message digest by hashing the message and then encrypts this message digest with his or her own private key. Encrypting a message digest with the sender's private key is called signing the message digest. The sender transmits the digital signature along with the original message to the receiver.

As Figure 2 shows, to test the digital signature, the receiver (verifier) must know the public key of the *true party*—the party the sender claims to be. Normally, the receiver obtains the public key of the true party by obtaining the true party's digital certificate. The digital certificate, among other things, contains the name and public key of the true party. The receiver obtains the true party's digital certificate once and then uses the public key in the digital certificate to test the digital signature in each message.

The receiver must obtain the digital certificate from a trusted certificate authority (CA). One problem with digital certificates is that certificate authorities are not regulated in most countries, leading to questions about their trustworthiness. Although European countries are

planning to create regulated CAs, the United States and most other countries are trusting market forces to self-regulate certificate authorities.

Is it possible to obtain public keys without using certificate authorities? Pretty Good Privacy (PGP) offers one way to do so. Each user has a "key ring" of trusted public key/name pairs. If User A trusts User B, User A may trust User B's key ring, which may, of course, contain keys received through further distributed trust. If an impostor can dupe even one user, trust in the impostor can spread widely. This is not a good way to manage large public systems of routers, DNS hosts, and other sensitive devices.

Beyond these traditional approaches, efforts are now underway, as noted below in the section on Web service security, to develop federated authentication methods that allow one-to-one and one-to-few exchanges of digital certificates and other ways to share public keys.

It is also possible to distribute public keys manually. This works well in small systems, but it does not scale well to very large systems.

HMACs

Another tool for message-by-message authentication is the key-Hashed Message Authentication Code (HMAC). For HMAC authentication, two parties share a secret key. To send a message, one of the parties appends the key to the message, hashes the combination, and adds this hash (the HMAC) to the outgoing message. To test an arriving message, the receiver also adds the key to the message and hashes the combination. This creates another HMAC. If the received and computed HMACs are the same, the sender knows the secret key, which only the other party should use.

HMACs require less processing power than digital signatures because HMACs only involve hashing, which is a fast process. In contrast, public key encryption and decryption, which are used in digital signatures, are extremely processing intensive.

However, a secret key for HMAC authentication needs to be created and distributed securely for *each pair* of communicating parties. In large systems of routers and hosts, this can be highly problematic. One approach to reduce this problem is to use public key authentication for initial authentication, then use Diffie-Hellman key agreement or public key distribution (using either the RSA or DSA protocol) to send the secret keys between pairs of communicating parties. However, these approaches only work if there is good initial authentication.

Another "solution" to the key distribution problems is to use community keys, which are shared by all communicating parties in a community. The problem here, of course, is that if a single member of the community is compromised, attackers reading its community key will be able to authenticate themselves to all other members of the community. In addition, community keys are rarely changed because of the need to coordinate the change among many users. When there are many users communicating with a key that is rarely if ever changed, there is a large volume of communication encrypted with the same key. With a large volume of communication, cryptanalysts often can crack the key. Using community strings for security is a very bad idea.

Figure 2: The need for digital certificates with digital signatures. Source: Panko 2004.

Another problem with HMACs is repudiation. In repudiation, a party that sent a message denies that they sent it. With digital signatures, repudiation is technically impossible because only the true party should know the true party's private key, so only the true party could have sent the message. Digital signatures give nonrepudiation.

However, with HMACs, both sides know the shared secret key. So if the sender argues that the repudiated message was fabricated by the receiver, there is no possible technical counter-argument. HMACs do not give nonrepudiation.

ADDING OVERLAY SECURITY TO INDIVIDUAL DIALOGUES

As noted above, the first approach to creating standards-based security is for users to add security to individual existing dialogues. Effectively, this overlays security on the Internet for individual dialogues works without requiring the creation of completely new Internet standards.

Cryptographic Protection Systems (CPSs)

Secure dialogues require that confidentiality, authentication, and integrity be protected. This is a somewhat complex process involving several phases.

Cryptographic Protection System Phases

Establishing a secure dialogue with a CPS typically involves four sequential phases (although the specific operations and the order of operations can vary among cryptographic protection systems). Figure 3 illustrates these phases. The first three are quick handshaking phases at the beginning of the dialogue. After the secure dialogue is established, the two parties usually engage in a long ongoing secure conversation.

- First, the two parties must select security standard options within the range offered by a particular cryptographic protection system. For instance, in encryption for confidentiality, the system may offer the choice of a half dozen encryption methods. The communicating parties must select one to use in their subsequent exchanges. The chosen methodology may offer several options; these too must be negotiated.
- Second, the two parties must authenticate themselves to each other. Although initial authentication might seem like it should be the first step instead of the second, the two parties need the first phase to negotiate which authentication method they will use to authenticate themselves.

- Third, the two parties must exchange one or more secrets (keys are examples of secrets) securely. These secrets will be used in the ongoing dialogue phase that will take place after the initial three "hand-shaking" phases of the CPS are finished.
- Fourth, the security of the communication is now established. The two parties now engage in ongoing dialogue with message-by-message confidentiality, authentication, and integrity. Typically, nearly all communication takes place during this ongoing dialogue phase.

The User's Role

Few users have the training to select security options intelligently, much less handle authentication and other tasks. Consequently, cryptographic protection systems work automatically. The user selects a communication partner, and the systems of the two partners work through the four phases automatically.

At most, users may have to authenticate themselves to their own systems by typing a password, using an identification card, using biometrics, or using some other approach. This user authentication phase tends to be the weak link in CPSs because of poor security practices on the part of users, such as using weak passwords.

The Policy Role

Different security options have different implications for the strength of a cryptographic protection system's security. Users rarely are capable of selecting intelligently among options. Consequently, companies must be able to set policies for which methods and options will be acceptable under different circumstances, and they must be able to enforce these policies by promulgating them and enforcing their use.

Figure 4 shows how policy guides security in IPsec, which we will see later. In IPsec, security often is handled by IPsec gateways. When two IPsec gateways begin to communicate, they establish security associations, which are contracts for how security will be done. A policy server can tell the IPsec gateways what security association parameters they may select or not select. This ensures that the IPsec gateways do not select security associations that are too weak for the traffic they will carry. This approach works with host computers as well as with IPsec gateways.

PPP and PPTP VPNs

Dial-Up Security and PPP at the Data Link Layer

Early computer systems used dial-up security. As Figure 5 shows, the user dialed into a server, generally using the Point-to-Point Protocol (PPP) (RFC 1661, 1994) at the

Figure 3: Cryptographic protection system (CPS).
Source: Panko 2004.

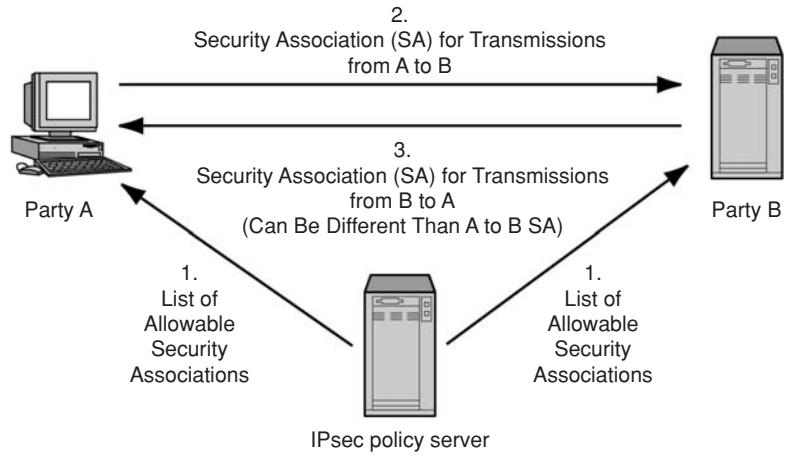

Figure 4: Policy-based security associations in IPsec.

Source: Panko 2004.

data link layer. Later, companies added security to this approach by creating remote access servers (RASs) for sites. The user dialed into the RAS, authenticated himself or herself (usually with a password), and then received access to all servers at a site or to selected servers.

If a company has several remote access servers, it normally uses a RADIUS server or some other authentication server to store authentication information remotely, as Figure 5 shows. This way, all RASs use the same authentication data. Otherwise, if a firm has several RASs, their authentication data may be inconsistent. An adversary may try different RASs until they find one that is configured incorrectly.

PPP can be used without security, but PPP offers moderately good encryption and several options for authentication ranging from nothing to very strong. Again, the dialogue partners must select the security options they wish to employ.

Tunneling

Although PPP is secure, it is limited to a single data link because it operates at the data link layer, as Figure 6 illustrates. However, when a connection is made over the Internet, each connection between a host and a router or between two routers is a separate data link. PPP cannot function over the Internet.

Consequently, Internet-based data link layer security approaches must use tunneling. In tunneling, a data link layer frame is placed within the data field of a packet—the

opposite of the usual situation. Placing a message within another message is called tunneling.

The packet is sent from the user computer to the RAS, across multiple links. Finally, the RAS receives and reads the tunneled (encapsulated) frame. Although this effect seems needlessly complex, it allows us to use traditional PPP user-RAS security over the Internet.

Again, when a message is placed inside another message—especially within a packet—this is called tunneling. We will see later that IPsec also uses tunneling in one of its operating modes (tunneling mode, of course). Tunneling is a delivery technology, not a security technology (Panko, 2004). Many security articles and even textbooks confuse the two.

PPTP

The main tunneling protocol for PPP is the Point-to-Point Tunneling Protocol (PPTP) (RFC 2637, 1999). As its name suggests, PPTP does not have its own security. Rather, PPTP is a way to tunnel PPP frames over the Internet. PPTP uses PPP security methods (encryption and authentication), extending them over an entire Internet connection instead of over a single dial-up data link. PPTP has a number of moderate security weaknesses, but it is good for low-threat or medium-threat environments.

L2TP

Although PPTP works and is attractive, it is limited to transmission over an IP network such as the Internet.

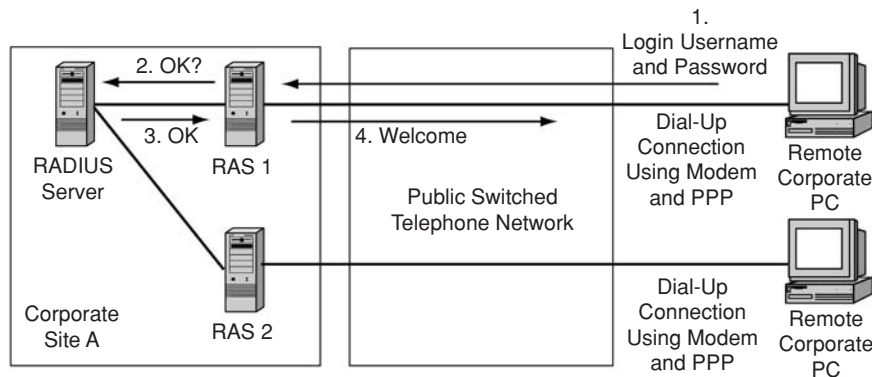

Figure 5: RADIUS authentication.
Source: Panko 2004.

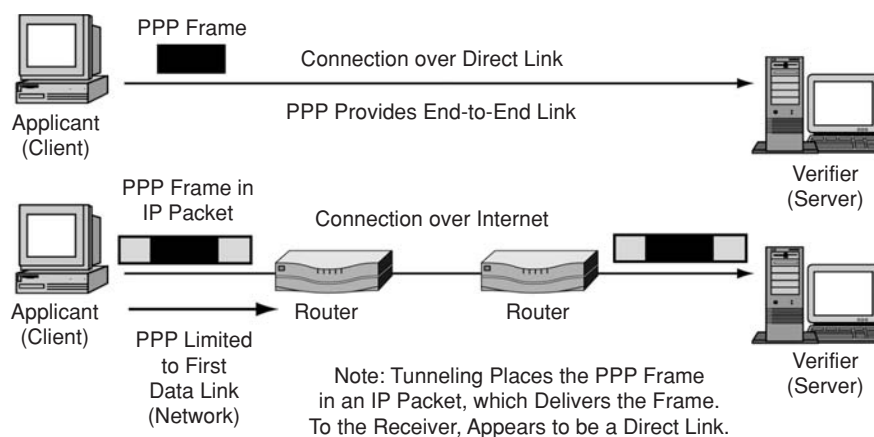

Figure 6: Tunneling PPP.
Source: Panko 2004.

The newer Layer 2 Tunneling Protocol (L2TP) (RFC 2661, 1999) can tunnel frames over a number of transmission mechanisms, including IP, Frame Relay, and ATM, to name just three (Tonsley, Valencia, Rubens, et al., 1999).

However, L2TP does not offer security by itself. It requires users to rely on the IPsec protocol discussed next to provide security at the Internet layer during transit. L2TP is a pure tunneling protocol, not a security protocol at all.

IPsec VPNs

The internet layer (the OSI Network layer) is the core layer in TCP/IP internetworking. The Internet Protocol (IP) is the main packet standard at this layer. IP comes in two versions—IP Version 4 (IPv4) and IP Version 6 (IPv6). IPv4 is the dominant version in use on the Internet today, but IPv6 is beginning to grow, especially in Asia, where relatively few IPv4 addresses were allocated when the Internet was first created.

The IPsec Effort

The Internet Engineering Task Force (IETF) has been working to retrofit IP to be more secure. Their effort has crystallized around a group of standards collectively called IPsec (IP security) (RFC 2411, 1998). Although IPsec was initially planned for IPv6, the IETF has developed it to work with IPv4 as well.

Encryption and Authentication

The dominant way to use IPsec is to employ the encapsulated security protocol (ESP) option, which offers both encryption and authentication. We will focus on ESP rather than on the authentication header (AH) option, which only provides authentication. AH is useful primarily when encryption is illegal; this is a rare situation.

Tunnel Mode

As Figure 7 shows, IPsec can operate in two modes: tunnel mode and transport mode. We will discuss tunnel mode first.

In tunnel mode, IPsec is handled by IPsec gateways at the two sites of the communicating parties, not by the computers of the communicating parties themselves.

The packet to be delivered securely is tunneled by encapsulating it in another packet, encrypting the original packet, adding authentication, and sending the encapsulating packet from one IPsec gateway to the other. Although attackers can read the IP header of the encapsulating packet, they cannot read the secured packet; nor can they change the secured packet without the change being obvious.

Tunnel mode is attractive because it does not impose expensive installation and configuration burdens on each host. It does not require the individual hosts to have IPsec software on their computers or know how to configure the software. In fact, the users may not even be aware that IPsec is protecting their packets over the Internet. Even more importantly, it is not necessary to obtain a digital certificate for each host and install one on each host if tunnel mode is used; only the IPsec gateways need digital certificates.

The disadvantage of tunnel mode is that it does not provide any protection for the packet as it travels *within* the two sites. The focus is entirely on security during the Internet stage of transmission.

Transport Mode

In contrast, as Figure 7 also shows, IPsec's transport mode offers *end-to-end* encryption and authentication between the two computers in a dialogue. This approach provides security not only while packets travel through the Internet but also when the packets are passing through local site networks on their way to and from the Internet. Although the Internet exposes traffic to many attackers, there also are dangers within corporate networks. In fact, some of the worst attacks are made by corporate insiders working within corporate networks.

Although the end-to-end security of transport mode is attractive, it comes at a substantial price. Larger firms have thousands or even tens of thousands of PCs. Transport mode requires the configuration of IPsec software and a digital certificate on every PC to be protected. This is extremely expensive.

A more modest problem is that transport mode packets must have the IP address of the receiving computer in the destination address field of the packet header. If sniffers

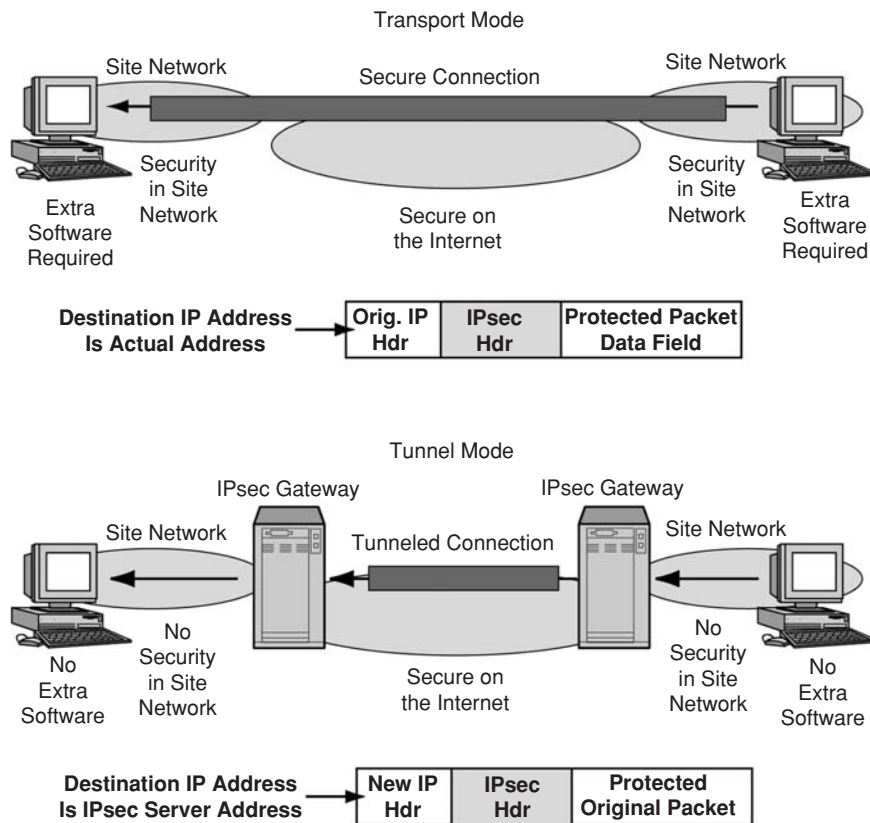

Figure 7: IPsec in tunnel mode and transport mode.
Source: Panko 2004.

can be placed along the route of these packets, attackers will be able to learn the IP addresses of many corporate hosts. This is a first step in most types of Internet-based attacks. In contrast, tunnel mode packets only have the IP addresses of the receiving IPsec gateway in their destination address fields. This only tells attackers about the IP address of a single machine that usually is well hardened against attacks.

Combining Tunnel Mode and Transfer Mode

One solution to the relative weaknesses of the two modes is to use both. The user can use transport mode to provide end-to-end security but also to use IPsec in tunnel mode between sites to hide IP addresses.

IPsec in IPv4 and IPv6

As noted at the beginning of this section, IPsec can be used with both IPv4 and IPv6. However, with IPv6, the use of IPsec is *mandatory* (Microsoft, 2004). With IPv4, however, IPsec is optional.

SSL/TLS VPNs

IPsec is a very complex security mechanism, but it has the advantage of transparency. This means that IPsec protects *all* higher-layer traffic at the transport and application layers automatically, without requiring higher-layer protocols to do any work or even be aware of this protection.

In some applications, dialogues are limited to World Wide Web or at most WWW and e-mail. Under these conditions, the costly burden of implementing IPsec is not

justified, and many firms turn to a simpler protocol, Transport Layer Security (TLS), which was originally created by Netscape as Secure Sockets Layer (SSL) and was then renamed Transport Layer Security (TLS) by the Internet Engineering Task Force when the IETF took over the standard’s development (RFC 2246, 1999). If your URL begins with “https”, then you are using SSL/TLS.

While IPsec provides a blanket of protection at the internet layer, SSL/TLS creates a secure connection at the transport layer. This secure connection potentially can protect all application layer traffic. Unfortunately, SSL/TLS requires that applications be *SSL/TLS-compliant* to benefit from this protection. Although all browsers and WWW servers can use SSL/TLS, only some e-mail systems can use SSL/TLS, and few other applications can benefit from SSL/TLS protection at the transport layer.

SSL/TLS was created for electronic commerce, in which a residential client PC communicates with a merchant server. SSL/TLS requires the merchant to authenticate itself to the client using digital certificates and digital signatures. However, few residential client PC owners have digital certificates. So while SSL/TLS permits client authentication using a digital certificate, it makes client authentication optional. This lack of mandatory client authentication is a major security vulnerability that is intolerable in many situations. If SSL is used in dialogue security, client authentication should be required.

Vendors have begun to create semi-proprietary techniques to create remote access SSL/TLS VPNs for corporate use, and these techniques have become very popular.

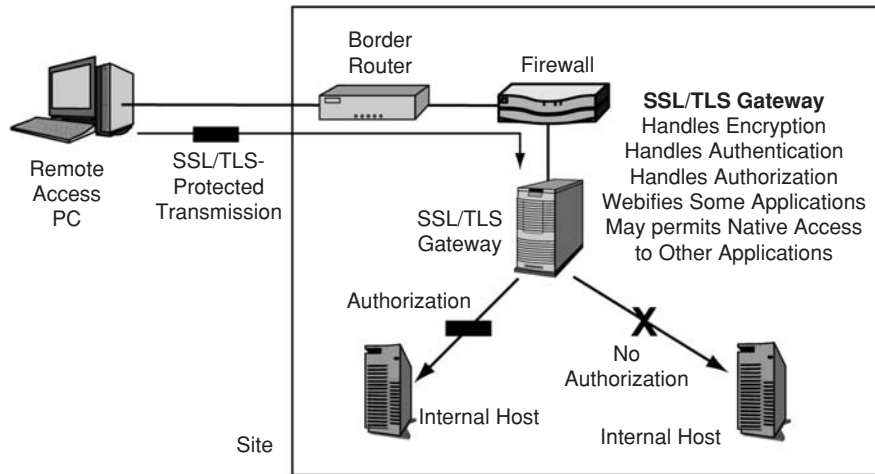

Figure 8: SSL/TLS using gateway operation.

As Figure 8 shows, the user firm places an SSL/TLS gateway server at each site, and users have an SSL/VPN connection to this gateway server. The gateway server provides initial client PC authentication using passwords or some other proprietary mechanism. The gateway server then connects the user to internal servers.

SSL/TLS gateway servers can even get around the limitations of SSL/TLS's HTTP focus. Of course, they can protect HTTP traffic easily because SSL/TLS does this automatically.

In addition, most SSL/TLS gateways can “webify” non-HTTP applications such as Microsoft Outlook—sending screen images over HTTP. If the browser will accept a downloaded add-in, many SSL/TLS gateways can even give the user protected access to traditional applications. However, both webification and application access via browser downloads requires proprietary techniques.

The main attraction of SSL/TLS is that the user can use any PC that has a browser, including those in Internet cafes. Unfortunately, trace information from the user's session continues to reside on the PC after the session. Plug-in browser software to remove these traces can be added to the browser, but this requires operating system privileges that users are not likely to have when they work on PCs in Internet cafes.

Multilayer Security

As Figure 9 shows, security can be applied at several standards layers. A major principle of security is defense in

depth. Vulnerabilities are discovered in almost all security protections from time to time. Until they are fixed, the attacker has free access—unless the attacker must break through two or more lines of defense. With multiple protections in place, the company will still be protected while it repairs a broken security countermeasure.

Consequently, companies would be better protected if they added dialogue security to more than one layer, say by implementing both IPsec and application security. However, this is expensive, so it is not common.

Dialogue Security and Firewalls

Although adding security to dialogues passing through the Internet is attractive, it creates problems for firewalls. Firewalls need to examine arriving and leaving packets. However, almost all cryptographic protection systems encrypt packets for confidentiality.

Unless these packets are decrypted before passing through the firewall, the firewalls cannot scan their packets for attack signatures. Consequently, companies that buy added security by implementing cryptographic protection systems (CPSs) tend to lose some scanning security. This places a heavier burden on end stations to do scanning, and many end stations are client PCs whose owners lack the willingness, much less the knowledge, to do packet scanning.

One solution is to decrypt all incoming packets before they reach the border firewall, by placing a cryptographic gateway between the border firewall and the

Layer	Cryptographic Protection System
Application	Kerberos
Transport	SSL/TLS
Internet	IPsec
Data Link	PPP, PPTP
Physical	Not applicable. No messages are sent at this layer—only individual bits.

Figure 9: Multilayer security.

border router. However, this leaves the cryptographic gateway unprotected from Internet attacks. If the cryptographic gateway is taken over by attackers, the results can be disastrous.

ADDING SECURITY TO INDIVIDUAL INTERNET STANDARDS

Although adding dialogue security to individual dialogues works, it would be better for Internet standards themselves to offer high security. For instance, if DNS servers are disabled so that clients cannot find application servers, dialogue security will do little good.

When the Internet was first created, none of its standards offered any security. Today, several TCP/IP standards offer security. Unfortunately, the closer one examines their security features, the less adequate many appear. Fortunately, the IETF has a broad program to add security to a broad range of existing Internet standards individually.

A Broad IETF Commitment

The Danvers Doctrine

In 1995, a meeting of the IETF in Danvers, Massachusetts reached a consensus that the IETF should develop strong security for all of its protocols (Schiller, RFC 3365, 2002). Originally, the consensus was limited to a decision to use strong encryption keys rather than weak encryption keys that met existing export restrictions. Soon, however, this Danvers Doctrine expanded into a consensus to develop strong security for all TCP/IP protocols. As a first step, all RFCs are now required to include a section on security considerations. As we will now see, considerable progress has also been made in adding security to individual TCP/IP standards.

User Choice

Although all TCP/IP standards are to be given strong security, the IETF decided that it should be the option of individual organizations whether or not to implement security in individual protocols. In part, this decision reflects a desire not to force security on anyone. In part, it also reflects the fact that some networks are in protected environments that do not require security. However, an important consequence of the decision to leave security up to organizations is that organizations must decide which security options to use or not use.

There are five broad layers of functionality in networking—physical, data link, internet, transport, and applications. Implementing security at all layers would be horrendously expensive and generally unnecessary.

Consequently, many organizations will only wish to implement security at one layer. Although this would provide security, individual security technologies often are found to have vulnerabilities. To maintain protection during these periods of vulnerabilities, organizations probably will wish to implement security in the protocols at two layers at least, as noted earlier.

Security and Vulnerabilities

Security in Protocols

In discussing the security of Internet protocols, there are two issues. One is whether security has been built into the protocol at all and to what degree it has been placed in the protocol. This is the aspect of Internet protocol security we focus on in this article.

Protocol and Implementation Vulnerabilities

Another aspect of Internet protocol security is whether the protocol or its implementation has vulnerabilities that attackers can exploit. In some cases, the protocols themselves are exploitable because of design oversights. In more cases, vendor implementations cause problems. For instance both the BIND program, which is dominant for Domain Name System servers, and the Sendmail program, which is dominant on UNIX Simple Mail Transfer Protocol servers, both have had long and troubled histories of security vulnerabilities.

Implementation vulnerabilities are especially dangerous when the same flaw is discovered in multiple vendor code bases. (For example, in February 2001, two major vulnerabilities were found in the Simple Network Management Protocol Version 1 programs of multiple vendors.) This too can result in Internet-scale disruptions.

The worst case scenario is a serious vulnerability in a protocol itself because this will affect all products and may take some time to change. In 2003, for example, the TCP Reset vulnerability was discovered. It is difficult to insert messages into a TCP segment stream because TCP uses 32-bit sequence numbers. This gives over 4 billion possible sequence numbers. An attacker normally must guess the precise next sequence number that the receiver is expecting. However, TCP acknowledgements contain a Window size field. In an odd choice, the TCP standard specifies that if a TCP segment has its RST (reset) bit set, then the receiver will accept any sequence number within the Window size range. This greatly reduces the number of sequence numbers an attacker must try to cause the target to accept a RST message, which will break its connection with its communication partner. This is a denial-of-service attack. BGP, which has long sessions and uses large Window size values, is especially vulnerable to this attack. This is disturbing because BGP is critical for exchanging routing information between Internet core routers and between corporate border routers and Internet core routers. As discussed in the section on BGP later in this article, using TCP authentication can reduce the TCP Reset danger.

Lack of Code Diversity

For some protocols, a single code base is used by most or all vendor implementations. For instance, most DNS servers use BIND. In e-mail, use is dominated by SENDMAIL on Unix systems and Exchange on Microsoft mail servers. This means that if a vulnerability is found, an attack can produce Internet-scale disruptions. This is called the potato famine problem because the Irish Potato Famine was caused by a lack of genetic diversity in the Irish potato crop. The failure of many systems due to the same problem is also called a common mode failure.

Tardy Patching

In addition, when vendors release patches for vulnerabilities, many firms fail to install patches quickly or at all. This makes some vulnerabilities exploitable for weeks, months, or even years after they are discovered. All too often, firms only patch vulnerabilities in earnest when a virus or hackers create widespread damage.

Perspective

Although protocol and implementation vulnerabilities are important, they are situation-specific. This article focuses on security within Internet standards themselves.

The Core Three: IP, TCP, and UDP

There are three core standards at the heart of the Internet. These are IP, TCP, and UDP.

IP

The main job of the Internet Protocol (IP) (RFC 791, 1981) is to move packets from the source host to the destination host across the Internet, which consists of thousands of networks connected by routers. IP is a hop-by-hop protocol designed to govern how each router handles each IP packet it receives.

A packet may travel over one to two dozen routers as it passes from the source host to the destination host. Many core routers in the Internet backbone handle so much traffic that they can barely keep up with demand. To reduce the work done on each router, IP was designed as a simple, unreliable, and connectionless protocol. Although packet losses on the Internet are modest, IP is a “best effort” protocol that offers no guarantee that packets will arrive at all, much less arrive in order. Given this minimalist vision for IP, it is hardly surprising that security was completely left out of IP’s core design. Given continuing router overload, it would be difficult to make IP secure throughout the Internet.

IPsec was created to add security to the Internet Protocol, making IPsec at least somewhat more than a security overlay method. However, IPsec cannot achieve its promise without a truly worldwide system of certificate authorities.

TCP

To compensate for IP’s unreliability at the internet layer, TCP/IP was given a reliable sibling protocol, the Transmission Control Protocol (TCP) (RFC 793, 1981) at the transport layer. However, TCP was not created with security. When TCP was created, in the early 1980s, security technology was far too immature to be implemented. Today, there are no plans to add security to TCP given the IETF’s focus on IPsec and IPsec’s ability to provide security for higher-layer protocols. Later, however, we will see that TCP does have an authentication option, but it is only used in BGP.

UDP

When transport layer error correction is not required or is not practical, applications specify the User Datagram Protocol (UDP) (RFC 768, 1980) at the transport layer. Like TCP, UDP was created without security and is also

not likely to receive security extensions because of the IETF’s reliance on IPsec to protect UDP.

Administrative Standards

The “core three” Internet standards do most of the work of the Internet. However, several other administrative protocols are needed to keep the Internet functioning. We will look at security in the most important of these standards.

ICMP

IP merely delivers packets. It does not define any internet layer supervisory messages. To compensate for this lack, the IETF created the Internet Control Message Protocol (ICMP) (RFC 792, 1981) to carry supervisory information at the internet layer. ICMP messages are carried in the data fields of IP packets. ICMP messages allow hosts to determine if other hosts are active (by “pinging” them). ICMP also allow hosts to send error messages to other hosts and allows hosts to tell other hosts or routers to act differently than they have been acting. ICMP is a powerful tool for network managers.

Unfortunately, this power also makes ICMP a popular tool for hackers. Making ICMP less useful to hackers would also tend to make it less useful to network administrators, so the IETF has done nothing to implement ICMP security. For this reason, most corporate firewalls block all ICMP traffic except for outgoing pings (echo messages) and returning pongs (echo reply messages).

If ICMP were given good authentication, however, corporations might be more willing to allow it through firewalls. In addition, authenticated ICMP would protect against attacks generated within the firewalls at individual sites. However, there are no current IETF activities to add authentication and other security to ICMP. The reason may be that ICMP messages are carried in the data fields of IP packets, which can be protected by IPsec, including the authentication of the sending ICMP process.

Domain Name System (DNS)

Richard Clarke, former national coordinator for security, infrastructure protection, and counter-terrorism for the president of the United States, has characterized the domain name system (DNS) as one of the two greatest danger points on the Internet. (Later we will look at the second item on Clarke’s list, BGP.)

In a sense, DNS is the telephone directory of the Internet. The domain name system (DNS) allows a source host to find the IP addresses of a target host if the source host only knows the target host’s host name [RFC 1034, 1987].

The domain name system has multiple servers organized in a hierarchy. These are called DNS servers, or, sometimes, name servers.

There are two likely attacks on DNS servers. First, attackers may be able to “poison” the databases in DNS servers. When user computers send DNS request messages to poisoned servers, they will get incorrect IP addresses that send users to pornography sites, to sites containing Trojan horses, and to other undesirable sites. Companies can even poison their competitor’s DNS listing so that all e-mail messages go first to the attacking company before being relayed to the victim’s mail servers.

DNS poisoning is not just a theoretical concern. As long ago as 1997, users trying to reach InterNIC.com twice found themselves redirected to a competitor, alterNIC.com. The redirection episodes only stopped when a judge ordered alterNIC.com to stop the redirection. At the time, InterNIC.com was the only registrar for .com, .edu, .org, and .net. There have been many other instances of DNS poisoning since then. DNS poisoning is also known as DNS spoofing.

To address problems with DNS poisoning attacks, the IETF DNSSEC (DNS security extensions) Working Group is developing an authentication approach based on public key encryption with digital signatures (Rose, 2002). There are a (relatively) limited number of high-level DNS servers, so giving each a public key and a private key is not too daunting a challenge. As long as DNS servers do not get taken over so that their private keys can be stolen, authentication should be very good. Complicating matters somewhat, in mid-2004, the DSNSEC Working Group created *bis* versions of most of its RFCs to make DNSSEC somewhat weaker but easier to implement. Although DNSSEC is incomplete, a number of DNS servers now support its main elements. For more information, go to (<http://www.dnssec.net>).

Second, there is the possibility that attackers will use denial-of-service attacks to make DNS servers unavailable to users. Most client users only know the host names of the servers they use. Consequently, if the DNS were to fail for some period of time, clients could no longer reach servers.

As noted earlier, DNS is hierarchical, and if all DNS servers at the highest level are subjected to successful DoS attacks, clients would soon begin to lose the ability to access many servers. At the top level of the DNS server hierarchy, there are only 13 root DNS top-level domain (TLD) servers run by 10 different organizations; one of them periodically feeds changes to the others. Nearly all of these servers, furthermore, use the BIND DNS server program, which has a long history of vulnerability.

Although these root DNS hosts are geographically distributed, most use the same software, leaving them open to common mode attacks if vulnerabilities are found. Also, geographical distribution is not strong protection when

there are only 13 targets to attack. In later 2002, a brief denial-of-service attack degraded the service given by nine of the 13 root DNS hosts. Had this attack been more intense, and had it continued over many hours or even some days, service disruption would have begun across the Internet.

The threat raised by such concentrated DNS resources is very real. The root DNS servers are well protected with both technical and human protections. However, below the root servers are top-level domain (TLD) DNS servers for the various generic (.com, .edu, etc.) and national (.jp, .ca, etc.) top-level domains. The degree to which the DNS servers of these top-level domains are distributed and have code diversity is unknown.

In addition, there are literally tens of thousands of corporate second-level domain DNS servers. Firms are required to have two and preferably three DNS servers. However, if these two or three servers are attacked, corporate communication will stop.

In traditional DNS, only the host names and IP addresses of servers are recorded. However, DNS has been extended by the IETF to dynamic DNS (DDNS). In this newer protocol, clients that receive temporary IP addresses from DNCP servers can register their temporary IP addresses with the firm's DNS server. This is very good because it extends the usefulness of DNS. However, it raises obvious poisoning security concerns that have not been addressed by the IETF.

Simple Network Management Protocol (SNMP)

The goal of the Simple Network Management Protocol (SNMP) is to allow a central administrative computer (the manager) to manage many individual managed devices. Figure 10 shows that the manager talks to an agent on each device. The manager does this by sending the managed devices Get messages (which ask for information on the device's status) or Set messages (which tell the managed device's configuration).

Obviously, SNMP is a powerful management tool. Unfortunately, it also is a golden opportunity for attackers. It potentially allows attackers to learn a great deal of information about target networks through Get commands. It

Figure 10: Simple network management protocol (SNMP).
Source: Panko 2004.

also allows them to inflict an endless amount of damage through the malicious use of the Set command to create misconfigurations on large numbers of devices. These misconfigurations can make the devices unusable or can even make the devices interfere with the operation of other devices.

SNMP Version 1 had no security at all, making the protocol extremely dangerous given its power. SNMP Version 2 was supposed to add security, but an inability to settle differences within the IETF prevented full security from being built into SNMP.

Version 2 did receive one authentication advance. To send SNMP messages to a Version 2 SNMP agent, a manager would have to know the agent's "community string," which is like a password. In practice, most firms have all of their agents use the same community string. In fact, many do not even change the vendor's default community string, which often is "public". In any case, SNMPv2 sends community strings in messages without encryption, so attackers with sniffers can quickly learn community strings.

There actually are four different possible community strings for manager-agent communication: read-only access to device agents, read/write access, read/write/all (which allows the modification of device settings), and trap (trap messages are warnings of problems sent by agents on managed devices) (Beckenbauer, 2002). Given the dangers inherent in writing and modification, many firms only set the read-only community string, and many products only set the read-only community string by default.

Only in Version 3 (<http://www.snmpink.org/SNMPv3.html>) did security get built into SNMP extensively. Version 3 offered confidentiality (optional), message-by-message authentication, message integrity, and time stamps to guard against replay attacks. It also offers the possibility of giving different devices different access to MIB data based on security restrictions.

Unfortunately, SNMP v3 authentication and message integrity is based on HMACs, which require the network administrator to know a secret bit string that is different for each managed device. This difficult situation could be alleviated if the standard specified the use of digital certificates for managers. Authentication and integrity would then only require that managed devices know the manager's public key, and there is no problem with shared public keys. In addition, public key encryption would allow the secure exchange of symmetric keys for bulk encryption for confidentiality. However, the large number of devices involved and the desire to keep processing loads on managed devices low (public key encryption is highly processing-intensive) has made public key authentication and integrity unattractive to standards makers.

For more information about SNMP security, read Blumenthal and Wijen (1998).

LDAP

Increasingly, companies store security information and other critical corporate information in central repositories called directory servers. To query data in a directory server, devices commonly use the Lightweight Directory Access Protocol (LDAP), which governs search request and responses.

The Internet Engineering Task Force has long understood the importance of creating good security for LDAP in light of the extreme importance of information contained in the directory. The core security focus of LDAP must be authentication because successful impostors could learn large amounts of damaging information about a firm if they could get wide access to this data by claiming to be a party with broad authorization to retrieve data. They could also do extensive damage by "poisoning" the directory with bad data.

The first version of the standard, LDAP v1, had no security and generally was rudimentary. LDAP v2 provided authentication options for the first time. It permitted initial anonymous, simple, and Kerberos 4 authentication.

- Anonymous authentication means that no authentication is needed for some users. These users would be given access to certain information on the server, much as anonymous FTP users are allowed to download information from selected parts of an FTP server. Generally speaking, anonymous authentication should be turned off on directory servers that contain any sensitive information.
- Simple authentication requires the user to transmit a username and password. This information is sent in the clear, without encryption. Anyone who reads the username and password will be able to authenticate themselves later as the party. This only provides protection against the accidental usage of LDAP.
- Kerberos 4 authentication uses a central authentication server separate from the directory server. Unfortunately, Kerberos 4 has known weaknesses. Most notably, Kerberos 4 uses a long-term pre-shared secret key to communicate with each device. If enough traffic uses this key, a cryptanalyst can determine the key and then impersonate the device. (Kerberos Version 5 only uses the long-term key for initial authentication and then uses a session key for remaining communication during a time-limited session.)

The latest version of the Lightweight Directory Access Protocol (LDAPv3) (RFC 2251, 1997) also supports anonymous and simple authentication. Again, anonymous authentication should not be turned on for sensitive servers. In addition, sites that use simple authentication should protect application-level LDAP traffic with lower-layer protection, most commonly SSL/TLS at the transport layer. This ensures that eavesdroppers will not be able to read the username and password.

LDAP v3 also supports the Simple Authentication Security Layer (SASL) (RFC 2222, 1997). This method allows the searcher and the directory server to authenticate each other in several ways, including Kerberos 5, HMACs, and external authentication. "External authentication" means that the parties can do authentication any way they wish, essentially taking authentication outside the LDAP process. For instance, if the searcher and directory server create a SSL/TLS connection at the transport layer, the authentication that takes place at that layer may be sufficient. SASL is extremely flexible, but companies using it must ensure that a sufficiently strong authentication option is selected.

Although LDAP v3 offers good authentication, it does not support public key authentication using digital signatures except through SASL or if the organization using it uses SSL/TLS and digital certificates for both parties to secure LDAP traffic.

LDAP v3 makes encryption for confidentiality optional. This may seem odd, but many firms use SSL/TLS at the transport layer to protect LDAP traffic. SSL/TLS does encryption for confidentiality, and many firms feel that also encrypting LDAP traffic at the application layer as well would be needlessly expensive.

A good source of information about LDAP security is Harrison (2002).

Address Resolution Protocol (ARP)

When a router receives a packet, it looks at the packet's destination IP address. Based on this destination IP address, the router sends the packet back out another interface (port), to the destination host or to a next-hop router (NHR) that will next handle the packet. We will use the term "target" for the destination host or next-hop router.

The destination IP address in the packet gives the target's IP address. However, to deliver the packet, the router must encapsulate the packet in a data link layer frame and deliver the frame to the target. This requires the router to know the data link layer address of the target, for instance, the target's Ethernet MAC address.

If the router does not know the target's data link layer address on an Ethernet network, the router must use the Address Resolution Protocol (ARP) (RFC 2251, 1997). The router first broadcasts an ARP request message to all hosts on the subnet connected to the port out which the packet is to be sent. In an Ethernet network, the broadcast MAC destination address is forty-eight ones. Switches on the subnet will deliver frames with this address to all hosts on the subnet. All hosts, on the subnet, furthermore, will accept frames with all-ones destination addresses.

Within a broadcast frame, the router sends an ARP request message. The ARP request message contains the IP address of the target. All hosts except the target ignore this message. The target, however, recognizes its IP address and sends an ARP reply message back to the router. This message tells the router the target's data link layer address.

Now that the router knows the target's data link layer address, the router takes the IP packet it has been holding and places it in a frame with the target's data link layer address in the destination address field. The router sends this frame to the target.

To handle future packets to the same destination IP address, the router also places the target's IP address and data link layer address in the router's ARP cache. When the next packet addressed to this IP address arrives, the router will not have to do ARP. It will simply look up the data link layer address in the ARP cache.

The Address Resolution Protocol assumes that all hosts are trustworthy. However, an attacker host can use this trust to make an attack. Specifically, an attacker's host can send ARP reply messages with the attacker's data link layer address and all possible IP addresses on its subnet. Due to the fact that ARP is stateless, routers should accept ARP response messages even if the router did not send an

ARP request message. This approach will poison the ARP cache, causing the router to send all messages intended for most hosts on the subnet to be sent to the attacker.

In some cases, after reading frames, the attacker passes them on to the intended destination host. It may also be able to relay traffic going in the opposite direction. In this man-in-the-middle attack, the two sides are unaware that their traffic is being read and perhaps added to.

The widely available arpsniff program implements man-in-the-middle attack with extreme ease. However, the computer in the middle has to be on the same broadcast or ring subnet as the other two communicating partners for it to work. This makes arp spoofing difficult to implement. However, if a computer on a subnet is hacked remotely, the attacker does not have to be on the victims' subnet.

Currently, there are only preliminary efforts within the IETF to add authentication to the Address Resolution Protocol, under the ARPsec label.

ARP only works on Ethernet and other broadcast networks. Other protocols for finding host data link layer addresses associated with IP addresses are used for other types of non-broadcast network technologies. These generally suffer the same security exposures that ARP does.

Dynamic Host Communication Protocol (DHCP)

It is possible to manually configure a client PC by typing in its IP address and other configuration parameters needed to communicate over the Internet or a corporate internet. Servers typically are configured manually. However, client PCs normally are configured automatically by getting these configuration parameters from a Dynamic Host Configuration Protocol (DHCP) host (RFC 2131, 1997).

When a client PC boots up, it realizes that it has no IP address. It broadcasts a DHCPDISCOVER message to learn what DHCP servers are reachable. Each DHCP server that receives the discover message sends back a DHCPOFFER message that gives an offer specifying what IP address it will provide, a lease time (how long the client may keep the IP address), and other configuration information.

The client PC selects one offer and sends a DHCPREQUEST to the selected server. The DHCP server sends back a DHCPACK message acknowledging the acceptance and providing configuration parameters, including an IP address, subnet masks, DNS addresses, and other information. The client PC is now configured.

DHCP is built on connectionless UDP, which makes adding security difficult in general. More specifically, DHCP does not authenticate the client or the DHCP server, and this allows several possible attacks. For an example, an attacker posing as a client PC can repeatedly request DHCP service, each time accepting an IP address. Within a few seconds, the DHCP server will be drained of available IP addresses. If a legitimate client then requests configuration service, it will not be able to get an IP address and so will not be able to use the Internet or an internal corporate internet.

The attacker also can impersonate a DHCP server. The attacker will then respond to all DHCPDISCOVER messages with a very attractive offer (long lease duration, and so forth). If a client accepts this configuration

information, this information may cause the client to send packets that cannot be delivered or to act in other ways that harm itself or other hosts.

The IETF is now working on DHCP authentication. RFC 3118 (2001) defines two authentication options for DHCP. The first involves a key that is shared by the client PC and by the DHCP server. This key, however, is transmitted in the clear. This easily-read transmission approach is only useful for protecting the client against a host that *accidentally* installed a DHCP server.

The second option requires each client to use a pair-shared secret key with each DHCP server. Only the DHCP server and the client will know this key. The client and server use this pair-shared secret to add a key-hashed message authentication code (HMAC) to each message. If companies adopt this option, they can have fairly strong authentication, although the authentication will not be as strong as it would be if digital signatures and digital certificates were used.

Dynamic Routing Protocols Operation. When a packet arrives at a router, the router compares the packet's destination IP address with the rows in its routing table. Each row represents a route to a subnet, network, or larger cluster of IP addresses that contains the destination IP address. The router finds all matches, selects the best match, and sends the packet back out according to instructions found in the best-match row.

How do routers get the information in their routing table? Quite simply, they talk to each other frequently, exchanging data on what they know, especially about recent changes. This communication is governed by dynamic routing protocols. These protocols specify both message exchanges and the types of information that will be exchanged.

Security Concerns. Dynamic routing protocols are dangerous because spoofed messages can seriously poison routing tables and therefore can cause routers to black hole or mis-deliver most or all traffic. They can even cause a router to deliver all packets to a single target destination, creating an intense denial-of-service attack. Unfortunately, dynamic routing protocols traditionally have not used cryptographic authentication or other protections.

IETF Efforts. There are several routing protocols in common use, including OSPF, BGP, EIGRP, and IS-IS. Historically, each of these standards evolved separately, including security features. Today, however, the IETF has a working group on Routing Protocol Security Requirements (rpsec). As we will see, all current IETF routing protocols at least have HMAC authentication.

RIP. For communication within small firms, the IETF created a simple routing protocol called the Routing Information Protocol (RIP). Due to its simplicity, RIP has three main constraints (Panko, 2004).

First, RIP selects routes on the basis of the number of hops between routers to get to a destination network or subnet. Selecting the route with the least number of hops generally works well in simple networks but works poorly in large networks. Large networks usually have a

mix of LAN and WAN links with widely different costs and speeds. Sending data over a WAN link is much more expensive than sending data over a LAN link, but RIP does not consider these costs or other factors.

Second, RIP only works in networks with a maximum of sixteen hops. In effect, it can only count to sixteen because its hop count field only has four bits. Again, this is not a problem in small networks.

Third, RIP does not scale well. Every minute or so, depending on configuration parameters, each router broadcasts its routing table to all routers on its subnet and also to all hosts on its subnet. With large routing tables, the disruptions caused by this intrusive broadcasting would create serious host and network performance problems. Again, however, RIP is for small networks.

Just as it has a simple general design, RIP initially had no security. RIP version 2 (RFC 2453, 1998), however, brought RIP security up to date. Most notably, RIPv2 has three authentication modes:

- Null authentication (RFC 1583) (no authentication at all)
- Simple password authentication (RFC 1583), in which the password is sent in the clear in every packet. This method is useful for systems that are accidentally set up as RIP routers.
- MD5 HMAC Authentication (RFC 2328). This method uses HMACs. RIP broadcasts to all other routers out of each interface, so all routers connected to a subnet must share the same subnet secret. Looked at another way, a router must have a different secret on each interface.

As in most other standards, there is no digital signature authentication. RIPv2 does have HMAC authentication, but this uses a community secret compared to a pair-shared secret.

The rpsec's publications discuss other problems with RIPv2's authentication and various ways to address them.

OSPF. For larger networks, most firms use the Open Shortest Path First (OSPF) dynamic routing protocol. This is a more sophisticated protocol for three reasons (Panko, 2004). First, it gives routers richer information about possible routes, so that routers can select best-match rows with greater effectiveness. Second, OSPF can serve large networks. Third, OSPF scales well because it only sends messages when there are changes and because selected area routers can centralize communication in a hub-and-spoke topology instead of sending messages in a dense mesh. OSPF should be used in all but the simplest networks.

OSPF Version 2 (RFC 2328, 1998) has the same authentication options as RIP. This includes the weakness of using group-shared HMAC secrets among all OSPF routers in an area. Jones and Le Moigne (2004) discuss other security vulnerabilities in OSPF. These vulnerabilities can lead to some attacks even if HMAC authentication is used. OSPF Version 3 is used with IP Version 3.

BGP. Both RIP and OSPF are interior dynamic routing protocols that are only used *within* the networks of

individual corporations. However, firms need an exterior dynamic routing protocol to communicate with their Internet service provider's router. In addition, ISPs need an exterior dynamic routing protocol to communicate with one another.

On the Internet, a single exterior dynamic routing protocol is dominant: the Border Gateway Protocol (BGP). "Gateway" is the old term for "router," so BGP is a protocol for communication between border routers at the edges of their networks.

Richard Clarke, former national coordinator for security, infrastructure protection, and counter-terrorism for the president of the United States has labeled BGP as one of the two greatest dangers on the Internet. As noted earlier, Clarke's other nomination is DNS. DNS is dangerous because it potentially could be forced to redirect all Internet traffic in harmful ways. BGP is dangerous because if it is compromised, traffic over the Internet could be redirected in harmful ways by the routers that actually move traffic. The DNS danger is like vandals removing or switching around road signs. The BGP danger is like vandals blowing up bridges.

The most recent version of BGP, BGPv4 (see RFC 1771, 1995), has been in use for more than a decade and is used almost universally on the Internet. Despite its critical importance to the Internet, BGPv4 has no cryptographic security at all. However, BGP runs over TCP on Port 179, and a large number of BGP users employ an authentication mechanism in TCP (Stewart, 1999). This mechanism, described in RFC 2385 (1998), uses a pair-shared HMAC using MD5 (although the RFC calls it an MD5 digital signature). If a BGP message is contained in a TCP segment with an improper HMAC, the transport layer discards the message before BGP even sees it.

Dialogues protected with MD5 HMACs are difficult to hijack. Attackers must not only guess TCP sequence numbers. They must also guess or learn the secret shared by the two routers being connected via TCP.

For stronger security, the two routers exchanging BGP messages can connect via IPsec with at least initial public key authentication. They could also connect via SSL/TLS. In either case, the two routers would need to have public and private keys. In addition, the routers would have to be fast enough to handle the large amount of additional work needed for IPsec or SSL/TLS. This approach does not work for other routing protocols, which use broadcasting (RIP) or multicasting (OSPF).

BGP routers have many options, which have varying levels of security and vulnerability. Windowsecurity.com (2002) has developed a template for securing BGP on the Cisco routers that dominate corporate and Internet use.

EIGRP and IS-IS. There are two other dynamic routing protocols to mention. For interior routing, many firms use Cisco's proprietary EIGRP interior dynamic routing protocol, which can handle the packets of multiple standards architectures in an integrated way. (RIP and OSPF are limited to IP packets.) In addition, OSI offers IS-IS, which would at least provide security by obscurity (not recommended). However, this article is about Internet security standards, and Internet transmission requires IP transmission.

Dynamic Routing Protocol Security: Perspective. To date, the focus on dynamic routing protocol security has been authentication. Unless IPsec or SSL/TLS are used to transmit BGP4 messages, the highest level of authentication for BGP4 is MD5 HMACs with pair-shared secrets. In addition, for interior routing, the highest level of security for RIP and OSPF is MD5 HMACs with group-shared secrets.

Another issue is that authentication assumes trust. If an attacker gets inside an organization managing a router or somehow compromises a router, they will be able to send poisoned routing information to other routers, and these other routers are likely to trust the information.

One way to reduce the danger of spurious trust is to block all incoming packets containing dynamic routing protocol information at the firm's border firewall—or at least, to limit incoming packets containing such information to one or two specific external routers.

Application Layer Standards

To users, the Internet is attractive because of its application standards for the World Wide Web, e-mail, and other popular services. While decent security is present for some application standards, many application standards continue to have only weak security—if they have any at all.

Hypertext Transfer Protocol (HTTP) over SSL/TLS

To communicate with a WWW server, a browser uses HTTP Version 1.1 (RFC 2616, 1999). HTTP is a simple protocol that offers no security by itself. However, all browser and WWW server programs support SSL/TLS security, and the use of SSL/TLS in e-commerce applications and other sensitive applications is overwhelming. HTTP over SSL/TLS uses Port 443 rather than HTTP's normal Port 80.

SSL/TLS allows both the browser and the webserver to authenticate each other using digital signatures and digital certificates. However, only the server is *required* to use a digital signature to authenticate itself. This is done because few PCs running browsers have digital certificates. Obviously, not requiring client authentication is a serious problem for protecting web servers against attack.

E-Mail Security

Security for e-mail is perhaps the great scandal in Internet Engineering Task Force history. Competing cliques within the IETF have consistently simply refused to cooperate in selecting security standards for e-mail. Consequently, companies that wish to implement e-mail security have to use a non-standard method to do so.

Not surprisingly, sending application layer e-mail traffic over a secure SSL/TLS transport connection is the most popular way to secure e-mail in organizations today. SSL/TLS is well understood, offers consumer-grade security, and has been widely used for HTTP security for several years. Another approach, S/MIME (RFC 2633 1999), is used by fewer organizations.

A third approach, Pretty Good Privacy (PGP) (RFC 1991, 1996), is used primarily by individuals. Organizations have tended to stay away from PGP because PGP uses user-based transitive trust. (If User A trusts User B,

and if User B trusts User C, User A may trust User C). As noted earlier, this is not a good security policy. If a single user mistakenly trusts an impostor, others may unwittingly trust the impostor as well.

Also, PGP is now owned by a single vendor, making it a proprietary protocol. In addition, it has had a troubled development history. OpenPGP now offers a vendor-independent implementation of a near-PGP protocol, but there is no official reference standard for OpenPGP.

Remote Access Protocols: Telnet, Rlogin, Rsh, and SSH

The first ARPANET application was Telnet (RFC 854, 1983), which allows a user to log into a remote computer and execute commands there as if the user was a local user. This allows ordinary users to access remote services. It also allows system administrators to manage servers and routers remotely. This use of remote administration is attractive, but it must be done carefully or hackers will end up “managing” corporate servers and routers.

Unfortunately, Telnet has poor security. For example, Telnet does not encrypt host usernames and passwords. Sniffers can intercept usernames and passwords, allowing hackers to log in as these users with all of the privileges of these users.

Telnet should never be used for remote administration because hackers intercepting root passwords would be able to execute any commands on the compromised machine. Telnet is not alone in this respect. In the Unix world, rlogin and rsh do not even require passwords to gain access to a computer, although other conditions must apply.

For remote administration, some organizations turn to the Secure Shell (SSH) protocol, which offers good authentication, integrity, and authentication (Ylonen, Kivinen, Saarinen, *et al.*, 2002). Unfortunately, SSH Version 1 had security flaws, and although these have been fixed in SSH Version 2, many Version 2 implementations will also permit Version 1 connections, thus leaving the system open to attack. Another problem is that SSH is not an official TCP/IP protocol.

File Transfer Protocol (FTP) and Trivial File Transfer Protocol (TFTP)

Another early ARPANET service that continues to be popular on the Internet is File Transfer Protocol (FTP) (RFC 959, 1985), which allows a user to download files from a remote computer to his or her local computer and sometimes to upload files from his or her local computer to the remote computer. Unfortunately, FTP also sends usernames and passwords in the clear, making it very dangerous. In addition, while the use of Telnet has declined to the point where quite a few companies simply stop all Telnet traffic at their firewalls, FTP is still widely used. The FTPEXT Working Group is considering security for FTP. In addition, FTP can be protected by sending it over SSL/TLS if the FTP program allows this.

FTP has a simpler sibling, the Trivial File Transfer Protocol (TFTP) (RFC 1350, 1992). TFTP does not even require usernames and passwords, making it a darling of hackers who often use TFTP after taking over a computer to download their rootkits (collections of hacker programs) to automate their exploitation of the computer they now “own.”

Web Services

An important emerging application class is Web services. Web service protocols allow programs on different computers to interact in a standardized way. Web services are creating a new level of interoperability between programs on different computers.

The figure shows that Web service interactions often are “chained,” meaning that a single Web service message may initiate a series of other Web service messages.

Web services have only been operational since about 2000, and Web services standards are still rather embryonic. The three main Web service standards are SOAP, which governs the format of messages, UDDI, which is like a yellow pages and white pages for finding Web services relevant to a firm’s need, and WSDL, which tells a firm exactly how to work with a specific Web service. However, many other standards need to be set before Web services can be used with confidence.

As in many other applications, security was an afterthought for Web services standardization. Consequently, Web service security standards are even more embryonic than Web service standards in general. Worse yet, Web service security standards have suffered from conflicts among vendors.

The initial security standards for Web services (SOAP, UDDI, and WSDL) were created by the World Wide Web Consortium (W3C). However, Microsoft, which had been a major driving force behind the first three standards, pulled its support from W3C. Rumor suggests that Microsoft did this because W3C only creates standards if the technology is not encumbered by patents (Koch, 2003). Microsoft, according to the rumor, wished to preserve its intellectual property rights.

Whatever its motivation, Microsoft and its main partners, IBM and VeriSign, moved their standards development efforts to OASIS (the Organization for the Advancement of Structured Information Standards). Their efforts were based on the Microsoft/IBM/VeriSign standards efforts called WS- (because all standards begin with WS and a dash).

Sun Microsystems and its allies initially supported a different family of standards, ebXML. In fact, it has been suggested that the IETF gave the WS- standards a cold reception at the 2000 IETF meeting because Sun had the chair role (Newcomer, 2003). However, when the ebXML effort fell apart, Sun threw its weight behind the WS- standards efforts at OASIS.

To confuse matters even further, Microsoft and its allies created a new standards organization, WS-I, where the I stands for interoperability. Initially, WS-I’s purpose is to develop implementation profiles built from various Web services standards. Sun was excluded from WS-I but was eventually allowed to join as a board member.

In 2004, there was a major breakthrough when OASIS ratified the WS-Security standard submitted by Microsoft, IBM, and VeriSign in 2002. WS-Security, in a move toward openness, adopted several standards from W3C, including standards for encryption and digital signatures. In the near future, WS-Security should be extended to work with the OASIS SAML (Security Assertion Markup Language) standard, which specifies how organizations can exchange authentication information.

Unfortunately, WS-Security is only part of the framework created for Web service security by Microsoft, IBM, and VeriSign. To be effective, six more elements are needed: WS-Policy, WS-Trust, WS-Privacy, WS-Secure Conversation, WS-Federation, and WS-Authorization. Microsoft and its allies have not submitted these additional elements to OASIS, making the standardization of WS-Security a limited development.

Authentication is a complex issue for Web services standards. WS-Security does not have complete authentication, and Sun and its partners have developed a major authentication system under the auspices of the Sun-led Liberty Alliance. Although Sun has endorsed the Microsoft standards efforts, Microsoft has not done the same for the Liberty Alliance standards, probably because Microsoft has a competing authentication product, Passport.

Especially interesting aspects of the W3C standards are its XML Encryption and XML Signature standards, which are part of WS-Security. Obviously, these standards provide for encryption for confidentiality and digital signing. What makes them interesting is not their cryptographic methods but the fact that they can be applied to *parts* of a message as well as to the entire message. The capability to encrypt and sign parts of messages is important because some Web service messages go to more than one party, and only some parts of the message are relevant to (or should be read by) each party.

Web services security protocols have a long way to go before they are ready for use with confidence. In addition, the protocols that do exist still are subject to denial-of-service attacks and other dangers.

However, if a Web service interaction will only take place between two parties, it may be sufficient to protect and authenticate the communication using SSL/TLS. However, not having protection and authentication *within* messages via XML Encryption and XML Signature leaves Web services open to certain attacks.

Other Applications

There are many other Internet applications, and their standards vary widely in their degree of security. VoIP security is a particularly sensitive emerging standards application issue. In addition, database applications and many other applications are not even standards-based.

Unfortunately, many operating system installations automatically turn on quite a few applications without the knowledge of the systems administrators or users. For example, when SNMP vulnerabilities were found in 2002, it was discovered that many vulnerable machines should not have been running SNMP at all. An important rule in hardening clients and servers against attack is to turn off all applications that are not absolutely needed to run the computer.

THE STATE OF INTERNET SECURITY STANDARDS

Today, if two communication partners wish to communicate securely, they can do so by adding dialogue security on top of the nonsecure Internet transmission. For lightweight needs, they can turn to PPTP or SSL/TLS. For industrial-strength security, they can use IPsec.

General Insecurity

More generally, however, under the Danvers Doctrine, the standards that the Internet needs for message delivery (IP, TCP, and UDP), Internet supervisory standards (ICMP, DNS, SNMP, LDAP, etc.), and Internet application standards (WWW, e-mail, etc.) vary widely in security from none to semi-adequate. Consequently, the Internet today is rather fragile and open to seriously damaging attacks. Given the pace of security implementation in individual standards, the fragility of the Internet is not likely to change radically in the next two or three years. Even after more secure standards are developed, it will take several years for them to be widely adopted.

The Broad IETF Program

At the same time, there is an extremely broad concern with security across the IETF. Although some standards have better security than others, standards working groups appear to be playing leapfrog in their efforts to improve security across a broad spectrum of Internet standards.

The Authentication Problem

Digital Certificates

The most difficult problem in Internet security standards is authentication. Most Internet standards today from the IETF offer a maximum of HMAC message-by-message authentication.

However, unless authentication uses public key authentication (such as digital signatures) coupled with digital certificates managed by a reliable and well-regulated network of certificate authorities, authentication strength will only be moderate. However, creating large public key infrastructures will take years, and while European countries are moving to manage and regulate certificate authorities, the United States has adopted the let-the-market-do-it philosophy that has worked so well recently in the energy industry and in corporate financial reporting.

One option is to use public key authentication with digital certificates and then use HMACs for message-by-message authentication. Although this would lose nonrepudiation for individual messages, it would decrease the processing intensiveness of VPNs and other cryptographic protection systems. However, this still requires an infrastructure for managing public/private key pairs and digital certificates.

Distributed Authentication

Another problem is distributed authentication. There is unlikely to be a single global authentication authority. Consequently, multiple authentication authorities must be able to work together. Most importantly, there must be mechanisms for implementing transitive trust, in which an authentication authority trusts credentials provided by another authentication authority. In public key authentication, there has long been the concept of a hierarchy of certificate authorities, but no single CA tree is likely to emerge across the world.

More federated one-to-one and one-to-few horizontal trust systems are now under development, especially for Web services. These include the Liberty Alliance, IBM,

and Microsoft (WS-* security) standards, and OASIS (the Organization for the Advancement of Structured Information Standards) standards.

The Primary Authentication Problem

One broad and deep problem in authentication is the primary authentication problem—proving the identity of a person or organization in the first place, say to give them a digital certificate or accept them as an employee. Identity theft has long allowed impostors to obtain fraudulent drivers' licenses and other authentication instruments. Even within closed systems, such as corporate networks, the prime authentication problem can be daunting. For consumer authentication and other large communities, the technical and operational problems for credible initial authentication are extremely daunting.

Protection from Denial-of-Service Attacks

One security threat that has barely been faced so far is the prospect of denial-of-service attacks. Although a few standards have taken some steps to reduce DoS attack risks, this is an area of little general development within the IETF.

Internet Forensics Standards

One area that we did not look at in this paper is standards to make the internet forensic, that is, able to collect and analyze traffic data in a way that would make the prosecution of attacks possible. Without forensics standards, it will continue to be nearly impossible to find and prosecute attackers.

The Internet Engineering Task Force to date has shown no interest in developing forensics standards. In fact, in 1999, the IETF polled its members about whether the IETF should develop protocols to support law enforcement requirements for wiretapping voice conversations carried over the Internet. There was a strong preponderance of comments against developing standards for implementing wiretapping (Macavinta, 1999).

GLOSSARY

Community Key, AKA Community Secret Secret shared by multiple devices within a network.

Cryptographic Protection System (CPS) Standards-based system for automatically providing multiple protections in a dialogue between two parties.

Danvers Doctrine An Internet Engineering Task Force decision to add security to all or nearly all TCP/IP protocols.

Denial-of-Service Attacks Attacks that attempt to render a computer or network useless to its user; not addressed in most Internet security efforts.

Dialogue The transmission of multiple messages in both directions between two hosts.

Dialogue Security Security applied to a dialogue (ongoing message exchange between two parties); often added on top of nonsecure Internet transmission.

Digital Signature Message-by-message authentication system based on public key encryption. To work very

well, the parties should have digital certificates from trusted certificate authorities.

Dynamic Routing Protocol A protocol that routers use to communicate with one another to exchange information for their routing tables.

HMAC Key-Hashed Message Authentication Protocol. Message-by-message authentication system based on a secret key shared by two parties.

Internet Engineering Task Force (IETF) The body that creates TCP/IP standards for the Internet. Now engaged in a broad effort to add security to Internet standards.

In the clear When a message is transmitted without encryption for confidentiality or other cryptographic protections.

IPsec Family of standards for adding security to both IPv4 and IPv6 Internet Protocol transmission dialogues.

Kerberos Server Authentication system in which a central server gives out authentication and authorization information.

Multilayer Security Providing security at multiple standards layers in order to provide defense in depth.

Password Authentication Authentication in which the two sides know a password consisting of keyboard characters.

Policy Server In a security system, a server that tells devices how they must implement security

PPP Point-to-Point Protocol. Secure protocol for communicating over a point-to-point data link.

PPTP Point-to-Point Tunneling Protocol. Protocol that extends PPP transmissions over an internet; extends PPP security over the route.

RADIUS server A server that stores authentication data so that access servers can apply authentication criteria consistently. Name stands for Remote Authentication Dial-In User Service.

Remote Access Server (RAS) Security server at a site that terminates and manages a PPP connection or PPTP connection over the Internet

SSL/TLS Transport Layer Security (TLS). General standard for adding security at the transport layer. Formerly called Secure Sockets Layer (SSL) and still widely known by that name. Also called HTTPS because URLs beginning with "https" are requesting SSL/TLS security.

Virtual Private Network (VPN) Family of standards for adding security to a dialogue over an untrusted network, most commonly the Internet. Includes PPTP, IPsec, and SSL/TLS.

INTRODUCTION

Kerberos is an authentication service developed as part of Project Athena at MIT. The problem that Kerberos addresses is this: Assume an open distributed environment in which users at workstations wish to access services on servers distributed throughout the network. We would like for servers to be able to restrict access to authorized users and to be able to authenticate requests for service. In this environment, a workstation cannot be trusted to identify its users correctly to network services. In particular, the following three threats exist:

- A user may gain access to a particular workstation and pretend to be another user operating from that workstation.
- A user may alter the network address of a workstation so that the requests sent from the altered workstation appear to come from the impersonated workstation.
- A user may eavesdrop on exchanges and use a replay attack to gain entrance to a server or to disrupt operations.

In any of these cases, an unauthorized user may be able to gain access to services and data that he or she is not authorized to access. Rather than building in elaborate authentication protocols at each server, Kerberos provides a centralized authentication server with the function of authenticating users to servers and servers to users. Unlike many authentication schemes, Kerberos relies exclusively on symmetric encryption, making no use of public key encryption.

Two versions of Kerberos are in common use. Version 4 (Miller, Neuman, Schiller, & Saltzer, 1988; Steiner, Neuman, & Schiller, 1988) is still widely used. Version 5 (Kohl, 1989) corrects some of the security deficiencies of version 4 and has been issued as a proposed Internet Standard (RFC 1510).

This discussion begins with a brief discussion of the motivation for the Kerberos approach. Then, because of the complexity of Kerberos, it is best to proceed to a description of the authentication protocol used in version 4. This enables us to see the essence of the Kerberos strategy without considering some of the details required to handle subtle security threats. Finally, we examine version 5.

MOTIVATION

If a set of users is provided with dedicated personal computers that have no network connections, then a user's resources and files can be protected by physically securing each personal computer. When these users instead are served by a centralized time-sharing system, the time-sharing operating system must provide the security. The operating system can enforce access control policies based on user identity and use the logon procedure to identify users.

Today, neither of these scenarios is typical. More common is a distributed architecture consisting of dedicated user workstations (clients) and distributed or centralized servers. In this environment, three approaches to security can be envisioned:

1. Rely on each individual client workstation to ensure the identity of its user or users and rely on each server to enforce a security policy based on user identification (ID)
2. Require that client systems authenticate themselves to servers, but trust the client system concerning the identity of its user
3. Require the user to prove identity for each service invoked; also require that servers prove their identity to clients

In a small, closed environment, in which all systems are owned and operated by a single organization, the first or perhaps second strategy may suffice. In a more open environment, however, in which network connections to other machines are supported, the third approach is needed to protect user information and resources housed at the server. This third approach is supported by Kerberos. Kerberos assumes a distributed client-server architecture and employs one or more Kerberos servers to provide an authentication service.

The first published report on Kerberos (Steiner et al., 1988) listed the following requirements for Kerberos:

- **Secure:** A network eavesdropper should not be able to obtain the necessary information to impersonate a user. More generally, Kerberos should be strong enough that a potential opponent does not find it to be the weak link.

- **Reliable:** For all services that rely on Kerberos for access control, lack of availability of the Kerberos service means lack of availability of the supported services. Hence, Kerberos should be highly reliable and should employ a distributed server architecture, with one system able to back up another.
- **Transparent:** Ideally, the user should not be aware that authentication is taking place, beyond the requirement to enter a password.
- **Scalable:** The system should be capable of supporting large numbers of clients and servers. This suggests a modular, distributed architecture.

To support these requirements, the overall scheme of Kerberos is that of a trusted third-party authentication service that uses a protocol based on that proposed by Needham and Schroeder (1978). It is trusted in the sense that clients and servers trust Kerberos to mediate their mutual authentication. Assuming the Kerberos protocol is well designed, the authentication service is secure if the Kerberos server itself is secure.

KERBEROS VERSION 4

Version 4 of Kerberos makes use of DES (Data Encryption Standard), in a rather elaborate protocol, to provide the authentication service. Viewing the protocol as a whole, it is difficult to see the need for the many elements contained therein. Therefore, we adopt a strategy used by Bill Bryant of Project Athena (Bryant, 1988) and build up to the full protocol by looking first at several hypothetical dialogues. Each successive dialogue adds additional complexity to counter security vulnerabilities revealed in the preceding dialogue.

After examining the protocol, this chapter considers other aspects of version 4.

A Simple Authentication Dialogue

In an unprotected network environment, any client can apply to any server for service. The obvious security risk is that of impersonation. An opponent can pretend to be another client and obtain unauthorized privileges on server machines. To counter this threat, servers must be able to confirm the identities of clients who request service. Each server can be required to undertake this task for each client-server interaction, but in an open environment, this places a substantial burden on each server.

An alternative is to use an authentication server (AS) that knows the passwords of all users and stores these in a centralized database. In addition, the AS shares a unique secret key with each server. These keys have been distributed physically or in some other secure manner. Consider the following hypothetical dialogue (the portion to the left of the colon indicates the sender and receiver, the portion to the right indicates the contents of the message, and the symbol \parallel indicates concatenation):

- (1) C \rightarrow AS: $ID_C \parallel P_C \parallel ID_V$
- (2) AS \rightarrow C: *Ticket*
- (3) C \rightarrow V: $ID_C \parallel Ticket$,
 $Ticket = E_{K_V} [ID_C \parallel AD_C \parallel ID_V]$

where

- C = client
- AS = authentication server
- V = server
- ID_C = identifier of user on C
- ID_V = identifier of V
- P_C = password of user on C
- AD_C = network address of C
- K_V = secret encryption key shared by AS and V
- \parallel = concatenation.

In this scenario, the user logs on to a workstation and requests access to server V. The client module C in the user's workstation requests the user's password and then sends a message to the AS that includes the user's ID, the server's ID, and the user's password. The AS checks its database to see whether the user has supplied the proper password for this user ID and whether this user is permitted access to server V. If both tests are passed, the AS accepts the user as authentic and must now convince the server that this user is authentic. To do so, the AS creates a ticket that contains the user's ID and network address and the server's ID. This ticket is encrypted using the secret key shared by the AS and this server. This ticket is then sent back to C. Because the ticket is encrypted, it cannot be altered by C or by an opponent.

With this ticket, C can now apply to V for service. C sends a message to V containing C's ID and the ticket. V decrypts the ticket and verifies that the user ID in the ticket is the same as the unencrypted user ID in the message. If these two match, the server considers the user authenticated and grants the requested service.

Each of the ingredients of message (3) is significant. The ticket is encrypted to prevent alteration or forgery. The server's ID (ID_V) is included in the ticket so that the server can verify that it has decrypted the ticket properly. ID_C is included in the ticket to indicate that this ticket has been issued on behalf of C. Finally, AD_C serves to counter the following threat. An opponent could capture the ticket transmitted in message (2), then use the name ID_C and transmit a message of form (3) from another workstation. The server would receive a valid ticket that matches the user ID and grant access to the user on that other workstation. To prevent this attack, the AS includes in the ticket the network address from which the original request came. Now the ticket is valid only if it is transmitted from the same workstation that initially requested the ticket.

A More Secure Authentication Dialogue

Although the foregoing scenario solves some of the problems of authentication in an open network environment, problems remain. Two in particular stand out. First, we would like to minimize the number of times that a user has to enter a password. Suppose each ticket can be used only once. If user C logs on to a workstation in the morning and wishes to check his or her mail at a mail server, C must supply a password to get a ticket for the mail server. If C wishes to check the mail several times during the day, each attempt requires reentering the password. We can improve matters by saying that tickets are reusable. For

a single logon session, the workstation can store the mail server ticket after it is received and use it on behalf of the user for multiple accesses to the mail server.

Under this scheme, however, it remains the case that a user would need a new ticket for every different service. If a user wished to access a print server, a mail server, a file server, and so on, the first instance of each access would require a new ticket and hence require the user to enter the password.

The second problem is that the earlier scenario involved a plaintext transmission of the password [message (1)]. An eavesdropper could capture the password and use any service accessible to the victim.

To solve these additional problems, we introduce a scheme for avoiding plaintext passwords and a new server, known as the ticket-granting server (TGS). The new but still hypothetical scenario is as follows:

Once per user logon session :

- (1) $C \rightarrow AS: ID_C || ID_{tgs}$
- (2) $AS \rightarrow C: E_{K_c}[Ticket_{tgs}]$

Once per type of service :

- (3) $C \rightarrow TGS: ID_C || ID_V || Ticket_{tgs}$
- (4) $TGS \rightarrow C: Ticket_v$

Once per service session :

- (5) $C \rightarrow V: ID_C || Ticket_v$

$$Ticket_{tgs} = E_{K_{tgs}}[ID_C || AD_C || ID_{tgs} || TS_1 || Lifetime_1]$$

$$Ticket_v = E_{K_v}[ID_C || AD_C || ID_v || TS_2 || Lifetime_2]$$

The new service, TGS, issues tickets to users who have been authenticated to AS. Thus, the user first requests a ticket-granting ticket ($Ticket_{tgs}$) from the AS. This ticket is saved by the client module in the user workstation. Each time the user requires access to a new service, the client applies to the TGS, using the ticket to authenticate itself. The TGS then grants a ticket for the particular service. The client saves each service-granting ticket and uses it to authenticate its user to a server each time a particular service is requested. Let us look at the details of this scheme:

1. The client requests a ticket-granting ticket on behalf of the user by sending its user's ID and password to the AS, together with the TGS ID, indicating a request to use the TGS service.
2. The AS responds with a ticket that is encrypted with a key that is derived from the user's password. When this response arrives at the client, the client prompts the user for his or her password, generates the key, and attempts to decrypt the incoming message. If the correct password is supplied, the ticket is successfully recovered.

Because only the correct user should know the password, only the correct user can recover the ticket. Thus, we have used the password to obtain credentials from Kerberos without having to transmit the password in plaintext. The ticket itself consists of the ID and

network address of the user and the ID of the TGS. This corresponds to the first scenario. The idea is that this ticket can be used by the client to request multiple service-granting tickets. So the ticket-granting ticket is to be reusable. We do not wish an opponent to be able to capture the ticket and use it, however. Consider the following scenario: An opponent captures the login ticket and waits until the user has logged off his or her workstation. Then the opponent either gains access to that workstation or configures his workstation with the same network address as that of the victim. The opponent would be able to reuse the ticket to spoof the TGS. To counter this, the ticket includes a time stamp, indicating the date and time at which the ticket was issued, and a lifetime, indicating the length of time for which the ticket is valid (e.g., eight hours). Thus, the client has a reusable ticket and need not bother the user for a password for each new service request. Finally, note that the ticket-granting ticket is encrypted with a secret key known only to the AS and the TGS. This prevents alteration of the ticket. The ticket is reencrypted with a key based on the user's password. This ensures that the ticket can be recovered only by the correct user, providing the authentication.

Now that the client has a ticket-granting ticket, access to any server can be obtained with steps 3 and 4:

3. The client requests a service-granting ticket on behalf of the user. For this purpose, the client transmits a message to the TGS containing the user's ID, the ID of the desired service, and the ticket-granting ticket.
4. The TGS decrypts the incoming ticket and verifies the success of the decryption by the presence of its ID. It checks to make sure that the lifetime has not expired. Then it compares the user ID and network address with the incoming information to authenticate the user. If the user is permitted access to the server V, the TGS issues a ticket to grant access to the requested service.

The service-granting ticket has the same structure as the ticket-granting ticket. Indeed, because the TGS is a server, we would expect that the same elements are needed to authenticate a client to the TGS and to authenticate a client to an application server. Again, the ticket contains a time stamp and lifetime. If the user wants access to the same service at a later time, the client can simply use the previously acquired service-granting ticket and need not bother the user for a password. Note that the ticket is encrypted with a secret key (K_v) known only to the TGS and the server, preventing alteration.

Finally, with a particular service-granting ticket, the client can gain access to the corresponding service with step 5:

5. The client requests access to a service on behalf of the user. For this purpose, the client transmits a message to the server containing the user's ID and the service-granting ticket. The server authenticates by using the contents of the ticket.

This new scenario satisfies the two requirements of only one password query per user session and protection of the user password.

Table 1 Summary of Kerberos Version 4 Message Exchanges

(a) Authentication Service Exchange: To Obtain Ticket-Granting Ticket	
(1) C → AS:	$ID_C ID_{tgs} TS_1$
(2) AS → C:	$E_{K_C} [K_{c,tgs} ID_{tgs} TS_2 Lifetime_2 Ticket_{tgs}]$ $Ticket_{tgs} = E_{K_{tgs}} [K_{c,tgs} ID_C AD_C ID_{tgs} TS_2 Lifetime_2]$
(b) Ticket-Granting Service Exchange: To Obtain Service-Granting Ticket	
(3) C → TGS:	$ID_V Ticket_{tgs} Authenticator_c$
(4) TGS → C:	$E_{K_{c,tgs}} [K_{c,v} ID_V TS_4 Ticket_v]$ $Ticket_{tgs} = E_{K_{tgs}} [K_{c,tgs} ID_C AD_C ID_{tgs} TS_2 Lifetime_2]$ $Ticket_v = E_{K_v} [K_{c,v} ID_C AD_C ID_V TS_4 Lifetime_4]$ $Authenticator_c = E_{K_{c,tgs}} [ID_C AD_C TS_3]$
(c) Client/Server Authentication Exchange: To Obtain Service	
(5) C → V:	$Ticket_v Authenticator_c$
(6) V → C:	$E_{K_{c,v}} [TS_5 + 1]$ (for mutual authentication) $Ticket_v = E_{K_v} [K_{c,v} ID_C AD_C ID_V TS_4 Lifetime_4]$ $Authenticator_c = E_{K_{c,v}} [ID_C AD_C TS_5]$

The Version 4 Authentication Dialogue

Although the foregoing scenario enhances security compared with the first attempt, two additional problems remain. The heart of the first problem is the lifetime associated with the ticket-granting ticket. If this lifetime is very short (e.g., minutes), the user will be repeatedly asked for a password. If the lifetime is long (e.g., hours), an opponent has a greater opportunity for replay. An opponent could eavesdrop on the network and capture a copy of the ticket-granting ticket and then wait for the legitimate user to log out. Then the opponent could forge the legitimate user's network address and send the message of step (3) to the TGS. This would give the opponent unlimited access to the resources and files available to the legitimate user. Similarly, if an opponent captures a service-granting ticket and uses it before it expires, the opponent has access to the corresponding service.

Thus, we arrive at an additional requirement. A network service (the TGS or an application service) must be able to prove that the person using a ticket is the same person to whom that ticket was issued.

The second problem is that there may be a requirement for servers to authenticate themselves to users. Without such authentication, an opponent could sabotage the configuration so that messages to a server were directed to another location. The false server would then be in a position to act as a real server and capture any information from the user and deny the true service to the user. These problems are now examined in turn (refer also to Table 1, which shows the actual Kerberos protocol).

First, consider the problem of captured ticket-granting tickets and the need to determine that the ticket presenter is the same as the client for whom the ticket was issued. The threat is that an opponent will steal the ticket and use it before it expires. To get around this problem, let us have the AS provide both the client and the TGS with a secret piece of information in a secure manner. Then the client can prove its identity to the TGS by revealing the secret information, again in a secure manner. An efficient way of accomplishing this is to use an encryption key as the

secure information; this is referred to as a session key in Kerberos.

Table 1a shows the technique for distributing the session key. As before, the client sends a message to the AS requesting access to the TGS. The AS responds with a message, encrypted with a key derived from the user's password (K_C), that contains the ticket. The encrypted message also contains a copy of the session key, $K_{c,tgs}$, where the subscripts indicate that this is a session key for C and TGS. Because this session key is inside the message encrypted with K_C , only the user's client can read it. The same session key is included in the ticket, which can be read only by the TGS. Thus, the session key has been securely delivered to both C and the TGS.

Before proceeding, note that several additional pieces of information have been added to this first phase of the dialogue. Message (1) includes a time stamp, so that the AS knows that the message is timely. Message (2) includes several elements of the ticket in a form accessible to C. This enables C to confirm that this ticket is for the TGS and to learn its expiration time.

Armed with the ticket and the session key, C is ready to approach the TGS. As before, C sends the TGS a message that includes the ticket plus the ID of the requested service (message (3) in Table 1b). In addition, C transmits an authenticator, which includes the ID and address of C's user and a time stamp. Unlike the ticket, which is reusable, the authenticator is intended for use only once and has a very short lifetime. The TGS can decrypt the ticket with the key that it shares with the AS. This ticket indicates that user C has been provided with the session key $K_{c,tgs}$. In effect, the ticket says, "Anyone who uses $K_{c,tgs}$ must be C." The TGS uses the session key to decrypt the authenticator. The TGS can then check the name and address from the authenticator with that of the ticket and with the network address of the incoming message. If all match, then the TGS is assured that the sender of the ticket is indeed the ticket's real owner. In effect, the authenticator says, "At time TS_3 , I hereby use $K_{c,tgs}$." Note that the ticket does not prove anyone's identity but is a way to distribute keys securely.

It is the authenticator that proves the client's identity. Because the authenticator can be used only once and has a short lifetime, the threat of an opponent stealing both the ticket and the authenticator for presentation later is countered.

The reply from the TGS, in message (4), follows the form of message (2). The message is encrypted with the session key shared by the TGS and C and includes a session key to be shared between C and the server V, the ID of V, and the time stamp of the ticket. The ticket itself includes the same session key.

C now has a reusable service-granting ticket for V. When C presents this ticket, as shown in message (5), it also sends an authenticator. The server can decrypt the ticket, recover the session key, and decrypt the authenticator.

If mutual authentication is required, the server can reply as shown in message (6) of Table 1. The server returns the value of the time stamp from the authenticator, incremented by 1, and encrypted in the session key. C can decrypt this message to recover the incremented time stamp. Because the message was encrypted by the session key, C is assured that it could have been created only by V. The content of the message assures C that this is not a replay of an old reply.

Finally, at the conclusion of this process, the client and server share a secret key. This key can be used to encrypt future messages between the two or to exchange a new random session key for that purpose.

Table 2 summarizes the justification for each of the elements in the Kerberos protocol, and Figure 1 provides a simplified overview of the action.

Kerberos Realms and Multiple Kerberis

A full-service Kerberos environment consisting of a Kerberos server, a number of clients, and a number of application servers requires the following:

1. The Kerberos server must have the user ID (UID) and hashed passwords of all participating users in its database. All users are registered with the Kerberos server.
2. The Kerberos server must share a secret key with each server. All servers are registered with the Kerberos server.

Such an environment is referred to as a **Kerberos realm**. The concept of *realm* can be explained as follows. A Kerberos realm is a set of managed nodes that share the same Kerberos database. The Kerberos database resides on the Kerberos master computer system, which should be kept in a physically secure room. A read-only copy of the Kerberos database might also reside on other Kerberos computer systems. All changes to the database must be made on the master computer system, however. Changing or accessing the contents of a Kerberos database requires the Kerberos master password. A related concept is that of a **Kerberos principal**, which is a service or user that is known to the Kerberos system. Each Kerberos principal is identified by its principal name. Principal names consist of three parts: a service or user name, an instance name, and a realm name

Networks of clients and servers under different administrative organizations typically constitute different

realms. That is, it generally is not practical, or does not conform to administrative policy, to have users and servers in one administrative domain registered with a Kerberos server elsewhere. Users in one realm may, however, need access to servers in other realms, and some servers may be willing to provide service to users from other realms, provided that those users are authenticated.

Kerberos provides a mechanism for supporting such interrealm authentication. For two realms to support interrealm authentication, a third requirement is added:

3. The Kerberos server in each interoperating realm shares a secret key with the server in the other realm. The two Kerberos servers are registered with each other.

The scheme requires that the Kerberos server in one realm trust the Kerberos server in the other realm to authenticate its users. Furthermore, the participating servers in the second realm must also be willing to trust the Kerberos server in the first realm.

With these ground rules in place, we can describe the mechanism as follows (Figure 2): A user wishing service on a server in another realm needs a ticket for that server. The user's client follows the usual procedures to gain access to the local TGS and then requests a ticket-granting ticket for a remote TGS (TGS in another realm). The client can then apply to the remote TGS for a service-granting ticket for the desired server in the realm of the remote TGS.

The details of the exchanges illustrated in Figure 2 are as follows (compare Table 1):

- (1) C → AS: $ID_c || ID_{tgs} || TS_1$
- (2) AS → C: $E_{K_c} [K_{c,tgs} || ID_{tgs} || TS_2 || Lifetime_2 || Ticket_{tgs}]$
- (3) C → TGS: $ID_{tgsrem} || Ticket_{tgs} || Authenticator_c$
- (4) TGS → C: $E_{K_{c,tgs}} [K_{c,tgsrem} || ID_{tgsrem} || TS_4 || Ticket_{tgsrem}]$
- (5) C → TGS_{rem}: $ID_{vrem} || Ticket_{tgsrem} || Authenticator_c$
- (6) TGS_{rem} → C: $E_{K_{c,tgsrem}} [K_{c,vrem} || ID_{vrem} || TS_6 || Ticket_{vrem}]$
- (7) C → V_{rem}: $Ticket_{vrem} || Authenticator_c$

The ticket presented to the remote server (V_{rem}) indicates the realm in which the user was originally authenticated. The server chooses whether to honor the remote request.

One problem presented by the foregoing approach is that it does not scale well to many realms. If there are N realms, then there must be $N(N - 1)/2$ secure key exchanges so that each Kerberos realm can interoperate with all other Kerberos realms.

KERBEROS VERSION 5

Version 5 of Kerberos is specified in RFC 1510 and provides a number of improvements over version 4 (Kohl, Neuman, & Ts'o, 1994). This section begins with an overview of the changes from version 4 to version 5 and then looks at the version 5 protocol.

Differences Between Versions 4 and 5

Version 5 is intended to address the limitations of version 4 in two areas: environmental shortcomings and technical

Table 2 Rationale for the Elements of the Kerberos Version 4 Protocol (page 1 of 2)

(a) Authentication Service Exchange	
Message (1)	Client requests ticket-granting ticket
<i>ID_C</i> :	Tells AS identity of user from this client
<i>ID_{TGS}</i> :	Tells AS that user requests access to TGS
<i>TS₁</i> :	Allows AS to verify that client's clock is synchronized with that of AS
Message (2)	AS returns ticket-granting ticket
<i>E_{K_c}</i> :	Encryption is based on user's password, enabling AS and client to verify password, and protecting contents of message (2)
<i>K_{c,v}</i> :	Copy of session key accessible to client; created by AS to permit secure exchange between client and TGS without requiring them to share a permanent key
<i>ID_{TGS}</i> :	Confirms that this ticket is for the TGS
<i>TS₂</i> :	Informs client of time this ticket was issued
<i>Lifetime₂</i> :	Informs client of the lifetime of this ticket
<i>Ticket_{TGS}</i> :	Ticket to be used by client to access TGS
(b) Ticket-Granting Service Exchange	
Message (3)	Client requests service-granting ticket
<i>ID_V</i> :	Tells TGS that user requests access to server V
<i>Ticket_{TGS}</i> :	Assures TGS that this user has been authenticated by AS
<i>Authenticator_C</i> :	Generated by client to validate ticket
Message (4)	TGS returns service-granting ticket
<i>K_{c,tgs}</i> :	Key shared only by C and TGS; protects contents of message (4)
<i>K_{c,v}</i> :	Copy of session key accessible to client; created by TGS to permit secure exchange between client and server without requiring them to share a permanent key
<i>ID_V</i> :	Confirms that this ticket is for server V
<i>TS₄</i> :	Informs client of time this ticket was issued
<i>Ticket_V</i> :	Ticket to be used by client to access server V
<i>Ticket_{TGS}</i> :	Reusable so that user does not have to reenter password
<i>E_{K_{tgs}}</i> :	Ticket is encrypted with key known only to AS and TGS, to prevent tampering
<i>K_{c,tgs}</i> :	Copy of session key accessible to TGS; used to decrypt authenticator, thereby authenticating ticket
<i>ID_C</i> :	Indicates the rightful owner of this ticket
<i>AD_C</i> :	Prevents use of ticket from workstation other than one that initially requested the ticket
<i>ID_{TGS}</i> :	Assures server that it has decrypted ticket properly
<i>TS₂</i> :	Informs TGS of time this ticket was issued
<i>Lifetime₂</i> :	Prevents replay after ticket has expired
<i>Authenticator_C</i> :	Assures TGS that the ticket presenter is the same as the client for whom the ticket was issued; has very short lifetime to prevent replay
<i>E_{K_{c,tgs}}</i> :	Authenticator is encrypted with key known only to client and TGS, to prevent tampering
<i>ID_C</i> :	Must match ID in ticket to authenticate ticket
<i>AD_C</i> :	Must match address in ticket to authenticate ticket
<i>TS₃</i> :	Informs TGS of time this authenticator was generated
(c) Client/Server Authentication Exchange	
Message (5)	Client requests service
<i>Ticket_V</i> :	Assures server that this user has been authenticated by AS
<i>Authenticator_C</i> :	Generated by client to validate ticket
Message (6)	Optional authentication of server to client
<i>E_{K_{c,v}}</i> :	Assures C that this message is from V
<i>TS₅ + 1</i> :	Assures C that this is not a replay of an old reply
<i>Ticket_V</i> :	Reusable so that client does not need to request a new ticket from TGS for each access to the same server
<i>E_{K_v}</i> :	Ticket is encrypted with key known only to TGS and server, to prevent tampering
<i>K_{c,v}</i> :	Copy of session key accessible to client; used to decrypt authenticator, thereby authenticating ticket
<i>ID_C</i> :	Indicates the rightful owner of this ticket
<i>AD_C</i> :	Prevents use of ticket from workstation other than one that initially requested the ticket
<i>ID_V</i> :	Assures server that it has decrypted ticket properly
<i>TS₄</i> :	Informs server of time this ticket was issued
<i>Lifetime₄</i> :	Prevents replay after ticket has expired
<i>Authenticator_C</i> :	Assures server that the ticket presenter is the same as the client for whom the ticket was issued; has very short lifetime to prevent replay
<i>E_{K_{c,v}}</i> :	Authenticator is encrypted with key known only to client and server, to prevent tampering
<i>ID_C</i> :	Must match ID in ticket to authenticate ticket
<i>AD_C</i> :	Must match address in ticket to authenticate ticket
<i>TS₅</i> :	Informs server of time this authenticator was generated

Figure 1: Overview of Kerberos.

deficiencies. Let us briefly summarize the improvements in each area (the following discussion follows the presentation in Kohl et al., 1994).

Version 4 of Kerberos was developed for use within the Project Athena environment and, accordingly, did not fully address the need to be of general purpose. This led to the following **environmental shortcomings**:

1. **Encryption system dependence:** Version 4 requires the use of DES. Export restriction on DES as well as doubts about its strength are thus of concern. In version 5, ciphertext is tagged with an encryption type identifier so that any encryption technique may be used. Encryption keys are tagged with a type and a length, allowing the same key to be used in different algorithms and allowing the specification of variations on a given algorithm.
2. **Internet protocol dependence:** Version 4 requires the use of Internet protocol (IP) addresses. Other address types, such as the ISO (International Standards Organization) network address, are not accommodated. Version 5 network addresses are tagged with type and length, allowing any network address type to be used.
3. **Message byte ordering:** In version 4, the sender of a message employs a byte ordering of its own choosing

and tags the message to indicate least significant byte in lowest address or most significant byte in lowest address. This technique works but does not follow established conventions. In version 5, all message structures are defined using Abstract Syntax Notation One (ASN.1) and Basic Encoding Rules (BER), which provide an unambiguous byte ordering.

4. **Ticket lifetime:** Lifetime values in version 4 are encoded in an 8-bit quantity in units of five minutes. Thus, the maximum lifetime that can be expressed is $2^8 \times 5 = 1280$ minutes, or a little over 21 hours. This may be inadequate for some applications (e.g., a long-running simulation that requires valid Kerberos credentials throughout execution). In version 5, tickets include explicit start and end times, allowing tickets with arbitrary lifetimes.
5. **Authentication forwarding:** Version 4 does not allow credentials issued to one client to be forwarded to some other host and used by some other client. This capability would enable a client to access a server and have that server access another server on behalf of the client. For example, a client issues a request to a print server that then accesses the client's file from a file server, using the client's credentials for access. Version 5 provides this capability.

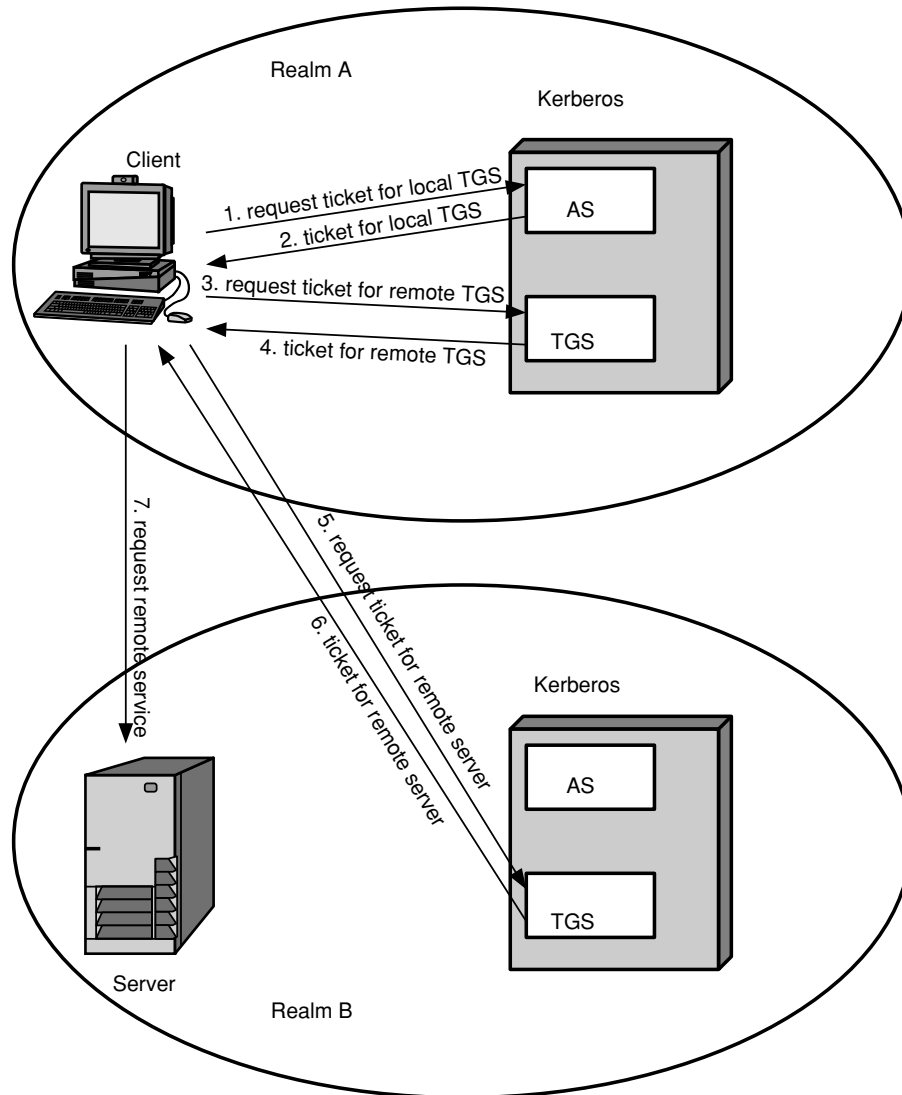

Figure 2: Request for service in another realm.

6. **Interrealm authentication:** In version 4, interoperability among N realms requires on the order of N^2 Kerberos-to-Kerberos relationships, as described earlier. Version 5 supports a method that requires fewer relationships, as described shortly.

Apart from these environmental limitations, there are *technical deficiencies* in the version 4 protocol. Most of these deficiencies were documented in (Bellare & Merritt, 1990), and version 5 attempts to address these. The deficiencies are the following:

1. **Double encryption:** Note in Table 1 [messages (2) and (4)] that tickets provided to clients are encrypted twice, once with the secret key of the target server and then again with a secret key known to the client. The second encryption is not necessary and is computationally wasteful.
2. **PCBC encryption:** Encryption in version 4 makes use of a nonstandard mode of DES known as propagating block chaining (PCBC). It has been demonstrated that

this mode is vulnerable to an attack involving the interchange of ciphertext blocks (Kohl, 1989). PCBC was intended to provide an integrity check as part of the encryption operation. Version 5 provides explicit integrity mechanisms, allowing the standard CBC mode to be used for encryption.

3. **Session keys:** Each ticket includes a session key that is used by the client to encrypt the authenticator sent to the service associated with that ticket. In addition, the session key may subsequently be used by the client and the server to protect messages passed during that session. However, because the same ticket may be used repeatedly to gain service from a particular server, there is the risk that an opponent will replay messages from an old session to the client or the server. In version 5, it is possible for a client and server to negotiate a subsession key, which is to be used only for that one connection. A new access by the client would result in the use of a new subsession key.
4. **Password attacks:** Both versions are vulnerable to a password attack. The message from the AS to the client

Table 3 Summary of Kerberos Version 5 Message Exchanges

(a) Authentication Service Exchange: To Obtain Ticket-Granting Ticket	
(1)	$C \rightarrow AS: \text{Options} \parallel ID_c \parallel Realm_c \parallel ID_{tgs} \parallel Times \parallel Nonce_1$
(2)	$AS \rightarrow C: Realm_c \parallel ID_c \parallel Ticket_{tgs} \parallel E_{K_c}[K_{c,tgs} \parallel Times \parallel Nonce_1 \parallel Realm_{tgs} \parallel ID_{tgs}]$ $Ticket_{tgs} = E_{K_{tag}}[Flag \parallel K_{c,tag} \parallel Realm_c \parallel ID_c \parallel AD_c \parallel Times]$
(b) Ticket-Granting Service Exchange: To Obtain Service-Granting Ticket	
(3)	$C \rightarrow TGS: \text{Options} \parallel ID_v \parallel Times \parallel Nonce_2 \parallel Ticket_{tgs} \parallel Authenticator_c$

includes material encrypted with a key based on the client's password. An opponent can capture this message and attempt to decrypt it by trying various passwords. If the result of a test decryption is of the proper form, then the opponent has discovered the client's password and may subsequently use it to gain authentication credentials from Kerberos. Version 5 does provide a mechanism known as preauthentication, which should make password attacks more difficult, but it does not prevent them.

The Version 5 Authentication Dialogue

Table 3 summarizes the basic version 5 dialogue. This is best explained by comparison with version 4 (Table 1). First, consider the *authentication service exchange*. Message (1) is a client request for a ticket-granting ticket. As before, it includes the ID of the user and the TGS. The following new elements are added:

- **Realm:** Indicates realm of user
- **Options:** Used to request that certain flags be set in the returned ticket
- **Times:** Used by the client to request the following time settings in the ticket:
 - from: the desired start time for the requested ticket
 - till: the requested expiration time for the requested ticket
 - rtime: requested renew-till time
- **Nonce:** A random value to be repeated in message (2) to ensure that the response is fresh and has not been replayed by an opponent

Message (2) returns a ticket-granting ticket, identifying information for the client, and a block encrypted using the encryption key based on the user's password. This block includes the session key to be used between the client and the TGS, times specified in message (1), the nonce from message (1), and TGS identifying information. The ticket itself includes the session key, identifying infor-

mation for the client, the requested time values, and flags that reflect the status of this ticket and the requested options. These flags introduce significant new functionality to version 5. For now, we defer a discussion of these flags and concentrate on the overall structure of the version 5 protocol.

Let us now compare the *ticket-granting service exchange* for versions 4 and 5. We see that message (3) for both versions includes an authenticator, a ticket, and the name of the requested service. In addition, version 5 includes requested times and options for the ticket and a nonce, all with functions similar to those of message (1). The authenticator itself is essentially the same as the one used in version 4.

Message (4) has the same structure as message (2), returning a ticket plus information needed by the client, the latter encrypted with the session key now shared by the client and the TGS.

Finally, for the *client-server authentication exchange*, several new features appear in version 5. In message (5), the client may request as an option that mutual authentication is required. The authenticator includes several new fields as follows:

- **Subkey:** The client's choice for an encryption key to be used to protect this specific application session. If this field is omitted, the session key from the ticket ($K_{c,v}$) is used.
- **Sequence number:** An optional field that specifies the starting sequence number to be used by the server for messages sent to the client during this session. Messages may be sequence numbered to detect replays.

If mutual authentication is required, the server responds with message (6). This message includes the time stamp from the authenticator. Note that in version 4, the time stamp was incremented by one. This is not necessary in version 5 because the nature of the format of messages is such that it is not possible for an opponent to

Table 4 Kerberos Version 5 Flags

INITIAL	This ticket was issued using the AS protocol and not issued based on a ticket-granting ticket.
PRE-AUTHENT	During initial authentication, the client was authenticated by the KDC before a ticket was issued.
HW-AUTHENT	The protocol employed for initial authentication required the use of hardware expected to be possessed solely by the named client.
RENEWABLE	Tells TGS that this ticket can be used to obtain a replacement ticket that expires at a later date.
MAY-POSTDATE	Tells TGS that a postdated ticket may be issued based on this ticket-granting ticket.
POSTDATED	Indicates that this ticket has been postdated; the end server can check the authtime field to see when the original authentication occurred.
INVALID	This ticket is invalid and must be validated by the KDC before use.
PROXIABLE	Tells TGS that a new service-granting ticket with a different network address may be issued based on the presented ticket.
PROXY	Indicates that this ticket is a proxy.
FORWARDABLE	Tells TGS that a new ticket-granting ticket with a different network address may be issued based on this ticket-granting ticket.
FORWARDED	Indicates that this ticket has either been forwarded or was issued based on authentication involving a forwarded ticket-granting ticket.

create message (6) without knowledge of the appropriate encryption keys. The subkey field, if present, overrides the subkey field, if present, in message (5). The optional sequence number field specifies the starting sequence number to be used by the client.

Ticket Flags

The flags field included in tickets in version 5 supports expanded functionality compared with that available in version 4. Table 4 summarizes the flags that may be included in a ticket.

The INITIAL flag indicates that this ticket was issued by the AS, not by the TGS. When a client requests a service-granting ticket from the TGS, it presents a ticket-granting ticket obtained from the AS. In version 4, this was the only way to obtain a service-granting ticket. Version 5 provides the additional capability that the client can get a service-granting ticket directly from the AS. The utility of this is as follows: A server, such as a password-changing server, may wish to know that the client's password was recently tested.

The PRE-AUTHENT flag, if set, indicates that when the AS received the initial request [message (1)], it authenticated the client before issuing a ticket. The exact form of this preauthentication is left unspecified. As an example, the MIT implementation of version 5 has encrypted time stamp preauthentication, enabled by default. When a user wants to get a ticket, he or she has to send to the AS a preauthentication block containing a random confounder, a version number, and a time stamp, encrypted in the client's password-based key. The AS decrypts the block and will not send a ticket-granting ticket back unless the time stamp in the preauthentication block is within the allowable time skew (time interval to account for clock drift and network delays). Another possibility is the use of a smart card that generates continually changing passwords that are included in the preauthenticated messages. The passwords generated by the card can be based on a user's password but be transformed by the card so that, in effect, arbitrary passwords are used. This prevents

an attack based on easily guessed passwords. If a smart card or similar device was used, this is indicated by the HW-AUTHENT flag.

When a ticket has a long lifetime, there is the potential for it to be stolen and used by an opponent for a considerable period. If a short lifetime is used to lessen the threat, then overhead is involved in acquiring new tickets. In the case of a ticket-granting ticket, the client would either have to store the user's secret key, which is clearly risky, or repeatedly ask the user for a password. A compromise scheme is the use of renewable tickets. A ticket with the RENEWABLE flag set includes two expiration times: one for this specific ticket and one that is the latest permissible value for an expiration time. A client can have the ticket renewed by presenting it to the TGS with a requested new expiration time. If the new time is within the limit of the latest permissible value, the TGS can issue a new ticket with a new session time and a later specific expiration time. The advantage of this mechanism is that the TGS may refuse to renew a ticket reported as stolen.

A client may request that the AS provide a ticket-granting ticket with the MAY-POSTDATE flag set. The client can then use this ticket to request a ticket that is flagged as POSTDATED and INVALID from the TGS. Subsequently, the client may submit the postdated ticket for validation. This scheme can be useful for running a long batch job on a server that requires a ticket periodically. The client can obtain a number of tickets for this session at once, with spread-out time values. All but the first ticket are initially invalid. When the execution reaches a point in time when a new ticket is required, the client can get the appropriate ticket validated. With this approach, the client does not have to use its ticket-granting ticket repeatedly to obtain a service-granting ticket.

In version 5, it is possible for a server to act as a proxy on behalf of a client, in effect adopting the credentials and privileges of the client to request a service from another server. If a client wishes to use this mechanism, it requests a ticket-granting ticket with the PROXIABLE flag set. When this ticket is presented to the TGS, the TGS is

permitted to issue a service-granting ticket with a different network address; this latter ticket will have its PROXY flag set. An application receiving such a ticket may accept it or require additional authentication to provide an audit trail. For a discussion of some of the possible uses of the proxy capability, see Neuman (1993).

The proxy concept is a limited case of the more powerful forwarding procedure. If a ticket is set with the FORWARDABLE flag, a TGS can issue to the requestor a ticket-granting ticket with a different network address and the FORWARDED flag set. This ticket can then be presented to a remote TGS. This capability allows a client to gain access to a server on another realm without requiring that each Kerberos maintain a secret key with Kerberos servers in every other realm. For example, realms could be structured hierarchically. Then a client could walk up the tree to a common node and then back down to reach a target realm. Each step of the walk would involve forwarding a ticket-granting ticket to the next TGS in the path.

PERFORMANCE ISSUES

As client-server applications become more popular, larger and larger client-server installations are appearing. A case can be made that the larger the scale of the networking environment, the more important it is to have logon authentication. The question is, what impact does Kerberos have on performance in a large-scale environment?

Fortunately, the answer is that there is little performance impact if the system is properly configured. Keep in mind that tickets are reusable. Therefore, the amount of traffic needed for the granting ticket requests is modest. With respect to the transfer of a ticket for logon authentication, the logon exchange must take place anyway, so again the extra overhead is modest.

A related issue is whether the Kerberos server application requires a dedicated platform or can share a computer with other applications. It probably is not wise to run the Kerberos server on the same machine as a resource-intensive application such as a database server. Moreover, the security of Kerberos is best assured by placing the Kerberos server on a separate, isolated machine.

Finally, in a large system, is it necessary to go to multiple realms to maintain performance? Probably not. The 32,000-node application cited earlier is supported by a single Kerberos server. Rather, the motivation for multiple realms is administrative. If you have geographically separate clusters of machines, each with its own network administrator, then one realm per administrator may be convenient. This is not always the case, however.

CONCLUSION

Kerberos is an authentication protocol based on conventional encryption that has received widespread support and is used in a variety of systems. It is designed to provide strong authentication for client-server applications. The Kerberos protocol uses strong cryptography so that a client can prove its identity to a server (and vice versa) across an insecure network connection. After a client and server have used Kerberos to prove their identity, they can

also encrypt all of their communications to ensure privacy and data integrity as they go about their business.

Kerberos does not solve all of the security problems facing a network manager, but it addresses many of the concerns raised in a client-server or similar networked environment. For the authentication application that Kerberos addresses, there are few other general-purpose alternatives. Most of the available solutions are limited to a single platform or single network operating system, whereas Kerberos is an Internet standard intended for use across all platforms and operating systems.

Kerberos is gaining increasing acceptance. For example, the Open Software Foundation's DCE (Distributed Computing Environment) uses version 5 of Kerberos for user authentication, and a number of vendors now offer Kerberos as part of their networking products. The public domain versions enjoy widespread use as well. As a tool for user authentication, Kerberos is likely to be one of the dominant approaches in the coming years.

GLOSSARY

Authentication A process used to verify the identity of a user involved in a data or message exchange.

Authentication Server A centralized Kerberos server with the function of authenticating users to servers and servers to users.

Kerberos An authentication protocol based on conventional encryption. In essence, Kerberos requires that a user prove his or her identity for each service invoked and, optionally, requires servers to prove their identity to clients.

Kerberos Realm An environment consisting of a Kerberos server, a number of clients, and a number of application servers.

Lifetime In Kerberos, the length of time for which a ticket is valid.

Nonce An identifier or number that is used only once.

Subkey A Kerberos client's choice for an encryption key to be used to protect this specific application session.

Ticket A package of information in a Kerberos exchange that includes identifiers and other parameters.

Ticket-Granting Server (TGS) A Kerberos server that creates tickets for use by Kerberos clients.

TCP/IP LIMITATIONS AND IPsec RESPONSE

Nowadays, most of the Internet flows are left unprotected against cyber attacks. A packet that traverses the network can be intercepted by any host connected to the network (and lying along the transmission path). The packet can be replayed and its content can be modified or reproduced. Even the checksums, which are part of the Internet Packet format, if used as a security mechanism, cannot protect a packet from unauthorized alteration. The checksums were intended to protect against corruption caused by malfunctioning devices. If the data alteration is intentional, the attacker can recompute the checksum, and the packet will appear to be perfectly intact. This situation exists mainly because no real protection mechanism has been integrated into TCP/IP stack.

In order to provide security to their existing systems, many companies use firewalls. Such systems stand between LANs (which are considered as a trusted network) and the outside domain (which represents the untrusted world). Firewalls attempt to analyze the incoming packets of information and determine if they contain valid information. Integrating firewalls is considered a good security solution, however, this solution fails to provide various important security services such as origin authentication and anti-replay.

Recently, there has been an increasing demand to protect Internet flows while continuing to use the existing infrastructure. To achieve this goal, IPsec (IP security protocol) has been standardized by the IETF for IPv4. Because of the need for an IPv4 upgrade, it was reasonable that the new version of the Internet Protocol (IPv6) should provide IPsec as a predefined security system. Moreover, because the Internet is a large open network, the transition to the new version of the IP will not be immediate. Implementation should be compatible and adaptable to IPv4 (AR series Router References Manual, 2003).

IPsec is a security protocol integrated to the IP layer, offering flexible cryptographic security services. These services are:

- **Data origin authentication/Connectionless data integrity:** This states that in a protected IP datagram, the source address, destination address, and datagram content cannot be maliciously modified in transit without detection by the receiver.
- **Replay protection:** This means that protected packets use a replay sequence number (provided from an increasing counter) to avoid replay attacks. Moreover, a replay sequence number window is defined, and only packets whose sequence number is in the window are accepted.
- **Confidentiality:** This means that an individual that is not taking part in a packet protection process (or security association) can not read the packet payload.

The above objectives are met through the use of traffic security protocols, which are the AH and the ESP. The IP AH protocol provides authentication for connectionless integrity and data origin authentication of IP packets. AH provides protection to an IP packet and to any further headers added by AH. The ESP protocol provides one or both of encryption for confidentiality and authentication for connectionless integrity and data origin authentication. ESP allows protection to an IP packet, but not to any further headers added by ESP. AH and ESP may be applied either alone or together to provide the desired set of security services for selected IP packets. They are designed to be algorithm-independent. This allows new algorithms to be added without affecting other parts of the implementation. The standards specify a set of default algorithms to ensure interoperability between IPsec implementations (Randall, Stephen, 1998). The use of these algorithms, with IPsec traffic protection and key management protocols, is intended to permit system and application developers to deploy high quality Internet layer

*Corresponding author

and cryptographic security technologies (AR series Router References Manual, 2003).

IPSec sets up security associations (SAs), which refer to a set of attributes that provide security services to the traffic it carries. These services are afforded to an SA by the use of AH, or ESP, but not both. If both AH and ESP protection are needed by a traffic stream, then two or more SAs are created to provide protection to the traffic stream. To secure typical bi-directional communication between two hosts, or between two security gateways, two Security Associations (one for each direction) are required (AR series Router References Manual, 2003). SA can be nested, allowing different IPSec relationships to be active on the same link.

In order to establish a SA, IPSec relies on the Internet security association and key management protocol (ISAKMP, (Maughan, Schertler, Turner, 1998)), which defines protocol formats and procedures for security negotiation. An SA defines the used cryptographic algorithms and keys. It must be established between two peers before using IPSec and be defined for one of the two IPSec protocols (AH or ESP).

In addition to the SA concept, two other notions characterize the IPSec response. They are the security policy and the notion of mode. Security Policy constitutes a major feature of IPSec because it defines the rules used by the protocols to establish the behavior of the IPSec Policy over the traffic that flows to/from/via a node where IPSec is implemented. An IPSec rule consists of a series of data that determine a certain treatment to a specified traffic. As an example of policy to define these rules can contain: (a) a list of traffic flows, which can be defined by their source addresses, destination address, transport-level protocol, and the port; (b) a flow action, which specifies what treatment (e.g., allow, block, or negotiate security) to apply; (c) authentication methods, which defines the options for authentication during the initialization process, etc.

IPSec can operate in two modes: transport mode and tunnel mode. The transport mode is used between end-system hosts. It cannot be applied by an intermediate node (Router), because of the fragmentation and reassembly requirements. It is used by adding a new header to the IP and applying the cryptographic functions. With this method, the IP packet is totally protected without the protection of all the header fields.

With the tunnel mode, a new IP packet is created using an IP-in-IP tunneling construction. The secure functions are applied to the new packet as in transport mode. Therefore, the whole inner original packet is protected by IPSec (including header and payload), since this packet forms the payload of the outer packet. This mode provides better protection against traffic flow analysis. It is the unique mode between two security gateways. Another protocol used to negotiate the cryptographic keys is the IKE (Internet Key Exchange protocol). However, due to space limitation, we will not cover this aspect of the IPSec suite.

IPsec ARCHITECTURE

There are two major databases in the IPSec scheme: the Security Policy Database and the Security Association

Database. The first database specifies the policies that determine the disposition of all IP inbound or outbound traffic from a host or security gateway in IPSec implementation. The security association database contains parameters that are associated with each security association. The main components of an IPSec architecture includes the A, the ESP, the Security Association Database (SAD), and the Security Policy Database (SPD).

Security Association Database

As defined below, a Security Association (SA) represents a contract between two peers and defines the security services that will be used between those two peers. The SA describes the cryptographic algorithms and the keys that will be used. The SAs are dynamic since they are expected to be regularly modified. The lifetime of an SA is limited by a maximum time duration or maximum number of protected bytes.

A security association is uniquely identified by a Security Parameter Index (SPI), an IP Destination Address, and a security protocol identifier (i.e., AH or ESP). By default, the Destination Address may be a Unicast address, an IP broadcast address, or a multicast group address. However, currently IPSec SA management mechanisms are defined only for Unicast address.

Two types of SA mode are defined: transport mode and tunnel mode SA. A transport mode SA defines a security association between two hosts. In IPv4, a transport mode security protocol header appears immediately after the IP header and any options, and before any higher layer protocols (e.g., TCP or UDP). In the same mode, in IPv6, the security protocol header appears after the base IP header and extensions, but it may appear before or after destination options, and before higher layer protocols (Kent, Atkinson, 1998).

A tunnel mode SA is essentially to be applied to a tunnel IP. Whenever the end of a security association is a security gateway, the SA should be in a tunnel mode. Therefore, a SA between two security gateways is always a tunnel mode SA since it is a SA between a host and a security gateway. We notice that for the case where traffic is destined to a security gateway (e.g., SNMP commands), which is acting as a host, a transport mode is allowed. Two hosts may establish a tunnel mode SA between them. The requirement for any transit traffic SA involving a security gateway to be a tunnel SA arises due to the need of avoiding potential problems with regard to fragmentation and reassembly of IPSec packets.

For a tunnel mode SA, there is an "outer" IP header that specifies the IPSec processing destination, and an "inner" IP header that specifies the final destination for the packet. The security protocol header appears after the outer IP header and before the inner IP header. If AH is employed in the tunnel mode, portions of the outer IP header afford protection, as well as all of the tunneled IP packet (i.e., all of the inner IP header is protected, as well as higher layer protocols). If ESP is employed in the same mode, the protection is afforded only to the tunneled packet, not to the outer header (Randall, Stephen, 1998).

As shown by Figure 1, data is normally processed at the network layer, where it is ultimately handed to the

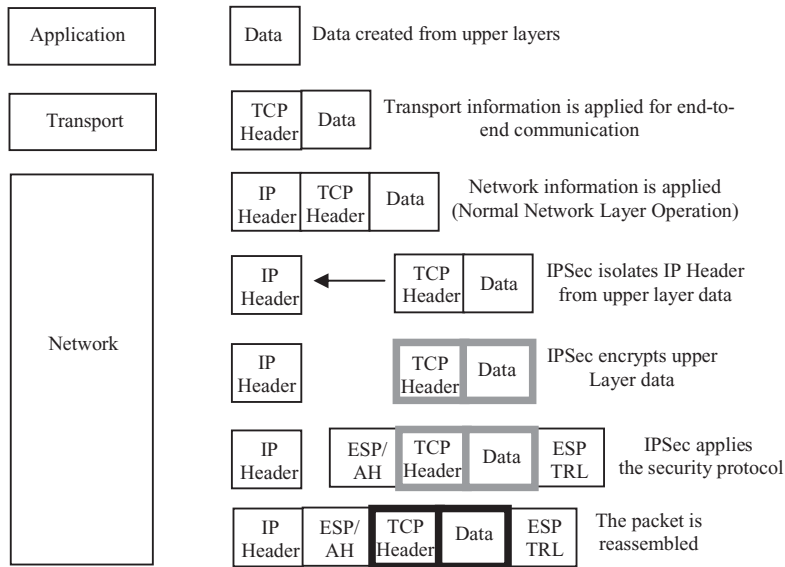

Figure 1: IPsec operations within transport mode (Tiller, 2001).

IPsec processing. In the transport mode, IPsec separates the original IP header from the remaining portions of the packet. The upper layer components are encrypted, and the AH header is calculated and inserted between the original IP header and the encrypted payloads of the original packet. By inserting an authentication protocol, the packet is afforded integrity of the data.

In the tunnel mode, IPsec encapsulates and encrypts the entire original packet and the AH protocol provides message integrity. After the creation of the authentication protocol header, a new IP header will be constructed to allow the remote client to send its data to the VPN gateway. Figure 2 presents the operation performed on the traffic of packets within a tunnel mode.

A SAD is designed by the IPsec response to contain all the SAs that are currently established with different IPsec peers. SAD is logically partitioned in two parts: the first part contains the SA protecting ingoing traffic, the second part contains the SA protecting outgoing traffic.

An SAD entry contains at least the following fields (Jourez, 2000):

- Destination IP address, IPsec protocol, and SPI: These are used to report on the packet destination, the IPsec protocol to be used (AH or ESP), and the Security Parameters Index (SPI), which is a 32 bit number, used to distinguish between the SA established to the same destination with the same IPsec protocol. These three values are a unique identifier for a specific SA.
- Sequence number counter: It is a 32 bit value used to generate a sequence number.
- Sequence counter overflow: This is a flag indicating whether a sequence number is exceeded. This value should prevent transmission of additional packets on the SA.
- Anti-replay window: This is a 32 bit counter and a bit-map or equivalent used to determine whether an inbound AH or ESP packet is a replay.

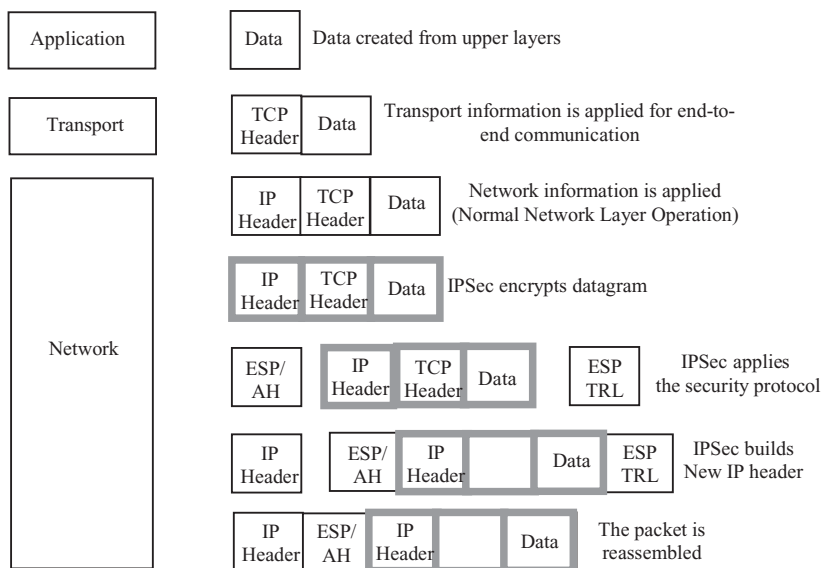

Figure 2: IPsec operations within tunnel mode (Tiller, 2001).

- **AH parameters:** This includes the authentication algorithm and the key to be used if AH is specified by the SA.
- **ESP parameters for authentication:** This includes the authentication algorithm and the key to be used if ESP is specified by the SA with authentication.
- **ESP parameters for ciphering:** This contains the encryption algorithm, the key and the initialization vector (IV) used if the SA specifies ESP.
- **Mode:** This field defines the mode used for the flow protection associated with the SA, i.e., tunnel or transport mode.
- **Lifetime of the SA:** This defines a time frame during which the SA will be used, or a maximum number of bytes protected by the SA.

A security policy may call for a combination of services for a particular traffic flow that is not achievable with a single SA. In such situations, it will be necessary to employ multiple SA to implement the required security policy. This is called “Security Association bundle” or “SA bundle.” It is applied to a sequence of SA through which traffic must be processed to satisfy a security policy. The sequence order is defined by the policy. The SA that comprises a bundle may terminate at different endpoints. For example, one SA may extend between a mobile host and a security gateway and the next SA, may extend to a host behind the gateway.

Security Policy Database

A security policy database (SPD) contains the policies defined by the security system manager. As mentioned in the previous section, policies specify the security services that must be enforced. The SPD must be consulted during the processing of all traffic (incoming and outgoing), including non-IPSec traffic. When the traffic must be processed by IPSec, the SPD contains information about which IPSec protocol is used. In order to support this, the SPD requires distinct entries for inbound and outbound traffic. It is logically partitioned into two parts: one part considers the incoming traffic, while the other part considers the outgoing traffic.

The SPD must discriminate between traffic afforded by IPSec protection and traffic allowed to bypass IPSec. For any outbound or inbound datagram, three processing choices are possible: discard, bypass, or apply IPSec. The first choice refers to the traffic that is not allowed by the host to traverse the security gateway, or to be delivered to an application. The second choice refers to the traffic that is allowed to pass without additional IPSec protection. The third choice refers to the traffic afforded by IPSec protection. For such traffic, the SPD must specify the security services to be provided, protocols to be employed,

and algorithms to be used. The SPD contains an ordered list of policy entries. Each policy entry is keyed by one or more selectors that define the IP traffic, encapsulated by this policy entry. These define the granularity of policies or SA. Each entry includes an indication of whether traffic matching this policy will be bypassed, discarded, or subject to IPSec processing. If IPSec processing is applied, the entry includes an SA (or SA bundle) specification, listing the IPSec protocols, modes, and algorithms to be employed, including any next requirements.

The selectors are defined by at least the following fields: destinations IP address, sources IP address, name (e.g., DNS user identifier, X.500 name, etc), data sensitivity level, transport layer protocol, and source and destination ports. A policy may specify whether a given SA must be negotiated for each different traffic flow matching the selector, or if a given SA may be used for those different flows. This is called the granularity of the policy. Finally, the policies in the SPD point to the SAs when they exist. This is a convenient way to retrieve a SA matching a specific policy.

Authentication Header

As mentioned above, AH ensures connectionless data integrity, data origin authentication, and optionally protection against replay for the entire packet. In fact, what is really authenticated is being in possession of shared secret, and not the IP address or the user having generated the packet. The authentication service offered by AH applies to the whole IP packet, payload as well as headers. Therefore, with AH, the data is readable, but remains protected from modification.

AH integrity and authentication are provided jointly, using an additional block added to protect the message. This block is called an Integrity Check Value (ICV). Thus, it is a generic term used to indicate either a Message Authentication Code (MAC) or a digital signature. Currently, all the proposed algorithms are obtained using a one-way hash function and a secret key. A generation of a digital signature is also possible to use a public key cryptography. Protection against replay is provided by a sequence number and its use can be selected by the recipient at the options negotiation moment.

The format of AH is depicted by Figure 3. It contains the following fields:

- **Next header.** This is an 8-bit value that gives the type of the payload that follows immediately the authenticator header (e.g., TCP, UDP).
- **Payload length.** This field contains an 8-bit value equal to the length of the AH, expressed as a number of 16-bit words contained in the header minus 1.
- **Reserved field.** This field is reserved for future use. Currently it is not used.

0	Next Header	Payload length	Reserved	31
Security Parameters Index (SPI)				
Sequence Number Field				
Authentication Data (variable)				

Figure 3: AH format (Doraswamy, Harkins, 1999).

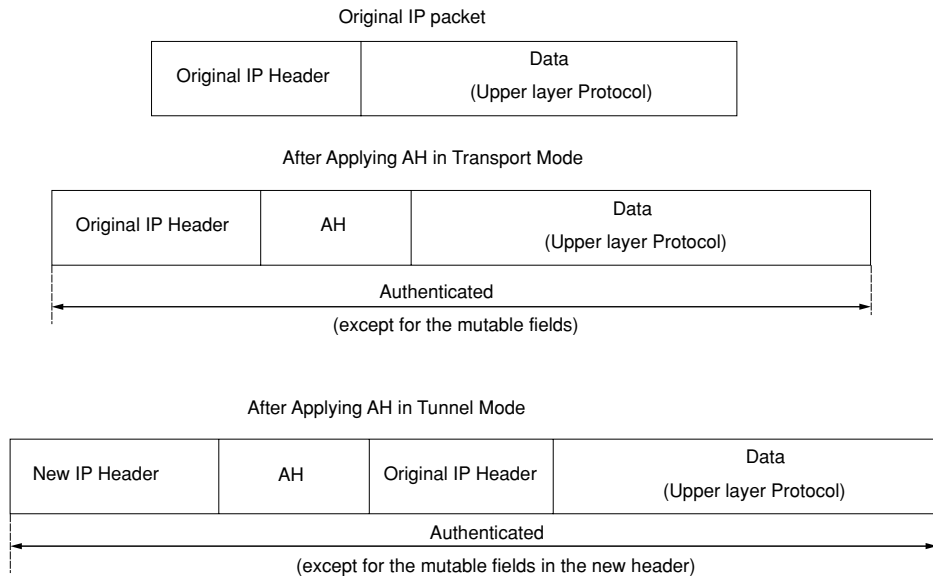

Figure 4: Position of AH in transport and Tunnel modes (IPv4) (Labouret, DAVIS, 2000, 2001).

- SPI field. This field is used to identify the appropriate SA.
- Sequence number. This field indicates the sequence number used for anti-replay. It is set by the source IPsec system and is monotonically increasing.
- Authentication data. This carries the authentication data using at least HMAC-MD5 and HMAC-SHA1 (Niels, Angelos, 2000). It is aligned to 32 bits by padding bits if necessary.

In the IPv6 context, AH is viewed as an end-to-end payload, and thus should appear after hop-by-hop, routing, and fragmentation extension headers. The destination extension header(s) options could appear either before or after the AH header depending on the semantics desired. In tunnel mode, the “inner” IP header carries the ultimate source and destination addresses, while an “outer” IP header may contain distinct IP addresses. Figure 4 indicates the position of AH and the service brought depending on the selected mode (transport or tunnel).

The authentication is computed over the whole IP packet in both tunnel and transport mode. This can lead to

some problems since there are fields in the IP header (like TTL field) that may be modified while flowing through the network. To solve this problem, IPsec proposes to reset to 0, the fields included in the authentication computation.

Encapsulating Security Protocol (ESP)

ESP can ensure confidentiality, original authentication and data integrity, anti-replay service, and partial flow confidentiality (Kent, Atkinson, 1998). The different services may be selected separately. As in AH, authentication and integrity are two services that are often regrouped under the term “Authentication”; they are provided by the use of a Message Authentication Code (MAC). Protection against replay can be selected only if authentication was applied. It is provided by a sequence number, which is checked by the receiver of the packets (Labouret, 2000). In addition to the fields used in AH, the following fields of ESP are depicted in Figure 5:

- Initialization Vector (IV). This a vector used by the (current) ESP encryption algorithms.

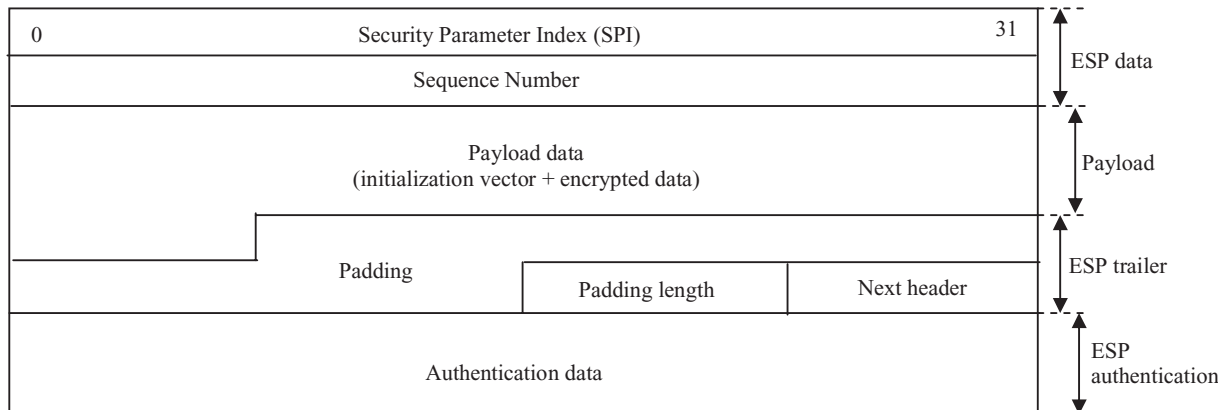

Figure 5: ESP format (Kent, Atkinson, 1998).

Figure 6: Position of ESP in transport and tunnel modes (IPv4) (Labouret, DAVIS, 2000, 2001).

- **Padding.** Padding bits are used to align the payload and the two following fields on a 32 bit boundary, as required by the encryption algorithm.
- **Pad length.** This is the size in bytes of the used padding.

If the confidentiality service is provided, then the Payload data, Padding, and Next header are encrypted. The initialization vector, which belongs logically to the Payload data is obviously never encrypted. In a minimal implementation, the selected encryption algorithm is DES. Other algorithms such as triple DES and AES may be used. In authentication service, ESP uses the same authentication algorithms as those used by AH. Figure 6 depicts the structure of an IPsec packets in its two modes of operation: transport and tunnel (Labouret, 2000).

IPsec PROCESSING

The IPsec processing is mainly classified into outbound versus inbound processing and AH versus ESP applications. Although the interface to various components of IPsec remains the same, packet processing is different between input and output. Protocol processing can be classified into SPD processing, SA processing, header processing, and transform processing. The SPD and SA processing are the same for both AH and ESP. The transform and header processing are differently realized with AH and ESP.

Outgoing Traffic Management

IPsec is applied to an outbound packet only after an IPsec implementation determines that there are associations between the packet and the SA. The first step in the IPsec processing is to query the SPD to find the applied policy on the outgoing packet. The selector is constructed from the traffic information found in the packet, such as, the source and destination IP address, the transport protocol, and the source and destination ports. The policy could specify the action to perform on the packet. If the packet must be discarded then, the action is performed and the IPsec processing ends. If the packet must be processed

(i.e., IPsec applied), then either a SA exists for the given traffic, and so the SA is retrieved from the SAD, or the SA does not exist, and thus a new SA has to be created for the traffic.

If the SA is retrieved, the system gets the mode to be applied. If the tunnel mode is provided, then a new packet is created. The original packet becomes the payload of the new packet. In this case, the information of the original packet is left unmodified except for the TTL field of the IP header. Therefore, the checksum of the original packet must be recomputed. The header of the new IP packet is constructed from the original header by copying or computing parameters based on the SA content. Once the new packet is created, it may be processed by AH or ESP according to the SA. The next header field should be filled with the identifier of AH or ESP. After the AH or ESP processing, the packet could be reprocessed again by IPsec, if a bundle of SA is applied, or relayed to the lower communication layer.

Finally, we notice that fragmentation may occur after the IPsec processing. Fragmentation is needed because the IP datagram can become larger than the maximum transport unit supported by the underlying layer. This operation reduces the size of the IP packet by splitting it into parts with smaller size. Figure 7 describes the five steps of the IPsec processing. These steps summarize the above discussion: (a) receiving packet; (b) querying the SPD to discover the policy to apply; (c) querying SAD to retrieve the appropriate SA; (d) processing packet by applying AH or ESP using the SA; and (e) relaying the produced packet. Steps b, c, and d are looped until there are no more policies to apply.

AH Outbound Processing AH is applied to an outbound packet through the following steps:

1. Insertion of the AH header in the IP packet in processing.
2. Generation of the sequence number, which is set to 0 at the generation of the SA. This number is incremented and copied with each AH processing into the corresponding field of AH.

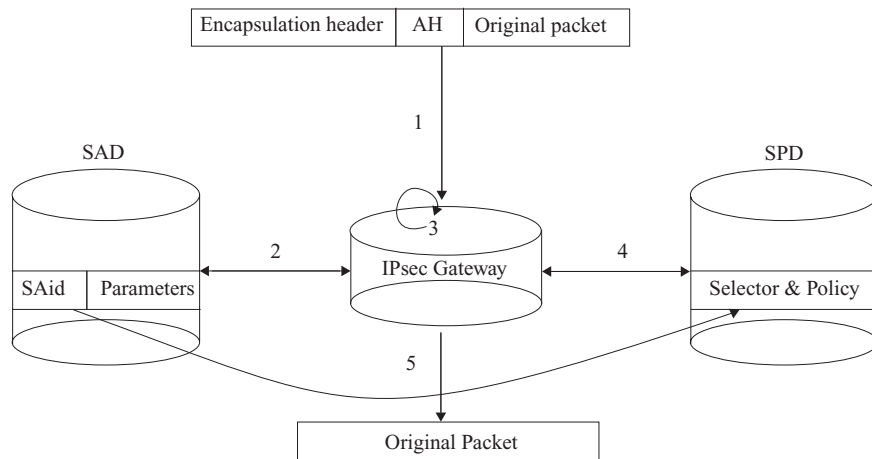

Figure 7: Outgoing traffic Processing (Jourez, 2000).

3. MAC computation. The algorithm of MAC computation defined by the SA is used to generate a message authentication code.
4. Padding. If required, the authentication data field is padded to align it to the IPv4 or IPv6 format
5. Fragmentation. The IP fragmentation can be applied to the packet after the AH processing

ESP Outbound Processing ESP is applied to an outbound packet only after an IPsec implementation determines that the packet is associated with an SA established for ESP processing. The steps for ESP outbound processing are (Jourez, Kent, & Atkinson, 2000, 1998):

1. Insertion of the ESP fields to the processed packet
2. Addition of the Padding if required. The fields Pad length and Next header are set to their values
3. Encryption. The ESP payload is encrypted using the algorithm and parameters specified by the SA. The application of the algorithm means that no ciphering is really applied
4. Generation of the sequence number. This is done in the same way as for AH processing
5. MAC computation. This is done if authentication is required. It is computed on the whole ESP packet with the exception of the last field containing the MAC. This step is skipped if authentication is not required
6. Fragmentation. If required, fragmentation is applied to the produced packet after the ESP processing.

Incoming Traffic Management

Before processing an incoming IP packet, the packet is reassembled. The IP packet that must be assembled is processed if its Next Protocol Field specifies AH or ESP. Otherwise, it is only checked using the SPD to verify if it matches the incoming policy. If the packet belongs to a traffic that does not have to be IPsec protected, then the packet is relayed; else, it is discarded.

For the other cases, the IPsec processing proceeds as follows: In the first step, the IP destination address, the IPsec protocol, and SPI are used to query the SAD in order to retrieve the SA used to protect the packet. In the

second step, the destination checks the selectors to verify that they are defined by the SA, and if it is not the case, the packet is discarded. In the third step, an entry policy checks the packet selector to find out if this policy has been enforced. In the final step, the original packet is routed to the outgoing interface. During IPsec processing, AH or ESP may be applied.

AH Inbound Processing The different steps of the AH incoming traffic processing are described as follows:

1. **Sequence number validation.** If the retrieved SA specifies anti-replay protection, the sequence number is checked. If it is already encountered, the packet is discarded, else it is accepted.
2. **MAC validation.** The MAC value is verified by recomputing its value based on the SA parameters. If the received MAC value and the computed MAC value are equal, then the packet is accepted. Then in the next step, the AH is removed, the anti-replay is adjusted if necessary, and the AH processing is finished.

A sliding window is used to detect the duplication of the sequence number. It maintains the received sequence numbers between the lower and the upper bound of the window. When an incoming sequence number is lower than the lower bound of the window, then the packet is discarded. When the incoming number is greater than the higher bound, the window is slid upward and the sequence number is kept. A minimum window size of 32 bit must be supported. Another window size (larger than the minimum) may be chosen by the receiver.

If the received sequence number of the packet falls within the window, then the receiver will proceed to ICV verification. If the ICV validation fails, the receiver has to discard the received IP datagram as invalid. The audit log entry for this event should include the SPI value, Source Address, Destination Address, the Sequence Number, and the Flow ID (in the case of IPv6). Then, and only if the ICV verification succeeds, the received window is updated only if the ICV verification succeeds.

ESP Inbound Processing The following steps are included in the ESP processing:

1. **Sequence number validation.** This is done in the same way as in the AH case.
2. **MAC (Message Authentication Code) validation.** If authentication is required, the MAC value is recomputed and checked. If the two codes are not equal, the packet is discarded, else the processing continues.
3. **Original packet reconstruction.** This is done by:
 - (a) decrypting the ESP Payload Data, Padding, Pad Length, and Next Header using the key, encryption, the algorithm mode, and the cryptographic synchronization data indicated by the SA;
 - (b) adding any padding as specified in the encryption algorithm specification; and
 - (c) reconstructing the original IP datagram from original IP header and the upper layer protocol information in the ESP Payload field for transport mode, or from tunnel IP header and the entire IP datagram in the ESP Payload field for the tunnel mode.

The reconstruction of the original datagram depends on the mode. At a minimum, in an IPv6 context, the receiver have to ensure that the decrypted data is an aligned 8-byte, to facilitate processing by the protocol identified in the Next Header field. If authentication has been selected, decryption and verification may be performed in serial or in parallel. If it is performed serially, then ICV verification should be performed first. If it is performed in parallel, verification must be completed before decryption. This order of processing facilitates the detection and the rejection of replayed packets by the receiver prior to decrypting the packet. This approach reduces the impact of denial of service attacks.

SECURITY POLICY MANAGEMENT

Security at the network layer can be used as a tool for at least two kinds of security architectures:

1. **Security gateways:** Security gateways use IPSec (Randall, Stephen, 1998) to enforce access control, protect the confidentiality and the authenticity of incoming and outgoing network, and to provide gateway services for virtual private networks (VPNs).
2. **Secure end-to-end communication.** Hosts use IPSec to implement host-level access control, to protect the confidentiality and the authenticity of network traffic exchanged between hosts, and to join virtual private networks.

As it has been stated, IPSec provides a reasonable basis for a wide range of protection schemes. This adds a large complexity to the SPD management, which becomes particularly critical where networks scale up and security policies get larger. When organizations deploy security gateways bridging heterogeneous regions that enforce different access controls and security policies, the wide range of choices of cryptographic parameters introduces the need for hosts and security gateways to identify and negotiate security parameters. Even more complexity arises as IPSec becomes the means through which various components enforce access control and VPN membership.

The level of protection offered by an IPSec is based on the requirements defined by the IPSec policies stored

in the Security Policy Database. Policies should be established, maintained, and protected.

IPSec Policy Capabilities

IPSec Policy aims at providing a scalable and decentralized framework for managing, discovering and negotiating. It helps governing access, authorization, cryptographic mechanisms, confidentiality, data integrity, and other IPSec services. IPSec Policy is useful for a wide range of IPSec applications and modes of operation. In particular, we have the followings:

- IPSec Policy hosts may serve as IPSec endpoints, security gateways, network management hubs, or a combination of these devices. For this purpose, they can manage:
 - end-users computers, which may be fixed or mobile workstations offering remote access;
 - firewalls, which allow different levels of access to different classes of traffic and users classes;
 - VPN routers, which support links to other VPNs that can be controlled by a different organization's network policies; and
 - web and other servers, which might provide different services depending on the source of a client request.
- IPSec Policy administration can be inherently heterogeneous and decentralized. Two hosts can establish a security association without sharing a common security policy.
- The SA parameters, established between any pair of hosts, do not have to be specified in advance. An IPSec Policy will often have to negotiate and discover the mutually-acceptable SA parameters when two hosts attempt to create a new SA. Moreover, hosts can use policies that are not directly specified by an IPSec Policy language. For example, a host's IPSec Policy might be derived from a higher-layer security policy managed by some other systems.
- IPSec Policy must be scalable to support complex policy administration schemes. In small networks, the administrator should often control security policies (remotely, if needed) and must have the ability to change the policy on many different hosts at the same time. In larger networks, a host's policy might be governed by different authorities. Different parts of a policy might be "owned" by different entities and be organized in a complex hierarchy. Thus, IPSec Policy must provide a mechanism for delegating specific kinds of authority to different entities (Jourez, 2000).

IPSec Policy Configuration

In order to provide an efficient framework for the construction of coherent security policies and guarantee their interoperability, an IPSec Policy management should include the following components (Jourez, 2000):

- **Policy Model.** A Policy Model defines a well defined semantics that captures the relationship between IPSec SA and higher-level security policies. Policy specification,

checking, and resolution should implement the semantics defined by the model. Moreover, the model should be independent of the specific policy mechanism.

- **Security Gateway Discovery.** The gateway discovery mechanism may be invoked by any host or gateway. Its goal is to determine if IPsec gateways exist between the initiator and the intended communication peer. The discovery mechanism may have to be invoked at any time, independent of existing security associations or other communication in order to detect topology changes.
- **Policy Specification Language.** In order to allow policy discovery, compliance checking, and resolution across a range of hosts, a common language is necessary to express the hosts' policies communicating with each other. Statements in this language are the output of policy discovery. They also provide the input to the policy resolution and compliance checking systems.
- **Policy Discovery.** A policy discovery mechanism must provide the essential information used by two IPsec endpoints to determine what kinds of SA are possible between the hosts. This is especially important for hosts that are not controlled by the same entity, and that might not initially share any common information about one another.
- **Security Association Resolution.** When two hosts have learned enough about each other's policies, it is possible to find an acceptable set of SA parameters that meets both hosts' requirements, and hence will lead to a successful creation of a new SA. Resolution aims to bridge heterogeneity between hosts' policies.
- **Compliance Checking.** When a host proposes the output of the SA resolution scheme, it must be checked for compliance with the local security policy. The created security of the SA should depend only on the correctness of the compliance checking stage. Even if the SA resolution scheme produces an incorrect result, it should not be possible to violate the specified policy of either host.

IPsec IMPLEMENTATIONS

IPsec can be implemented and deployed on end hosts and on gateways/routers depending on the security requirements of the users (Tiller, 2001). This section discusses the main features and implications of implementing IPsec on these network devices. There are merits of implementing IPsec in both routers and end hosts because they address different problems. The host implementation is most useful when security is implemented end to end. However, in cases where security is desired over a part of a network, router implementation is more useful.

Host Implementation

The host implementation has the following advantages. First, it provides an end to end security to implement all modes of IPsec. Second, it provides security to maintain the ability of user authentication in establishing IPsec connections. This kind of implementations can be classified into two classes: OS integrated implementation and Bump in the stack implementation.

OS Integrated In the host implementation, IPsec may be integrated within an OS. As IPsec is a network

protocol, it may be implemented as part of the network layer (Doraswamy, Harkins, 1999). IPsec layer needs the use of the IP layer service to construct the IP header. There are various advantages of integrating IPsec with the OS. Among these are:

- This creates tight integration to the network layer as IPsec can benefit the network services such as fragmentation, and PMTU. In this case, implementation becomes very efficient.
- It is easier to provide security services
- All IPsec modes are supported

Bump in the Stack For companies providing solutions for VPNs and intranets, OS integrated solution has one serious disadvantage. On the end hosts, they have to work with the features provided by the OS vendors. This may limit their capabilities to provide advanced security solutions. To overcome this limitation, IPsec is implemented between the network and the data link layers. This is commonly referred to as a Bump in the Stack (BITS) implementation.

The major issue in this implementation is the duplication of effort. It requires implementing most of the features of the network layer such as fragmentation and route tables. Duplicating functionality leads to complications because it becomes more difficult to manage other issues such as fragmentation, PMTU, and routing.

An advantage of BITS implementation is its capability to provide a complete solution. This can be attractive to vendors providing integrated solutions such as firewalls. Vendors may prefer to have their own client when their OS may not have all the required features to provide a complete solution.

Router Implementation

The router implementation offers the ability to secure any packet between parts of a network. For example, an organization may want to secure only the packets destined to a distant branch as these packets traverse the Internet in order to build its VPN or Intranet. The IPsec implementation provides security using a tunnel mode (Doraswamy, Harkins, TILLER, 1999, 2001).

The following advantages are provided by router implementation:

- Ability to secure packets between two networks over a public network such as Internet.
- Ability to authenticate and authorize users, who enter the private network. This is the capability that many organizations use to permit their employees to telecommute their connections over the Internet to build VPN or Intranet.

There are two types of router implementation:

- **Native implementation:** This is similar to the OS integrated implementation on the hosts. In this case, IPsec is integrated with the router software.
- **Bump in the Wire (BITW):** This is similar to BITS implementation. In this case, IPsec is implemented in devices

Figure 8: BITW deployment architecture (Doraswamy, Harkins, 1999).

attached to the physical interface of the router. These devices normally do not use any routing algorithm but the scheme is used only to secure packets. BITW is not a long-term solution as it is not possible to have a device attached to every interface of the router.

An example of the network architecture for the BITW implementation is shown in Figure 8.

In Figure 8, IPS_{AB} is a device that implements IPsec and R_A , R_B , R_C are routers. One of the secured links is between IPS_{AB} and R_B . The IPsec implementation has many implications on the packet-forwarding routers capabilities. They are expected to forward packets as fast as possible. Although, IPsec may not be used in the Internet core, the implementations should still be efficient. The packets that do not require security should not be affected because of the IPsec use. They should be forwarded at normal rates. Many implementations use some other hardware to perform signature operations, random number generation, encryption/decryption, and hashes calculation. There are special chipsets that assist the basic router hardware with security operations.

Another issue with router implementation is the IPsec contexts. Memory on the routers is still a scarce commodity, although this is changing as memory prices are falling. Since the router has to store huge routing tables and normally does not have very large storage for virtual memory support, maintaining too many IPsec contexts is a difficult issue.

LIMITATIONS, PERSPECTIVES AND ADVANCED ISSUES OF IPSEC

As described in the previous section, IPsec has the potential to add a useful layer of security to Internet traffic. The provided protections include source authentication, message integrity and confidentiality, anti-replay protection, and some sort of access control. Those protections qualify IPsec to be used efficiently in VPN gateways and remote hosts. The proliferation of Wireless LANs, 3G wireless networks, and mobile workers have made it highly desirable for remote hosts to be able to move among multiple networks (IP subnets) and even across different air interface technologies (Byoung-Jo, Srividhya, 2001). However, IPsec may risk two opposing types of failure. First, it may become so complex that it cannot be implemented in the hosts. Second, IPsec may fail to meet the needs of many

components, which may be added with nonstandard (or proprietary) extensions (Frankel, 2001).

Advantages of IPsec

One of the main features of IPsec is that encrypted packets can be routed or switched on any network that supports IP traffic with no need to upgrade the network elements. This enables the packets to flow through LANs, Extranets and Intranets easily and transparently. It also means that there is no need for any modifications in the end hosts configurations. Unlike SSL, which only works with HTTP, IPsec can secure connections for all TCP/IP applications including a variety of protocols such as FTP, HTTP, SMTP, and TELNET. Moreover, due to its transparency, IPsec can also use other security layer protocols such as SSL and S/MIME. In addition, VPN solutions using IPsec as the basis for a common protocol can interoperate by opening up new services for securely sharing data.

Another advantage of IPsec comes from the fact that it is independent of network topologies. Since IPsec is adding security to the well-supported TCP/IP protocols, it interoperates with all network topologies including Ethernet, Token Ring, and PPP. Unlike other tunneling protocols like PPTP and its many variations like L2TP and STEP (none of them offers encryption), IPsec provides effective standards based on tunneling, authentication and encryption algorithms (Padmaraj, Nair, 2000).

The level at which IPsec protection is provided, the IP layer, constitutes also a major advantage. This means that all types of Internet traffic can be protected using IPsec, independently from the application conducting the communication. It also means that the granularity of protection can have a wide spectrum: A single SA can protect, for example, all communications between two hosts or two networks. The level and type of IPsec protection to be applied, as well as the keys to provide that protection, are both flexible and negotiable. Because specific applications do not have to be IPsec aware, users can be better protected. Moreover, a network administrator can determine and enforce either network or host policies.

Another important advantage of IPsec is that it can be deployed incrementally; unlike other network-related protocols or technologies. A business that leases private communication lines to link multiple sites can replace gradually one or more of those lines with an IPsec-protected VPN connecting the related sites. Moreover, IPsec is not limited to Enterprise wide use. A user who accesses remotely a PC can use IPsec to protect those communications (Frankel, 2001).

IPsec Limitations

Currently, the major operating systems and a growing number of devices are integrating standard compliant IPsec implementations. The current wide support to IPsec is significant. It will allow IPsec to be used as a universal security solution. However, IPsec is typically used only as an all or nothing protection for connecting two sites privately together or remote users to a central site and for end-to-end protection of application protocols. It is also rarely used for protecting the various control protocols of the Internet. This is unfortunate as the

original goal of IPsec was to enable the protection of all types of communications between Internet nodes.

Other limitations of IPsec include (Arkko, Nikander, 2003):

- Lack of the power in policy specifications: The expressive power of the security policy entries needs to be increased in order to cover more information than the pair of addresses, the upper layer protocol identifier and the ports. Recent requirements have included description such as ICMP message types. Another shortcoming is the fact that IP addresses have not been extended by using semantic information. Given the example of the use of dynamic address assignment, and the growing use of mobility, privacy addressing, and multi-homing, an IP address does not identify this kind of hosts. A third lack is present because IPsec policies and security association parameters are tightly bound with IP addresses, this limits the freedom of the nodes when choosing the addresses used for communications. Given that not all protocols use static port numbers and that port numbers are not universally available in security gateways, decisions cannot always be made based on port numbers.
- Lack of application control over policies: Application control of policies is needed in various situations. First, it may be necessary to use IPsec in cases where there are no distinguishable selectors. Second, policies may need to be configured by applications for better quality assurance. Also, protocols can become widely deployed without the activation of the security. Third, end-host applications could set up the necessary entries since in many cases the expected policies are standardized. Some standard specifications require that the application is aware of the underlying security mechanisms, or at least when security mechanisms are activated.
- Lack of support for authorization and the inability to link authorization decisions with security processing: Not all peers have the same privileges. For example, the administrator of a host that is remotely connected has different privileges than an unknown peer connecting locally through IPsec. All peers whose identities are authenticated within a specific trust domain may still have different privileges. In order to use certificates for authorization, it is typically necessary to use either attribute certificates, create a separate certificate infrastructure for each different application, or introduce standardized extensions to the certificate formats to be able to express the authorization that the certificate represents. The traditional alternative, using local access control lists is not a viable option in a large network. More importantly, the security processing decisions require information from the application layer, or vice versa. In the current IPsec architecture all security processing is expected to be performed at the IPsec layer, and the application does not know if IPsec is being used. This makes it hard to accommodate finer decisions.

CONCLUDING REMARKS

According to the categories of IPsec limitations observed in the previous section, the following improvements

appear necessary for the wider use of IPsec in securing applications (Arkko, Nikander, 2003):

- Make available a mechanism for applications to control policies. A specific application providing at least a default configuration for IPsec is recommended. This mechanism should help ensure that security is not accidentally turned off, and improve interoperability. It might help in dealing with the port number agility problem. The drawback of the approach is that it adds an additional problem to the applications. However, there is a trade-off between a one-time effort in software construction and manual configuration effort by all users, making the application based solution beneficial in the longer run. Unfortunately, such default configurations may not always suffice. For instance, the default configuration may not be compatible with specific requirements for protecting all traffic.
- Allow applications to make authorization decisions. One approach to allow applications to control authorization is to create an application programming interface (API) between IPsec and applications. The creation of this interface is particularly easy when the applications are parts of the IP stack such as in IPv6 control signaling. A standardized API would also make it possible for user space applications to rely on IPsec in order to provide meaningful security information to them. However, it is not enough to copy the IPsec security policy database functionality to the application layer; the application layer policy information has to be presented in semantic form. For instance, policies are based on application concepts rather than port numbers. In order to make use of the API, applications need tools to deal with authorization questions. Moreover, an application may have a need to perform certificate chain validation to a particular trusted root. Such needs can be satisfied either through the use of API or via specific libraries. The use of certificates for authorization purposes requires certificate mechanisms extensions to represent authorization information in an easy manner.
- Reduce the reliance on IP addresses in the policies. This reduction applies to IPsec security associations in policy entries and in application layer policies. An example of this approach is available in the form of the Host Identity Protocol (HIP) proposal. Reducing reliance on IP addresses is necessary to allow for address agility. While the enhancement of the expressive power of IPsec policies appears necessary, it seems hard to decide exactly how much more expressive policies should be used.
- Use IPsec in mobile environment: IPsec permits access to resources in protected corporate intranets while working remotely through an IPsec tunnel. Currently, IPsec does not support Mobile IP movements without breaking and re-establishing IPsec tunnels. Attempts have been made to solve this problem, including the establishment of IPsec tunnels over Mobile IP to enable mobility (Byoung-Jo, Srividhya, 2001).

GLOSSARY

Authentication Header (AH) provides authenticity guarantee for packets, by attaching strong crypto checksum to packets.

Encapsulating Security Payload (ESP) provides confidentiality guarantee for packets, by encrypting packets with encryption algorithms.

IPSec is a set of extensions to the IP protocol family providing cryptographic security services that provide for confidentiality and authentication of individual IP packets.

Security Association (SA) is a contract between two parties indicating what security parameters, such as keys, algorithms, and rules that were negotiated and agreed upon by two nodes.

Security Policy A set of rules that defines the network security parameters of an entity, including authentication, access control, content security, logging, network address translation, and other security components.

Transport mode IPSec mode of operation in which the data payload is encrypted, but the original IP header is left untouched.

Tunnel mode IPSec mode of operation in which the entire IP packet, including the header, is encrypted and authenticated and a new header is added, protecting the entire original packet.

INTRODUCTION

The IPsec (Internet Protocol Security) protocol cryptographically protects messages sent over the Internet on a packet-by-packet basis, as opposed to other protocols such as secure sockets layer (SSL) or secure multipurpose Internet e-mail extension (S/MIME) that encrypt larger messages before breaking them into packets. The major advantage of the IPsec approach is that it can be done transparently to applications. It can be done by the underlying operating system—or even by an external networking device—without making any changes to applications. IPsec is commonly used to *tunnel* messages between two trusted networks over an untrusted network, where the ultimate sending and receiving machines are not aware of any cryptographic processing.

In order that the IPsec end points be able to protect messages cryptographically, they must agree on which cryptographic algorithms and keys to use. To detect and discard long delayed and replayed packets, they must also agree on sequence numbers and keep them in sync. This shared state is called a *security association*, or SA. Although all of this shared state could in theory be configured manually (and indeed, in some cases it is), it is more flexible and robust to have the end points initialize this shared state when needed using the *Internet key exchange* (IKE) protocol. Typically this is done when either end point starts up, and in some circumstances SAs will be forgotten and reinitialized if there are no packets to forward for an extended period. When IPsec is used to protect communication between a mobile end point (e.g., an employee’s laptop computer) connecting through a public network to a protected corporate network, IKE is used to initialize an SA each time the mobile end point restarts or changes address.

Before IKE can be used to initialize an SA, the two end points need some information about one another. The initiator must know the address of the other end point, and if packets destined to multiple destinations are to be tunneled to this intermediate end point the initiator must know that. Both end points must know what sort of authentication they will require of the other end before being

willing to establish the SA, and they must know what cryptographic algorithms they are willing to use. To allow the two end points to have their configurations updated independently, it is desirable to allow either or both end points to support multiple options and for them to find acceptable shared settings as part of the IKE negotiation. Otherwise, communications would fail in the interval between the updates of the two end points.

IKE is a protocol by which two parties (call them “Bob” and “Alice”) establish an SA for the IPsec protocol. An SA is the shared state necessary to carry on a cryptographically protected conversation, including cryptographic keys, sequence numbers, identity of the other side, and policies for what traffic should be allowed. IKE negotiates cryptographic algorithms to use for the exchange, negotiates the types of traffic acceptable on the SA, performs mutual authentication, and establishes shared keys for the SA. There are two kinds of SA for carrying user data. The more commonly used is ESP (encapsulated security payload), which usually carries encrypted and integrity-protected data. The other is AH (authentication header), which carries data that is integrity protected but not encrypted. IKE version 1 is documented in RFCs (Requests for Comment) 2407 (Piper, 1998), 2408 (Maughan, Schertler, Schneider, & Turner, 1998), and 2409 (Harkins & Carrel, 1998). The protocol underwent a major revision for fixing flaws, increasing efficiency, and simplification in IKE version 2, which is currently an Internet draft. IKE has some additional features such as denial of service protection, identity hiding, the ability to traverse NATs (network address translators), and the ability for a firewall to assign an internal address. This chapter discusses the operation of the basic protocol and the rationale for various options and extensions.

IKE USAGE SCENARIOS

There are three distinct scenarios in which IPsec and IKE are used. Rather than using three separate protocols to support them, IKE (and to a lesser degree IPsec) supports protocol variations for the three scenarios: gateway to

Figure 1: Internet Protocol Security (IPsec) used gateway to gateway.

gateway, end point to gateway, and end point to end point, each detailed in this section.

Gateway to Gateway

It is common for an organization to have an internal network (or intranet) connected to the Internet via a *firewall* or *gateway*. The systems deployed on the internal network often are not securely configured, so by filtering communications at the border, some degree of protection from external attacks can be applied en masse while still allowing the uses enabled by the insecure configurations to go on within the organization. If such an organization is geographically dispersed and its only means of communication between campuses is via the Internet, the filtering done by the firewall or gateway may prevent the internal applications from operating between campuses. Further, an organization may be concerned that sensitive e-mail traffic may be intercepted by eavesdroppers on the Internet. Although this could be addressed by deploying a secure e-mail solution such as S/MIME, an easier to deploy solution is to use IPsec to encrypt all “internal” traffic while it passes over the Internet. The protection is not as strong (because it is still exposed to internal eavesdroppers), but for many organizations it is considered adequate.

To address both of these problems, an organization can deploy IPsec-enabled gateways at its points of connection to the Internet. These gateways are configured with the set of addresses that are considered “internal” and for each such address the gateway through which packets to that address should be routed. The gateways set up pairwise IPsec SAs between one another. When a packet arrives destined for an internal address on another campus, that packet is wrapped in an IPsec packet, encrypted, and integrity protected. At the receiving gateway, the IPsec packet is decrypted, verified, and forwarded without having to pass the checks that would be done if the packet were coming in from the Internet. This allows insecure intranet applications to work between campuses and ensures that internal mail and other communications are encrypted when on public networks. Figure 1 illustrates the gateway-to-gateway IPsec scenario.

When IKE is setting up SAs between gateways, there are typically few enough gateways that manual configuration of addresses and cryptographic keys is feasible—and in fact easier than dealing with a public key infrastructure. There is no need to deal with revocation should a gateway be compromised; it would simply be removed from the configurations of the other gateways. Authentication and naming of individual gateways is similarly not an important issue. Gateways really need only know that they are talking to another gateway of the same organization. Once so assured, the gateways will allow unfiltered traffic

to flow between the two parts of the internal subnet. This is the most straightforward use of IKE and IPsec.

End Point to Gateway

Another use of IPsec and IKE that is rapidly growing is the ability to connect a portable “roaming” end point into an organization’s intranet using some public network (Figure 2). The growing popularity of wireless connectivity in public places makes it convenient for a traveler with a laptop computer to establish a high-speed connection to the Internet at some unpredictable address and use IPsec to securely tunnel to a corporate intranet. This scenario also occurs when people have cable modems or DSL (digital subscriber line) connectivity to the Internet from their homes and want to connect to their office networks.

There are a number of important differences in this scenario. The portable or home computer is not likely to be at a fixed address, so the gateway cannot be configured to know its address. In fact, the gateway will never initiate an SA. It will wait until remote computers request connections to the internal network. These remote computers are not likely to establish SAs to all of an organization’s gateways. More likely, each will pick a single gateway and failover to another if the first one fails. Packets sent from within the internal subnet to the remote computer’s address might end up at any gateway, however, and most will not know what to do with it. This problem is fixed by having the gateway own a pool of addresses on the internal subnet and assign one of those addresses to each remote computer connected. The remote computer then acts as though it were at that address but connected to the Internet through a gateway at its real address. Packets it sends have two headers—just like a packet that has been wrapped by a gateway. The outer header contains the address it got from its local Internet provider and the address of the gateway. The inner header contains the address the gateway assigned it and the address of the machine on the internal network that it wants to talk to. The gateway unwraps this packet, so the machine on the internal subnet sees an ordinary packet coming from one of the addresses belonging to the gateway. The network will automatically route return packets to the gateway, and the gateway will

Figure 2: Internet Protocol Security (IPsec) used from an end point to a gateway.

Figure 3: Internet Protocol Security (IPsec) used end-to-end SA = security association.

wrap them and send them on the SA currently associated with that address.

Unlike the gateway-to-gateway scenario, the portable computer is likely to not have its own IP address but rather be using a network address translator (or NAT) to allow multiple machines to share an IP address. These are commonly used, for example, to allow home users to connect multiple machines to a single cable modem or DSL line.

Typically, it is not the portable computer that is authenticated to the gateway but its human user. The expectation is that the computers might be stolen and should not be usable without the authorized person present, and it may be the case that the user is allowed to use any of a large pool of machines. Because an easy-to-use public key infrastructure for people remains to be deployed, authentication is most often by means of a password or some sort of physical authentication token (such as a smart card or challenge-response calculator). Gateways, in contrast, are more likely to have public keys and certificates.

One property this scenario shares with the gateway-to-gateway case is that authorization policy is fairly simple. The gateway does not care who the user is (except perhaps for auditing), and the user does not care to which gateway he connects. Once the user and gateway are satisfied they are talking to good peers, they pass traffic bypassing the filters the gateway imposes on Internet traffic.

End Point to End Point

A major intended use for IPsec, so far mostly unrealized, is to replace SSL as the preferred means to protect data cryptographically between computers on a network (Figure 3). This scenario is different from the others. First, there is no need for two sets of source and destination addresses because the end points of the IPsec SA and the end points of the communication are the same. IPsec optimizes this case by having IKE negotiate *transport mode*, in which the inner IP header is not included. When two sets of addresses are included, the IKE SA is said to use *tunnel mode*. In the IKE negotiation, the initiator can offer this optimization and the responder can (optionally) accept it. Doing so saves a few bytes in each packet, and the effort of encrypting and parsing them.

Perhaps more important, in this scenario, the identities authenticated as part of the IKE negotiation can be reused by applications running on the two systems for access control decisions (eliminating the need for some other authentication protocol to be used by applications). In the first two scenarios, the identities are only used to decide whether communication is to be allowed. Separate authentication protocols must be run on the tunneled connections. The configuration challenge in this

scenario is for end points to know when IPsec protection should be used. If IPsec were universally deployed, running IKE would be part of the startup sequence when any end point tried to communicate with another. If a client node today tried to open an IPsec connection to a server, however, its request would most likely be rejected or ignored. Manually configuring clients with information about which servers support IPsec works well enough for demonstrations, but supporting this on a large scale will require deployment of some new Internet infrastructure. There is a proposal for storing this information in Domain Name System (DNS), but so far deployment is only experimental.

IKE PROTOCOL HANDSHAKE

Although the IKE protocol allows many variations, the following describes a simple and common execution of the IKEv2 protocol in four messages (the minimum). After these four messages have been processed, the two end points will have agreed on cryptographic algorithms and keys for both the IKE protocol itself and an IPsec SA for passing data (either ESP or AH). They will also have agreed on the kinds of data that will be passed over the SA and the starting sequence numbers.

In the basic exchange (Figure 4), the initiator (Alice) proposes one or more sets of cryptographic algorithms that are acceptable for the SA; Bob chooses among them and sends a single set back. Two such negotiations take place, one for the IKE SA (used to protect only messages used in the IKE protocol) and one for the ESP or AH SA (used to protect subsequent data).

The first two messages of the exchange perform a Diffie-Hellman exchange, in which Alice randomly chooses N_A and A and sends N_A and $g^A \bmod p$, Bob randomly chooses N_B and B and sends N_B and $g^B \bmod p$, and they both protect subsequent messages with keys generated as a function of N_A , N_B , and $g^{AB} \bmod p$.

In the second two messages, Alice and Bob identify themselves, authenticate themselves, and negotiate the cryptographic algorithms and kinds of data traffic to be passed over the ESP or AH SA. Because the second two messages are encrypted, an eavesdropper will not see even the names of the two participants (although in many cases these can be guessed from the IP addresses).

The *proof* provided in the second two messages must be based on some cryptographic authentication mechanism. For Alice to authenticate herself to Bob, she must prove knowledge of some secret that Bob knows is associated with Alice. The preferred types of keys are either a secret

Figure 4: Basic Internet key exchange (IKF).

key known to both Alice and Bob, or a pair of private keys (where each party knows the corresponding public key of the other). In either case, the keys are used to protect the integrity of the IKE exchanges.

Authentication Keys

IKE was designed presuming that Alice and Bob would each have private keys and certificates, and be enrolled in a public key infrastructure. Unfortunately, public key infrastructure has been slow to roll out on the Internet, and many IPsec deployments still use secret keys to authenticate. There is nothing inherently less secure about secret key-based authentication, but it is much more difficult to administer securely. Some administrator must configure secrets into each pair of IPsec end points. To authenticate using secret keys, IKE assumes that there has been some sort of out-of-band mechanism whereby Alice and Bob are configured with a shared secret. In the case of public keys, IKE allows each side to transmit a certificate (or sequence of certificates), as well as an indication of preferred certificate issuers (in case several certificates are available). IKEv1 allowed the use of encryption with public keys as an alternative to signing for authentication, but this option was rarely used and was dropped from IKEv2.

Initial Diffie–Hellman Exchange

A real-time protocol is said to have *perfect forward secrecy* (PFS) if an attacker who records the entire session and then breaks into both communicating parties and learns all long-term secrets (or subpoenas them) after the session has ended, still cannot decrypt the session. There are two methods in use for achieving PFS, both using public key cryptography. One is by use of the Diffie–Hellman protocol. The other is for one party to create an ephemeral public key pair, certify the ephemeral public key with that party’s long-term key, and have the other side communicate the session secret encrypted in the ephemeral public key. The former method is used in IKE. The latter is used in one of the variations of SSL designed for exportability.

Diffie–Hellman is a protocol that establishes a shared secret. It is based on the assumption that the discrete log problem is difficult to solve. The discrete log problem is stated as follows: given g , p , and $g^X \bmod p$, what is X ? The protocol, between Alice and Bob, has each choose a private exponent (Alice chooses A , Bob chooses B), then raise g to that private exponent, $\bmod p$, transmit the result to the other, and then have each raise what is received from the other side to their own private exponent. The result will be that both calculate $g^{AB} \bmod p$. An eavesdropper who saw both messages would still have no way of calculating $g^{AB} \bmod p$.

The Diffie–Hellman exchange must be authenticated. Otherwise, an active attacker, Trudy, who is on the communication path between Alice and Bob could act as a man-in-the-middle, establishing a key between Alice and Trudy and a separate key between Trudy and Bob (Figure 5). Trudy can then act as go-between for the entire session, decrypting traffic received from Alice and re-encrypting it for Bob, and doing the equivalent for traffic from Bob to Alice. She can also monitor, record, or even modify the messages as she processes them.

Figure 5: Man-in-the-middle attack.

Less-than-perfect forward secrecy can still be useful. In reality, it is unlikely that an attacker will manage to break into a system at the exact instant when a session ends. If the attacker were to break in a moment before the session ended, it would be able to steal the session key. It is reasonable to expect that some time will elapse before the communicating parties will be compromised. This means that some trade-off can be made between efficiency and “perfection.” For a protocol such as IKE, based on Diffie–Hellman, the same $g^A \bmod p$ can be used for many sessions (to save the work of computing g^A), provided that A and the session key are forgotten after any session using A is ended (thus this is only useful where multiple sessions are taking place in parallel). If A is remembered after sessions end, forward secrecy will be less than perfect.

In case both Alice and Bob are reusing their private Diffie–Hellman exponentials across sessions, the IKE exchange additionally has them exchange nonces (numbers that are randomly chosen from a large space) for each session. The session key is a function not only of the Diffie–Hellman key, but also the nonces. This ensures that even if the Diffie–Hellman keys are the same for two sessions, the session secrets will be different (provided the nonces are not also identical). It is important that the secret session keys be different for each session, because otherwise an attacker could take packets recorded from the first session and replay them as part of the second session.

Negotiation of Cryptographic Algorithms

It would undoubtedly yield a simpler protocol if the protocol specification gave fixed parameters for all the cryptography, but there are many reasons today’s protocols generally include a negotiation to determine the cryptographic algorithms and their public parameters. One is to allow easy replacement of a protocol that is found to have weaknesses with one that is stronger. Another is to allow interoperability when, for instance, different countries have their own preferred algorithms. Similarly, export or import laws might preclude using the strongest cryptography.

Alice and Bob should negotiate to find the strongest set of algorithms that they are both capable of supporting. This negotiation must occur before the cryptographic part of the handshake because the cryptographic portion of the handshake cannot occur until there is agreement about what cryptographic algorithms to use. It is therefore

important to avoid a “downgrade attack,” in which an attacker removes the strong alternatives from the list of alternatives offered.

The way to detect a downgrade attack (and renegotiate as a result) is to protect the offered list of choices cryptographically. To do this, Alice and Bob can each certify their initially sent lists in a subsequent message after the cryptographic algorithms have been chosen. If the list as received is incorrectly certified or differs from what was initially transmitted, this can be detected at that point and the handshake can start over again. IKEv2 includes the entire contents of the first two messages of the exchange in the calculation of the proof that authenticates the two parties. IKEv1 was subject to this attack (see Zhou, 2000).

Identity Hiding

One of the goals of IKE was to enable hiding the identities (names) of the communicating parties from attackers. In IKEv2, identities are hidden from eavesdroppers because they are encrypted using the negotiated Diffie–Hellman key. Furthermore, the responder does not reveal its name until the initiator has authenticated, making it impossible to determine responder names through probing unless one is authorized to communicate with the responder. With IKEv1, the story is more complicated; which names were protected from which attacks varied according to the type of exchange and the type of authentication key being used. In the case of authentication using public encryption keys, if at least one of the parties knows the other’s public encryption key in advance, identities can be hidden from both passive and active attackers because one party can send its identity encrypted in the other side’s public key, together with whatever is necessary to authenticate, such as sending a certificate (also encrypted in the other side’s public key).

IKEv1 attempted to provide similar protection in the case of a preshared secret key, but the scheme does not work in most scenarios. Because the responder has a different shared key with each potential correspondent, it would not know which key to use to decrypt the message containing the initiator name. The only way around this was for the responder to do a trial decryption with each potential initiator’s key or somehow to determine the initiator’s identity from its IP address. This variation was removed from IKEv2.

In the case of public signature keys, although identities can be hidden from passive attackers (attackers that only eavesdrop), the identity of each party must be revealed to the other. Whichever side reveals its identity first will be vulnerable to discovery (of his or her identity) if the other side is an attacker. Kaufman and Perlman (2000) argued that, under the circumstances, it would be preferable to preserve Alice’s identity (the initiator) from active attack, because the initiator would most likely be a client, and the responder, Bob, would be a server at a fixed address. However, because IPsec is intended to be peer-to-peer, and the handshake can be initiated from either side, the argument was made in the initial version of IKEv2 that if Bob revealed his identity first, there would be the possibility of a polling attack in which anyone could initiate an IKE handshake and have Bob reveal his identity.

It is not clear how important this attack is in practice, but the IPsec working group decided in favor of avoiding the probing attack against Bob. This was somewhat controversial, with arguments within the IKEv2 working group ranging from “it’s more important to protect the initiator’s identity from active attack” to “identity hiding is an exotic and unimportant threat, and we’ve wasted too much time on it already.”

When “legacy authentication” was added, it was decided to do it by adding the already designed EAP (extended authentication protocol [RFC2284; Blunk & Vollbrecht, 1998]) into the exchange (see the subsequent section, Extended Authentication Protocol). Many argued that in this exchange, in which the initiator was clearly a human, it was more important to hide the initiator’s identity than the responder’s. However, the consensus was that the initiator’s identity was still hidden from passive attackers and that identity hiding from someone actively impersonating Bob’s IP address was not sufficiently important to reopen the argument about whether it is more important to hide the initiator or responder identity from an active attacker.

Negotiation of Traffic Selectors

There is a policy database associated with IPsec that specifies what processing should be done for various types of traffic, based on sets of IP addresses for sources and destinations, and TCP and UDP port numbers (which sometimes reveal what application is communicating). When a data-passing SA is established, IKE negotiates the traffic that should be allowed on that SA. In IKEv1, one side proposes traffic parameters, and the other side can just accept or reject. IKEv2 allows a counterproposal of a subset of what was proposed. This allows the traffic parameters to be updated independently at the two IPsec end points with the lesser of the two values being negotiated while they disagree.

EXTENSIONS AND VARIATIONS

Denial of Service Protection

At the time when IKE version 1 was being designed, there were DoS (denial of service) attacks in which one node would initiate many connections to a server, using up all its state or computation resources (or both). Typically the attacker would send such packets with a forged IP source address to avoid prosecution for mounting the attack and to make it difficult to configure a rule into a firewall to drop packets from the attacker. (Subsequently, DDoS [distributed denial of service] attacks, for which the mechanism described here does not help, became more common. If the design were started today, this feature would probably not be included.)

One of the candidate proposals for IKE version 1 was known as Photuris (RFC2522 [Karn & Simpson, 1999]). The designers invented a mechanism, which has since been copied into a number of other protocols, known as a “stateless cookie.” This is a mechanism whereby Bob can verify, before devoting significant computational resources or any state to Alice, that Alice can receive messages at the IP address she is putting into the source

address of her packets. It is easy to put any address into the source address of an IP header, but it is more difficult to be able to receive packets sent to an address other than one's own IP address.

In Photuris, there was an initial exchange whereby Alice (an initiator) requests a cookie, Bob sends one, and then forgets about Alice. On her next message, she includes the cookie. The cookie has to be a value that is not predictable by anyone other than Bob, and is verifiable by Bob without Bob remembering what he sent. So the cookie is usually a value, which is a function of the initiator's IP address and a time-dependent secret known only to Bob.

In OAKLEY (RFC2412 [Orman, 1998]; another candidate protocol for IKE version 1), this design was extended to allow the initial exchange to be optional. If Bob is not under attack (as evidenced by not having an unusually high number of half-completed connections), Alice and Bob can skip the initial round trip. If Bob is under attack, he sends a cookie value and demands that Alice repeat her request, this time with a valid cookie.

PK2001 proposed a further enhancement whereby a cookie exchange could be included in the minimal four-message exchange (Perlman & Kaufman, 2001).

As finally specified, IKEv1 required a cookie exchange that did not protect from DoS attacks (because of some confusion within the standards committee). IKEv2 uses an OAKLEY-like mechanism that does protect against DoS attacks but sometimes extends the exchange to six messages. This was done in part to address the threats described in KPS2003 (Kaufman, Perlman, & Sommerfield, 2003).

Extended Authentication Protocol

In some cases, Alice is a human and does not have a cryptographic key. In this case, Alice might authenticate with a name or password or with a token card. A token card is a small object about the size of a small calculator with a display and sometimes a keyboard. There are several types. In one type, the token card displays the time of day (in units of minutes) encrypted with a key shared by that card and the server. In another type, the token card has a keyboard, Bob gives a challenge that the user must type into the keyboard, and the token card displays a function of the challenge and the token card's secret. Still another type is sequence based in which each time the token card is asked, it displays the next value, which is a function of the token card's secret and the sequence number.

IKE was initially designed with the assumption that there would be a cryptographic secret on each end, but support for what is called "legacy authentication" (use of passwords or token cards) was added. Because EAP can require a variable number of messages to complete, IKE was modified when using EAP to have a larger and variable number of messages before the exchange completes.

NAT Traversal

NAT (network address translation) is a technique by which nodes without global IP addresses can communicate to the greater Internet. A computer known as a NAT box has a pool of IP addresses, and when a node from

inside is communicating outside, the NAT box assigns an IP address from its pool and remembers the mapping so as to be able to route return traffic to the correct internal node.

Often there are not enough addresses in the pool of global IP addresses to assign a unique one for each node communicating outside. In that case, a NAPT (network address and port translation) box is used. NAPT uses the ports in the TCP and UDP headers to differentiate among internal nodes.

With IPsec-encrypted packets, the NAPT box cannot see (much less change) the TCP and UDP ports. As a result, ESP and AH cannot generally be used through a NAPT box. To get around this, a UDP port (4500) was allocated for carrying encapsulated ESP traffic. The IKE handshake optionally contains information about the source and destination addresses and ports that each end "sees." If a NAT or NAPT box is detected, both the IKE SA and the ESP SA packets are encapsulated in UDP and sent using port 4500.

DIFFERENCES BETWEEN IKEV1 AND IKEV2

Two Phases

The IKEv1 protocol was designed with two phases. The first phase is a four- or six-message mutual authentication handshake that is potentially expensive because it likely uses public key cryptography. The second phase is a three-message exchange that completes the negotiation of cryptographic parameters for the ESP- or AH-encoded data to follow. The protocol was designed with two phases so that the second phase could be repeated multiple times within the context of the first phase to do periodic rekeying or to negotiate multiple sets of session parameters between a single pair of nodes. The first phase establishes an SA known as the IKE SA with a shared secret key between the two identities. The IKE SAs shared secret can then be used to cheaply establish more SAs. The idea of two phases was introduced in ISAKMP (Internet security association and key management protocol; RFC 2407 [Piper, 1998]), with the assumption that ISAKMP would be used to establish many SAs between the same pair of end points for different protocols. Indeed, protocol numbers were assigned for using ISAKMP to establish SAs for protocols such as the routing protocols OSPF and RIP. In fact, only IPsec used IKE. In PK2001, it was argued that IKE could be significantly simplified by removing the second phase, but the feedback from the working group was that experience from IKEv1 proved the phases useful for two reasons (Perlman & Kaufman, 2001):

- First, two firewalls might be providing virtual private network service across the Internet on behalf of multiple client networks. Although it is likely not to be any less secure to have traffic for all customers run over the same SA with the same key, it apparently makes some customers feel safer if their traffic is segregated using unique keys.
- If there are multiple quality of service classes that have very different delivery speeds, and if traffic for all of them went over a single SA, the resulting packet reordering

might make it difficult for the recipient to ensure that packets were not duplicated through use of sequence numbers. This might present a storage efficiency problem for the recipient because it would have to remember all the sequence numbers received. If all traffic were expected to be delivered approximately in order, it would be reasonable to only remember sequence numbers within a reasonably small window. If the probability of a packet being delayed is reasonably low so that packet $n + k$ is delivered before packet n , it is reasonable for the recipient to drop packet n if it arrives after packet $n + k$. However, if traffic is delivered with different qualities of service, there is no such window, and the recipient must remember all sequence numbers received in order to recognize replayed packets.

IKEv2 effectively includes support for the two phases, although in a different way than IKEv1. The initial exchange in IKEv2 initializes both the IKE SA and the first data SA with four messages. If the end points wish to establish additional data SAs, they can do so with only two additional messages per SA established. This provides the same functionality as IKEv1 with fewer messages and less variability in the messages. Support for establishment of additional SAs is optional in IKEv2, so a minimal implementation that does not require this functionality need not implement it.

IKEv1 Handshake

IKEv1 has two types of phase 1 handshakes: “main mode,” which completes in six messages, and “aggressive mode,” which completes in three messages. Both exchanges do mutual authentication and establish a session key, but main mode also hides identities, at least from passive attackers. For both main mode and aggressive mode, there are four exchanges, designed for different key types. The key types are public signature keys, preshared secret keys, and two types of exchanges based on public encryption keys (because the first set was inefficient, requiring multiple public key operations). That makes eight handshakes for the first phase. There is a ninth handshake with three messages for the second phase known as “quick mode.”

Although all the handshakes are different, the basic structure of all the aggressive mode handshakes is that in message 1, Alice sends her Diffie–Hellman value, her nonce, and her identity, along with cryptographic proposals (Figure 6). In message 2, Bob sends his Diffie–Hellman

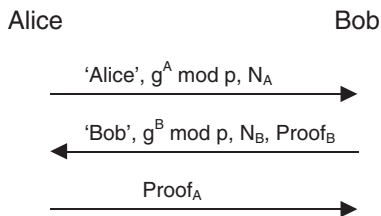

Figure 6: Internet Key exchange version 1 (IKEv1) aggressive mode exchange.

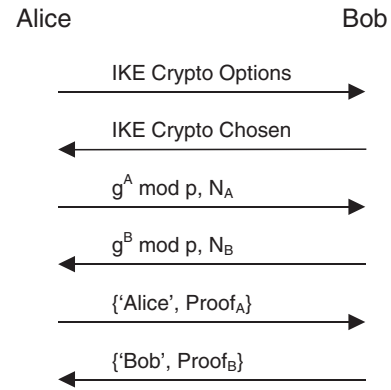

Figure 7: Internet Key exchange version 1 (IKEv1) main mode exchange.

value, his nonce, his identity, the chosen cryptographic protocols, and proof that he knows the key Alice associates with him. Then in message 3, Alice proves knowledge of the key Bob associates with her identity.

Again, although all the handshakes are different, the basic structure of all the main mode handshakes (Figure 7) is that in messages 1 and 2, Alice proposes and then Bob chooses cryptographic algorithms. In message 3, Alice sends a Diffie–Hellman value and a nonce. In message 4, Bob does the same. In message 5, Alice sends her identity and proof of knowledge of her key. In message 6, Bob does the same. Messages 5 and 6 are encrypted in a key that is derived differently in each of the handshakes. In particular, in the one mandatory-to-implement method (main mode with preshared secret keys), Alice sends her identity encrypted in a key that is a function, among other things, of the key she shares with Bob. The problem is that Bob cannot decrypt the message unless he tries all possible keys of all possible correspondents. This, among other problems, was fixed in IKEv2.

Quick mode (phase 2; see Figure 8) starts with the shared key established in phase 1. It consists of three messages. In message 1, Alice sends her choice of SPI (security parameter index) for the IPsec packets (the value Bob should fill into the AH or ESP header so that Alice will know the context in which to interpret the packets), a nonce, proposals for IP addresses and TCP/UDP ports for traffic on the SA, and optionally initiates an additional Diffie–Hellman exchange. Bob responds with his SPI choice, nonce, chosen traffic selectors. Additionally, if Alice initiated a Diffie–Hellman exchange, Bob includes

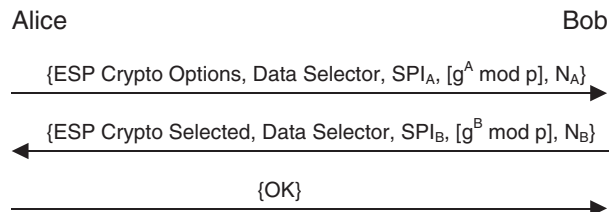

Figure 8: Internet Key exchange version 1 (iKEv1) quick mode (phase 2) exchange.

his own Diffie–Hellman response. Message 3 is just an acknowledgment by Alice that the handshake completed and traffic can now flow.

GLOSSARY

Active Attacker Someone trying to intercept or interfere with an encrypted communication who may eavesdrop on the conversation, attempt to impersonate one or the other end point, inject new or replayed messages, or modify messages in transit.

Advanced Encryption Standard (AES) A symmetric-key cipher also known as Rijndael, serving as successor to DES.

Denial of Service (DoS) A form of attack in which the goal is not to learn secret information or change any stored data, but simply to disrupt the functioning of a system—for example, overloading it to make it unresponsive.

Diffie–Hellman A public key cryptosystem used to agree on a secret (symmetric) key.

Distributed Denial of Service (DDoS) A form of denial of service attack in which the attack is not performed directly by the attacker but through a large number of compromised but otherwise innocent computers on the Internet (these computers are referred to as zombies).

Internet Key Exchange (IKE) The Internet Engineering Task Force standard protocol for initializing security associations for IPsec.

Passive Attacker An eavesdropper on an encrypted communication who does not initiate or modify any of the messages but tries to determine information about the encrypted content and/or encryption keys.

Perfect Forward Secrecy (PFS) A desirable property for a cryptographic protection mechanism. In a mechanism implementing perfect forward secrecy, an attacker who records a conversation and subsequently obtains all of the long term keys of the end points still cannot decrypt the recorded conversation.

Secure Internet Protocol (IPsec) The Internet Engineering Task Force standard protocol for cryptographically protecting IP packets.

Security Association (SA) The shared state in two IPsec end points, including cryptographic keys to be used to protect information, the kinds of information to be protected, addresses, sequence numbers, and names of correspondents.

Security Parameter Index (SPI) The field in the header of a message that indicates the connection context of the message (and hence the cryptographic keys and algorithms that should be used to process the message).

Transport Mode The technique used in an IPsec SA in which there is only a single pair of source and destination addresses, because the end points of the IPsec SA are the same as the end points of the communication.

Tunnel Mode The technique used in an IPsec SA in which there are two pairs of source and destination addresses. The outer addresses are used to route information between the IPsec end points, while the inner addresses route information between the communication end points.

SECURE COMMUNICATION CHANNELS Overview

This chapter provides an overview of how the SSL protocol and its variant the TLS protocol are used to establish and operate a secure communication channel. It is assumed that the readers of this chapter are nontechnical in their academic background. As a result some space will be spent in explaining the background concepts necessary for a full understanding of SSL and TLS. If the reader requires more technical detail (Boncella, 2000) is suggested.

This chapter has five major sections. First is a discussion of the need for and history of secure channels. Second is an overview of the internetworking concepts necessary to appreciate the details of SSL and TLS protocols. Third is a brief review of cryptographic concepts used in SSL and TLS. Fourth is a detailed exposition of SSL and TLS. The chapter concludes with a discussion of SSL and TLS protocol's status—its strengths and weakness and threats and possible alternatives to it.

The Internet can be used to provide a number of communication services. A user can take advantage of e-mail, news posting services, and information gathering services through Web browsing to name a few of its uses. Under certain conditions the user's expectation is that the service to be provided is legitimate, safe, and private—legitimate in the sense that the providers of the service are who they say they are, safe in the sense that the services or information being provided will not contain computer viruses or content that will allow the user's computer system to be used for malicious purposes, and finally, private in the sense that the provider of the requested information or services will not record or distribute any information the user may have sent to the provider in order to request information or services. The server's expectation is that the requestor of the information or service

is legitimate and responsible—legitimate in the sense the user has been accurately identified, and responsible in that the user will not attempt to access restricted documents, crash the server, or use the server computing system as a means of gaining illegal access to another computer system. Both the server and the user have an expectation that their communications will be free from eavesdropping and reliable—meaning that their transmissions will not be modified by a third party. The purpose of Internet security is to meet the security expectations of users and providers. To that end, Internet security is concerned with client-side security, server-side security, and secure transmission of information.

Client-side security is concerned with the techniques and practices that protect a user's privacy and the integrity of the user's computing system. The purpose of client security is to prevent malicious destruction of a user's computer systems (e.g., by a virus that might format a user's fixed disk drive) and to prevent unauthorized use of a user's private information (e.g., use of a user's credit card number for fraudulent purposes).

Server-side security is concerned with the techniques and practices that protect the server software and its associated hardware from break-ins, server site vandalism, and denial-of-service attacks. The purpose of server-side security is to prevent modification of a site's contents; to prevent use of the server's hardware, software, or databases for malicious purposes; and to ensure reasonable access to a server's services (i.e., to avoid or minimize denial-of-service attacks).

Secure transmission is concerned with the techniques and practices that will guarantee protection from eavesdropping and intentional message modification. The purpose of these security measures is to maintain the confidentiality and integrity of user and server information as it is exchanged through the communication channel. This

chapter focuses on a solution to the requirement for a secure channel.

Secure Channels

The Internet can be used for electronic communication. Those who use the Internet for this purpose, on occasion, have the need for that communication to be secure. Secure communication can be ensured by the use of a secure channel. A secure channel will provide three things for the user: authentication of those involved in the communication, confidentiality of the information exchanged in a communication, and integrity of the information exchanged in the communication.

SSL and its variant TLS are protocols that can be used to establish and use a secure communication channel between two applications exchanging information. For example, a secure channel may be required between a user's Web browser and the Web server the user has accessed. The paradigm example is the transfer of the user's credit card information to a Web site for payment of an online purchase. Another example would be an employee using the Web to send his or her check routing information to her employer for use in a direct deposit payroll request.

In addition to Web services, other services that might be in need of a secure channel would be e-mail, file transfer, and news posting. A discussion of how these services utilize a secure channel is presented at the end of the SSL Architecture section.

History of Secure Channels—SSLv1 to v3, PCT, TLS, STLP, and WTLS

SSL is a computer networking protocol that provides authentication of, confidentiality of, and integrity of information exchanged by means of a computer network. Netscape Communications designed SSL in 1994 when it realized that users of its browser needed secure communications. SSL version 1 was used internally by Netscape and proved unsatisfactory for use in its browsers. SSL version 2 was developed and incorporated into Netscape Navigator versions 1.0 through 2.X. This SSLv2 had weaknesses (Stein, 1998) that required a new version of SSL. During that time—1995—Microsoft was developing PCT (private communications technology) in response to the weaknesses of SSLv2. In response, Netscape developed SSL version 3, solving the weakness of SSLv2 and adding a number of features not found in PCT.

In May 1996, the Internet Engineering Task Force (IETF) authorized the TLS working group to standardize a SSL-type protocol. The strategy was to combine Netscape's and Microsoft's approaches to securing channels. At this time, Microsoft developed its secure transport layer protocol, which was a modification of SSLv3 and added support for UDP (datagrams) in addition to TCP support.

In 2002, the WAP Forum (wireless access protocol) adopted and adapted TLS for use in secure wireless communications with its release of WAP 2.0 Protocol Stack. This protocol provides for end-to-end security over wireless or combined wireless and wired connections (Boncella, 2002; WAP Forum, 2002).

An in-depth understanding of secure channels in general and SSL and TLS in particular requires familiarity with two sets of concepts. The first is how the client-server computing paradigm is implemented using the transmission control/Internet protocols (TCP/IP). The second set of concepts deals with cryptography. In particular, one needs to be familiar with the concepts of encryption, both symmetric and asymmetric (public key encryption), key sharing, message digests, and certification authorities.

The first set of concepts, clients and servers using TCP/IP, is discussed in the following section, and the cryptography concepts are reviewed following TCP/IP discussion.

INTERNETWORKING CONCEPTS

Clients and Servers

The Internet is implemented by means of interconnection of networks of computer systems. This interconnection provides information and services to users of the Internet. Computer systems in this interconnection of networks that provide services and information to users of computer systems are called servers. Services are provided by programs running on those computer systems. Computer systems that request services and information use software referred to as client software or simply clients. The communication channel between the client and server may be provided by an Internet service provider (ISP) that allows access to the communication channel for both the server and client. The communication of the client with a server follows a request-response paradigm. The client, via the communication channel, makes a request to a server and the server responds to that request via a communication channel.

The Web may be viewed as a two-way network composed of three components:

1. Clients
2. Servers
3. Communication path connecting the servers and clients

The devices that implement requests and services both are called hosts because these devices are "hosts" to the processes (computer programs) that implement the requests and services.

Communication Paths

The communication path between a server and a client can be classified in three ways:

1. An internet
2. An intranet
3. An extranet

An internet is an interconnection of networks of computers. However, the Internet (with an upper case I) refers to a specific set of interconnected computer networks that allows public access. An intranet is a set of interconnected computer networks belonging to an organization

and is accessible only by the organization's employees or members. Access to an intranet is controlled. An extranet uses the Internet to connect private computer networks or intranets. The networks connected together may be owned by one organization or several. At some point, communication between hosts in an extranet will use a communication path that allows public access.

For a request or response message to travel through a communication path, an agreed-on method for message creation and transmission is used. This method is referred to as a protocol. The de facto protocol of the Internet is the TCP/IP protocol. An understanding of the client-server request-response paradigm requires an overview of the TCP/IP protocol. The TCP/IP protocol can best be understood in terms of the open system interconnection (OSI) model for data communication.

The OSI Model and TCP/IP

The open system interconnection model defined by the International Standards Organization (ISO) is a seven-layer model that specifies how a message is to be constructed for it to be delivered through a computer network communication channel. This model is idealized. In practice, few communication protocols follow this design. Figure 1 provides a general description of each layer of the model. The sender of the message, either a request or a response message, provides input to the application layer.

The application layer processes sender input and converts it to output to be used as input for the presentation layer. The presentation layer, in turn, processes this input to provide output to the session layer, which uses that output as input, and so on, until what emerges from the physical layer is a signal that can be transmitted through the communication channel to the intended receiver of the message. The receiver's physical layer processes the signal to provide output to its data link layer, which uses

Figure 1: Open system interconnection (OSI) model.

that output as input and processes it to provide output to the receiver's network layer, and so on, until that message is accepted by the receiver.

This process is depicted in Figure 2. Figure 2 also illustrates the signal (message) being relayed through the communication channel by means of intermediate nodes. An intermediate node is a host that provides a specific service with the purpose of routing a signal (message) efficiently to its intended destination.

Figure 3 depicts the TCP/IP protocol on the OSI model. For our purposes the TCP/IP protocol is made up of four layers. What follows is a brief overview of the TCP/IP protocol. For an introduction to the details of TCP/IP, consult Forouzan (2000).

The application layer contains a number of applications that a user may use as client processes to request a service from a host. The client processes are said to run on a local host. In most cases, the requested service will be provided by a remote host. In many cases, there will be a similarly named application on the remote host that will provide the service. For example, the user may open a Web browser and request HTTP (hypertext transfer protocol) service from a remote host to copy an HTML (hypertext markup language) formatted file into the user's Web browser. If the receiving host provides HTTP service, it will have a process running, often named HTTPD, that will provide a response to the client's request. Note that users need to specify the host by some naming method and the service they desire from that host. This is taken care of by the use of a universal resource locator (URL; e.g., <http://www.washburn.edu>). The application Layer produces a message that will be processed by the transport layer.

The client's request will pass through the local host's transport layer. The responsibility of the transport layer is to establish a connection with the process on the remote host that will provide the requested service. This client-process-to-server-process connection is implemented by means of port numbers. A port number is used to identify a process (program in execution) uniquely. Unique identification is necessary because local hosts and remote hosts may be involved in a number of simultaneous request-response transactions. The hosts' local operating systems, in concert with the TCP/IP protocol concept of port numbers, can keep track of which of several responses corresponds to the correct client process request on that local host and which request corresponds to the correct service on the remote host.

The transport layer will cut the message into units that are suitable for network transport. In addition to the port numbers, the transport layer adds information that will

allow the message to be reconstructed in the receiver's transport layer. Other information is added to these units that allows flow control and error correction. The output from the transport layer is called a segment. The segment is composed of the data unit and a header containing the information described earlier. Figure 4 shows this process.

The output of the transportation layer, a segment, is sent to the network or IP layer. The responsibilities of the IP layer include providing the Internet or IP address of the source (requesting) host and destination (response) host of the segment. One important part of the IP address is a specification of the network to which the host is attached. Depending on the underlying physical network, the segments may need to be fragmented into smaller data units. The information from the segment header is duplicated in each of these fragments as well as the header information provided by the network or IP layer.

The output of the IP layer is called a datagram. The datagram is passed to the lowest layer, where the physical addresses associated with the source and destination hosts' IP addresses are added. The physical address of a host uniquely identifies the host on a network. It corresponds to a unique number of the network interface card (NIC) installed in the host. An example is the 48-bit-long Ethernet address provided by the manufacturer of an Ethernet card. When the TCP/IP protocol is installed on a host, that host's physical address is associated with an IP address. The physical address allows a particular host to be independent of an IP address.

To understand Internet security, we need to be aware of three concepts associated with the TCP/IP protocol:

1. Port address
2. IP addresses
3. Physical addresses

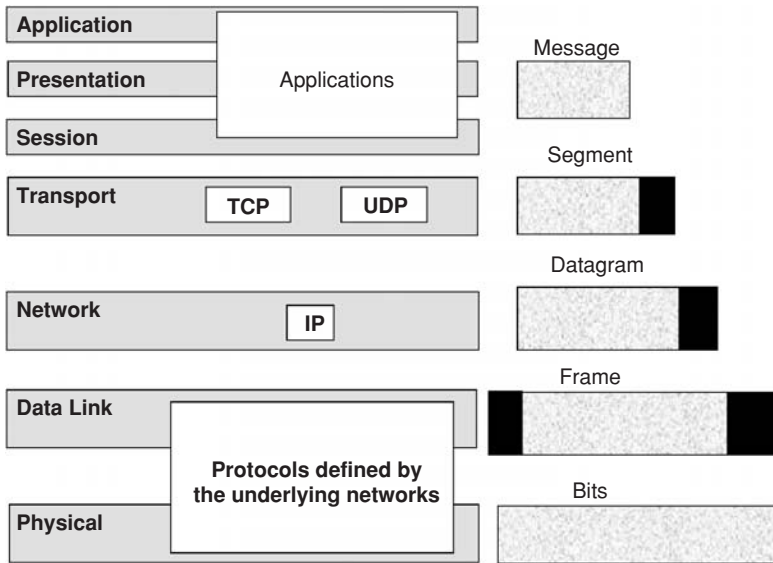

Figure 4: Transmission control/Internet protocol (TCP/IP) message delivery.

These concepts allow the request–response message to be exchanged by the intended processes (as specified by port numbers.). Those processes are running on hosts attached to the intended networks (as specified by the IP addresses) and, finally, running on the intended hosts (as specified by physical addresses). Figure 5 depicts these address assignments and the layers responsible for their assignments.

CRYPTOGRAPHIC CONCEPTS USED IN SSL AND TLS

The following is a brief review of these concepts. The details of each are provided elsewhere in the *Handbook of Information Security*. Volume 2, Part 3, will contain the details of most of these ideas.

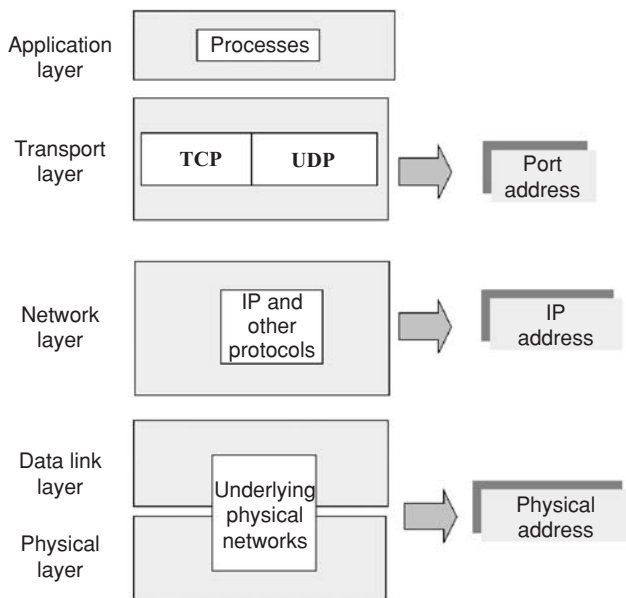

Figure 5: Address types and assignments in transmission control/Internet protocol (TCP/IP).

Encryption

Encryption is the process of converting plaintext (readable text) into ciphertext (unreadable text). Decryption is the process of converting ciphertext into plaintext. Usually this is done by means of a publicly known algorithm and a shared key. Encryption is vital in providing message confidentiality, client–server authentication, and message integrity. There are two methods of encryption: symmetric or secret key and asymmetric or public/private-key pair. Each method of encryption has its particular use. Symmetric encryption is used for encryption of the messages exchanged between a client and a server, whereas asymmetric encryption is used to exchange the common keys used by clients and servers in their symmetric encryption process. Asymmetric encryption may also be used for the encryption of messages.

Symmetric Encryption

There are two main types of symmetric encryption: stream ciphers and block ciphers. Stream ciphers combine 1 byte of the key with 1 byte of the plaintext to create the ciphertext in a byte-after-byte process. Block ciphers process plaintext in blocks of bytes, generally 8 or 16 bytes in length, into blocks of ciphertext.

RC4 is a widely used stream cipher. There are a number of block ciphers, including Data Encryption Standard (DES), Triple DES (3DES), and Rivest Cipher #2 (RC2). AES is another block cipher that is an improvement over DES in that it uses variable block sizes and has longer key lengths—128-, 192-, or 1256-bit keys. The specifics of these ciphers are discussed elsewhere in this volume.

Symmetric encryption requires the sender and receiver to share a secret key. This secret key exchange is a drawback of symmetric systems that is typically overcome by asymmetric or PKI systems.

Asymmetric Encryption

In asymmetric encryption a pair of keys, a public key and a private key, are used to carry out the encryption process. If the private key is used to create the ciphertext, then only

the corresponding public key can be used to decrypt that ciphertext and vice versa. Asymmetric (or public/private-key) encryption can be used for key sharing, encryption, and digital signatures.

Key Sharing

There are two means to carry out key sharing. One is “key exchange” in which one side of the message exchange pair generates a symmetric key and encrypts it with the public key of the private–public key pair of the other side. The other technique of key sharing is “key agreement.” In this technique each side of the message exchange pair cooperate to generate the same key that will be used for symmetric encryption. The RSA (named for its creators, Rivest, Shamir, Adelman) public key algorithm can be used for the key exchange technique. The Diffie–Hellman public key algorithm can be used for the key agreement technique. The details of these algorithms are discussed elsewhere in this text.

Message Digest Algorithms

Message digest algorithms are used to generate a “digest” of a message. A message digest algorithm computes a value based on the message content. The same algorithm and message content will generate the same value. If a shared secret key is included with the message before the digest is computed, then when the digest is computed the result is a message authentication code (MAC). If the client and server are sharing this secret key and know each other’s message digest algorithms, they can verify the integrity of the message exchange.

Two commonly used message digest algorithms are Message Digest #5 (MD5), which computes a 16-byte value (128 bits), and Secure Hash Algorithm 1 (SHA-1), which computes a 20-byte value (160 bits).

Digital Signatures

Digital signatures are used for nonrepudiation. Public-key algorithms can be used for digital signatures. RSA is a means of providing a digital signature by the sender encrypting a known pass phrase with his or her private key. This pass phrase is generally a message digest of the message being sent. Only the corresponding public key will decrypt the ciphertext of the pass phrase to the correct plaintext. It should be noted that not all public–private key systems are “reversible” like RSA. The digital signature algorithm (DSS) is another algorithm that can be used for this purpose.

Certification Authorities

A certification authority (CA) is a trusted third party that is responsible for the distribution of the public key of a public–private key pair. The CA does this by issuing (and revoking) public key certificates. A standard for these certificates is X.509v3. This standard defines the fields contained in the certificate. This is a widely accepted standard and is used by most CAs.

Figure 6: Secure socket layers (SSL) within transmission control/Internet protocol (TCP/IP).

SSL ARCHITECTURE Overview

SSL is composed of four protocols. Three of the four, SSL handshake protocol, SSL change cipher spec protocol, and SSL alert protocol, are used to set up and manage secure communication channels. The remaining protocol, the SSL record protocol, provides the security service required by applications. The SSL lies between the application layer and the TCP layer of the TCP/IP protocols. This architecture is represented in Figure 6.

Once a secure channel has been established the SSL takes messages to be transmitted, fragments the message into manageable blocks, optionally compresses the data, applies a message authentication code (MAC), encrypts, prefixes the SSL record header, and sends the result to the TCP layer. Ultimately these data blocks are received and the data are decrypted, verified, decompressed, reassembled in the receiver’s SSL layer, and then delivered to higher level clients. The technical details of these protocols are discussed in a number of places. The primary document is the Web page <http://wp.netscape.com/eng/ssl3/ssl-toc.html>.

A number of excellent secondary sources provide more background information as well as the specifications of the protocols. The interested reader is directed to Rescorla (2001) and Stallings (2003). The protocols used to establish a secure channel give SSL its flexibility for client–server communication.

SSL is flexible in the choice of which symmetric encryption, message digest, and authentication algorithms can be used. When an SSL client makes contact with an SSL server, they agree on the strongest encryption methods they have in common. Also, SSL provides built-in data compression. Data compression must be done before encryption.

For example, when an SSL connection is established for an SSL-protected HTTP connection, client-to-server and server-to-client communication is encrypted. Encryption includes the following:

URL of requested document
Contents of the document

Contents of browser forms
 Cookies sent from browser to server
 Cookies sent from server to browser
 Contents of HTTP header, but not particular browser to particular server

In particular, socket addresses—IP address and port number—are not encrypted; however, a proxy server can be used if this type of privacy is required.

Connection Process Preview

The connection process is shown in Figure 7. Figure 7 and the following narrative serve as an overview of this process. To establish an SSL connection, the client (browser) opens a connection to a server port. The browser sends a “client hello” message—Step 1. A client hello message contains the version number of SSL that the browser uses, the ciphers and data compression methods it supports, and a random number to be used as input to the key generation process.

The server responds with a “server hello” message (Step 2). The server hello message contains a session ID and the chosen versions for ciphers and data compression methods the client and server have in common. The server sends its digital certificate (Step 3) which is used

to authenticate the server to the client and contains the server’s public key (Step 4). Optionally, the server may request a client to authenticate. If requested, the client will send a signed piece of data unique to this handshake and known to both the client and server as the client’s means of authentication (Step 5). If the client cannot be authenticated, then connection failure results. Assuming a successful connection, the client sends a “ClientKey Exchange” message (Step 6). This message is a digital envelope created using the server’s public key and contains the session key chosen by the client. Optionally, if client authentication is used, the client will send a certificate verify message (Step 7). The server and client send a “ChangeCipherSpec” message (Step 8) indicating they are ready to begin encrypted transmission with the newly established parameters. The client and server send finished messages to each other (Step 9). The finished messages are MACs of their entire conversation up to this point. (Recall: a MAC, message authentication code, is a key-dependent one-way hash function. It has the same properties as the one-way hash functions called message digests, but they have a key. Only someone with the identical key can verify the hash value derived from the message.) Accordingly, if the MACs match, then messages were exchanged without interference, and hence the connection is legitimate. Once the secure channel is established, application-level data

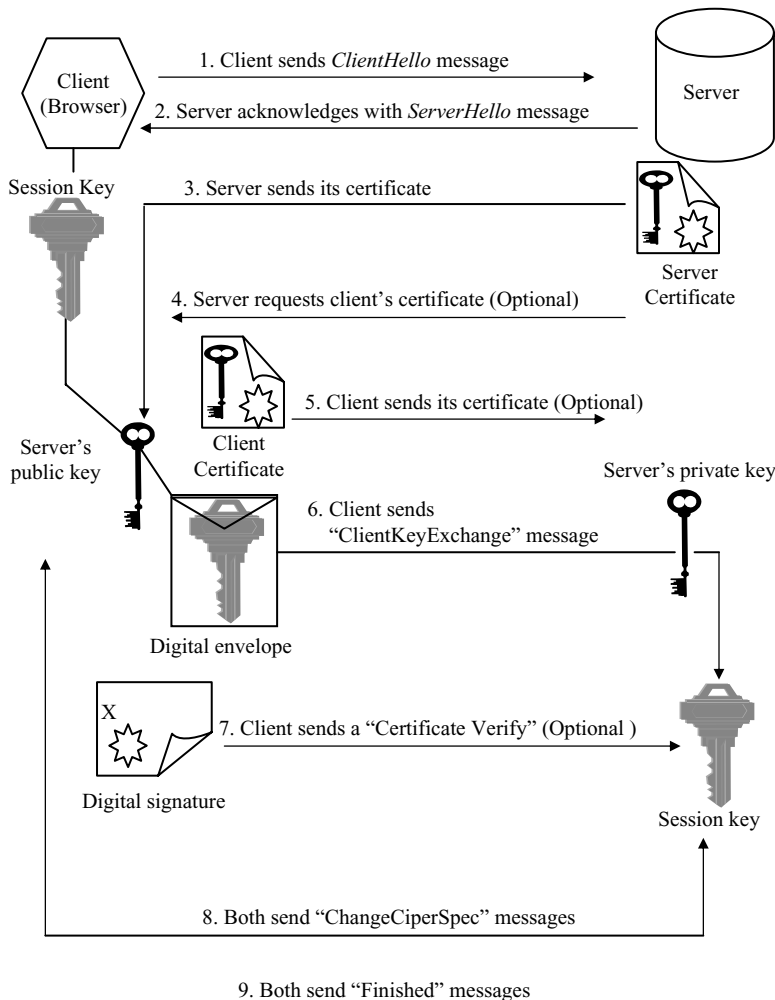

Figure 7: Secure socket layers (SSL) connection process.

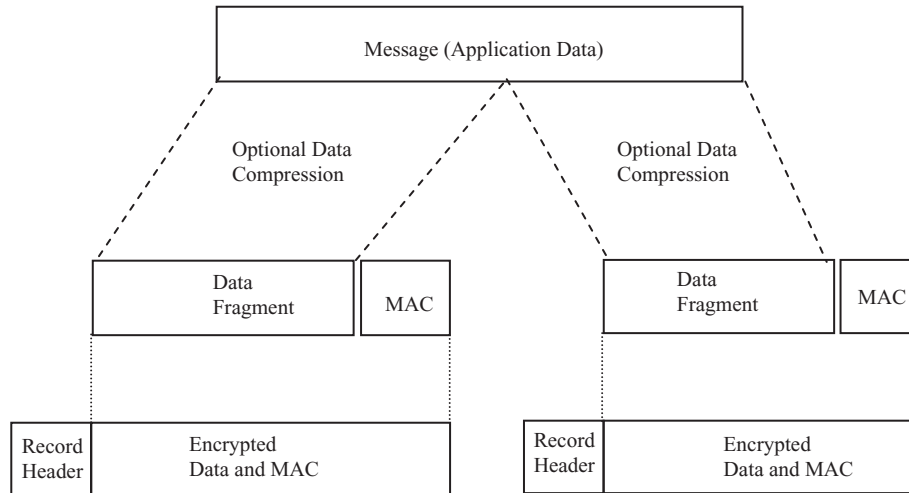

Figure 8: Secure socket layers (SSL) message protocol.

can be transmitted between the client and server using the SSL record protocol.

Record Protocol

The SSL record protocol provides two of the three essential requirements for secure transmission of data: confidentiality and message integrity. Confidentiality is provided by symmetric encryption that uses the shared session key exchanged between the client and server during the handshake protocol. This handshake protocol also defines a shared secret key that can be used to create a MAC, which can be used to ensure message integrity. The third requirement, authentication, is provided by the handshake protocol in its requirement of at least a server's certificate.

The record protocol processes a message by first breaking the message into fragments of equal fixed size, padding the last fragment as needed. The next step is optional compression of each fragment. Once the compression is completed, a MAC is computed for each fragment and appended to the fragment. The result is then encrypted using the key and algorithm agreed on by the client and server. An SSL record header is appended. Then this segment is passed to the TCP layer for processing. The received data are processed by the receiving protocol in the reverse process: data are decrypted, verified by means of the MAC, and decompressed if necessary, then the fragments are re-assembled, and the result is passed on to the destination application. This process is depicted in Figure 8.

TLS—Transport Layer Security

TLS is an attempt by the IETF to specify an Internet standard version for SSL. The current proposed standard for TLS is defined in RFC 2246 (2002). The proposed TLS standard is very similar to SSLv3. The TLS record format is identical to the SSL record format. There are a few differences between SSL and TLS. Some of these are how MAC computations are carried out, how pseudorandom functions are used, including additional alert codes and client certificate types, and how certificate verification and

finished message are carried out. The details of these differences are discussed in Stallings (2003).

SSL and TLS Protocols: Details

The preceding sections provide an overview of how a secure channel is set up and used. A better understanding of this process is obtained when a detailed examination of this process is presented. It is informative to work through each step of Figure 7 and detail how the protocols work to set up the secure channel. The following is an adaptation of information that may be found in specification documents for SSL (Netscape Communications, 1996, 1998).

Handshake Protocol

Of the four protocols that make up SSL and TLS, the handshake protocol is the most critical. This protocol is responsible for setting up the connection. It uses a sequence of messages that allows the client and server to authenticate each other and agree on encryption and MAC algorithms and their associated keys, as well as the key exchange algorithms to be used.

The format of the handshake protocol is simple, as depicted in Figure 9. The type field of the handshake protocol indicates 1 of 10 messages listed in Table 1. Length is the length of the message in bytes. Content is the parameters associated with the message type (cf. Table 1).

Step 1 of Figure 7 is the *ClientHello* message. Its parameters are as follows:

version The version of the SSL protocol by which the client wishes to communicate during this session. This should be the most recent version supported by the client.

random A client-generated random structure. This is a value 32 bytes long. The first four bytes are the time

Type	Length	Content
1 Byte	3 Bytes	≥ 0 Bytes

Figure 9: Handshake protocol layout.

Table 1 Handshake Protocol Messages

Message Type	Parameters
<i>HelloRequest</i>	Null
<i>ClientHello</i>	Version, random, session_id, cipher_suite, compression_method
<i>Serverhello</i>	Version, random, session_id, cipher_suite, compression_method
<i>Certificate</i>	Chain of X.509v3 certificates
<i>ServerKeyExchange</i>	Parameters, signatures
<i>CertificateRequest</i>	Type, authorities
<i>ServerDone</i>	Null
<i>CertificateVerify</i>	Signature
<i>ClientKeyExchange</i>	Parameters, signatures
<i>Finished</i>	Hash_value

of day the message was generated, and the remaining 28 bytes are created using a secure random number generator. This 32-byte value will be used as one of the inputs to the key generation procedure. The time stamp (first 4 bytes) prevents a possible “man in the middle” attack as well as protecting against reply attacks.

session_id The ID of a session the client wishes to use for this connection. This parameter will be *empty* if no session_id is available or the client wishes to generate new security parameters.

cipher_suites A list of the cryptographic options supported by the client, sorted descending preferences. If the session_id field is not *empty* (implying a session resumption request) this vector must include at least the cipher_suite from that session.

compression_methods A list of the compression methods supported by the client, sorted by client preference. If the session_id field is not *empty* (implying a session resumption request), this vector must include at least the compression method from that session. All implementations must support a null compression method (i.e., no data compression is used).

After sending the **client hello** message, the client waits for a **server hello** message. Any other handshake message returned by the server except for a **hello request** is treated as a fatal error.

Step 2 is the **server hello** message. The server processes the **client hello** message and responds with either a handshake_failure **alert** or a **server hello** message. The *ServerHello* message parameters are as follows:

server_version This field will contain the lower of that suggested by the client in the *ClientHello* message and the highest supported by the server.

random This structure is generated by the server and *must* be different from (and independent of) the *ClientHello* random structure.

session_id This is the identity of the session corresponding to this connection. If the *ClientHello* message session_id parameter was nonempty, the server will look in its session cache for a match. If a match is found and the server is willing to establish the new connection using the specified session state, the server will

respond with the same value as was supplied by the client. This indicates a *resumed* session and dictates that the parties *must* proceed directly to the *finished* messages. Otherwise this field will contain a different value identifying the new session. The server may return an *empty* session_id to indicate that the session will not be cached and therefore cannot be resumed.

cipher_suite The single cipher suite selected by the server from the list in the *ClientHello* message cipher_suites parameter. For *resumed* sessions, this field is the value from the state of the session being resumed.

compression_method The single compression algorithm selected by the server from the list in the *ClientHello* message compression_methods parameter. For *resumed* sessions, this field is the value from the resumed session state.

Step 3 is the *Certificate* message. If the server is to be authenticated (which is generally the case), the server sends its certificate immediately following the *ServerHello* message. The certificate type must be appropriate for the selected cipher suite’s key exchange algorithm and is generally an X.509.v3 certificate. The same message type is also used for the client’s response to a server’s *CertificateRequest* message.

If the server has no certificate or if a key exchange technique other than RSA or fixed Diffie–Hellman is used, the server will send *ServerKeyExchange* message. In this case, the parameters for this message will contain the values appropriate for the key exchange technique (see Stallings, 2003, for details).

In **Step 4** (optional), a nonanonymous server can optionally request a certificate from the client, if appropriate for the selected cipher suite. The *CertificateRequest* message has two parameters:

types A list of the types of certificates requested, sorted in order of the server’s preference.

authorities A list of the distinguished names of acceptable certificate authorities.

After **Step 3** (or optional **Step 4**), the server will send a *ServerHelloDone* message to indicate that the server has sent all the handshake messages necessary for the server hello phase. After sending this message, the server will

wait for a client response. When the client receives the *ServerHelloDone* message, the client will determine the validity of the server's certificate and the acceptability of the *ServerHello* message parameters. If the parameters and certificate are valid, the client will receive one or two messages.

Step 5 (optional) is the *Certificate* message. This is the first message the client can send after receiving a *ServerHelloDone* message. This message is only sent if the server requests a certificate. If no suitable certificate is available, the client should send a *NoCertificate* alert instead. This error is only a warning; however, the server may respond with a *FatalHandshakeFailure* alert if client authentication is required.

Step 6 is the *ClientKeyExchange* message. The content of the message will be based on the type of key exchange negotiated during the first phase of the handshaking process. The key exchange method is determined by the cipher suite selected and server certificate type. For example, if the client and server agree on the RSA key exchange method, the client generates a 48-byte *premaster_secret* and encrypts it with the public key from the server's certificate or uses the temporary public key from the server's *ServerKeyExchange* message.

If the server has requested a client certificate and it requires verification, the client will send a *CertificateVerify* message to provide explicit verification of its client certificate.

In **Step 8**, the client sends a *ChangeCipherSpec* message that indicates the client has switched to the negotiated cipher suit. All subsequent messages will be sent using those encryption algorithms and appropriate keys. It should be noted that the *ChangeCipherSpec* message is a separate protocol and not part of the handshake protocol. The purpose of this is to make SSL and TLS more efficient. The *ChangeCipherSpec* message consists of only 1 byte.

In **Step 9**, the client sends the handshake message *Finish*. The message is a concatenation of two message digest values. Each value is computed using a different message digest algorithm—MD5 and SHA—on the same data. The data are the master secret (described later) and the set of handshake messages sent up to this point.

In response to these two client messages, the server sends its version of the *ChangeCipherSpec* and a *Finished* message computer using that same data as the client. If this *Finished* message value differs from the *Finished* message value sent by the client then this indicates that the handshake has been modified and a secure channel may not be set up. When the client receives the *finish* message from the server, it does a comparison with its locally computed *finish* message value. If they match, then all is well; otherwise the secure channel may not be established.

Cipher Suites and Master Secrets

There are two more concepts that need to be presented to complete this discussion. In Step 1, the client sends a list of cipher suites to the server that the client is able to use. In Step 6, the client sends a *pre_master_secret* that will be used to compute the master secret. This master secret is then used to compute the *key_block*. This *key_block* is used to derive the keys that will be used with the algorithms

specified in the cipher suites. The details of each of these need to be presented.

Cipher Suites

The **cipher_suite** parameter of the *ClientHello* message provides a set of key exchange techniques, server authentication algorithms, bulk encryption algorithms, and message digest algorithms that the client can support. The client lists these sets in order of the client's preference. For example, one of the entries of this set may be

TLS_DHE_RSA_WITH_3DES_EDE_CBC_SHA

In this example, the key exchange technique is DHE, where DHE denotes ephemeral Diffie–Hellman. The Diffie–Hellman parameters are signed either by DSS or RSA. The signing algorithm used is specified after the DHE parameter. In this case, the signing algorithm is the RSA algorithm.

The bulk encryption and message digest algorithms follow the WITH delimiter, in which the bulk encryption is performed by 3DES_EDE_CBC, where 3DES_EDE_CBC denotes 3DES encryption using the encrypt–decrypt–encrypt mode in the cipher block chaining mode, and the message digest algorithm is SHA, where SHA denotes the secure hash algorithm.

Master Secret

The master secret creation is the vital component in setting up the secure channel. The master secret is used to compute the *key_block*. Once the *key_block* computed, it is partitioned into six keys that are used by the client and server in their communications. The computation of the *key_block* is as follows.

The *ClientKeyExchange* message provides the server with the *pre_master_secret* when using RSA. Otherwise this message contains the client's Diffie–Hellman parameters. The client and server use this 48-byte value along with the *ClientHello* random parameter value and *ServerHello* random parameter value (they both have copies of these) to create a hash value by using the MD5 and SHA algorithms in the same sequence on this common set of values. They will both compute the identical hash value. This value is the master secret that is shared (computed) by both. A similar process is used to compute the *key_block*, but instead of using the *pre_master_secret* in the computation, the *master_secret* is used. This results in a *key_block* that is “shared,” computed independently but to the same value, by the client and server.

The size of the *key_block* is determined by the cipher specifications. These specifications give the number of bytes required for the bulk encryption keys (i.e., one for the client to use and one for the server to use), MAC keys, and, if necessary, initialization vector keys. Initialization vectors (IV) are necessary if a bulk encryption algorithm will be using the cipher block chaining mode.

This “shared” *key_block* is partitioned in the same sequence by the client and server. The first set of bytes is used in the client MAC secret. The second set is used for the server MAC secret. The third set is used for the client bulk encryption key. The fourth set is used for the server bulk encryption key. The fifth set of bytes is used for the

Table 2 Secure Internet Services and Their Associated Port Numbers

Keyword	Secure Port Number	Function
https	443/tcp	SSL/TLS Protected HTTP
ssmtp	465/tcp	SSL/TLS Protected SMTP mail sending
spop3	995/tcp	SSL/TLS Protected POP3 mail receiving
imaps	993/tcp	SSL/TLS Protected IMAP mail server
ftps-data	989/tcp	SSL/TLS Protected FTP data sending
ftps	990/tcp	SSL/TLS Protected FTP control
nntps (snews)	563/tcp	SSL/TLS Protected Usenet News
ssl-ldap	636/tcp	SSL/TLS Protected LDAP

client initialization vector. Finally, the last set of bytes is used as the server's initialization vector.

Secure Internet Services Implemented Using SSL

Many services using the Internet run over TCP. It is a simple task to convert these services to run over SSL. In particular, Web browsing services, e-mail services, and network news posting services have been converted to use SSL when appropriate. Table 2 contains the key word of each service and the ports they are assigned when using SSL.

STATUS OF SSL

SSLv3 and TLS 1.0 and Commercial Use

SSL and TLS primarily function to protect Web traffic using HTTP. For this to work, both the client and the server need to be SSL or TLS enabled. All major Web browsers, including Netscape Navigator and Microsoft Internet Explorer, support SSL and TLS. These browsers allow the user to configure how SSL or TLS will be used. In Netscape Navigator 6.0, the user may consult the Security Preferences panel and open the SSL option under the Privacy and Security selection. In Internet Explorer, the user may consult the Security entry in the Advanced Tab on the Internet Options selection in the drop down menu item for Tools. An interesting option in both browsers is the choice of whether to save the downloaded page to the local cache. The downloaded page is no longer encrypted

and if it is saved to local storage it will be in plaintext. If the local machine is compromised or stolen (e.g., a laptop), that document is readable by any user.

When a secure channel has been established, these browsers will inform the user by means of a small padlock icon at the bottom of the browser. This indicates the page was downloaded using SSL or TLS. The URL of the Web page indicates if SSL is required on the part of the Web browser. A URL that begins with HTTPS indicates that SSL should be used by the browser. A number of Web servers support SSL and TLS. A sample of such programs is displayed in Table 3.

The details of what is required to install and set up an SSL/TLS Web server can be found in various of places. For a detailed overview, the reader is directed to Garfinkel and Spafford (2002) and to Stein (1998). For a technical discussion of what is required, the reader should consult Rescorla (2001).

Advantages, Disadvantages, Threats, and Alternatives to SSL/TLS

SSL and TLS provide server authentication, encryption of messages, and message integrity. This design has several advantages, disadvantages, threats, and alternatives.

Advantages

An important advantage of both SSL and TLS is they provide a generic solution to establishing and using a secure channel. This solution lies between the application and

Table 3 Web Servers That Support the SSL Protocol

Package	Creator	Obtain From
OpenSSL	OpenSSL Development Team	www.openssl.org
Apache mod_ssl (requires OpenSSL)	Apache Software Foundation	www.apache.org
Microsoft IIS	Microsoft Coporation	Bundled with WINNT, WIN2000 and WINXP
Netscape Enterprise and Suitspot	Netscape Communications	www.netscape.com
Covalent SSL (SSL Acclerator)	Covalent Technologies, Inc.	www.covalent.net
Apache Stronghold (commercial Apache)	C2Net	www.c2.net

TCP layers of the TCP/IP protocol suit. As illustrated in Table 2, this implies that any protocol that can be carried over TCP (e.g., ftp, nntp) can be guaranteed security using SSL or TLS.

Another advantage is that SSL's and TLS's designs are publicly available. Because of this, a large number of SSL and TLS implementations are available both as freeware and as commercial products. Furthermore, these implementations are designed as Application Programming Interfaces (APIs) that are similar to networking APIs. In a C/C++-based implementation, the SSL APIs emulate Berkeley sockets; in Java they emulate they Java socket class. As a result, it is a simple matter to convert a non-secure application into a secure application using SSL or TLS.

Disadvantages

When using SSL/TLS for security, it must be remembered that the packets that make up the message are encrypted at the TCP layer. As a result, the IP information will be in clear text. Anyone monitoring the communication will be able to determine the source and destination address of the messages. This kind of traffic analysis could lead to information that ought to remain confidential.

In e-commerce, the application of SSL and TLS has several disadvantages. Both protocols are able to solve the problem of transmitting a credit card number securely, but they are not designed to help with other aspects of that type of transaction. In particular, they are not designed to verify the credit card number, communicate and request authorization for the transaction from the consumer's bank, and ultimately process the transaction. In addition, they are not designed to carry out additional credit card services (e.g., refunds, back order processing, debit card transactions).

An additional disadvantage of SSL/TLS is security of a credit card information on the server. In particular, if the credit card number is cached on the server, it will be stored in plaintext. If the server becomes compromised, that number would be available in plaintext.

Finally, SSL/TLS is not a global solution. In the United States, systems that use strong encryption cannot be exported.

Threats to SSL/TLS

SSL/TLS are vulnerable to the "man in the middle" attack. Such an attack takes place when a malicious host is able to intercept the transmission to and from a client requesting an Internet service and the server providing the Internet service. The malicious host carries out an SSL/TLS exchange with both the client and the server. The result is that the malicious host appears to be a server for the client and also appears to be the client to the server. In fact, the malicious host is really an intermediary between them and will have access to the information being exchanged between the client and server. In particular, the malicious host will set up session keys for use with the client and another set of session keys for use with the server. This threat can be dealt with by the client's use of server certificates issued by a trusted certification authority (CA). For additional details, see Ellison and Schneier (2000).

Alternatives to SSL/TLS

In the area of e-commerce, an alternative to SSL that does not have the disadvantages just cited is SET (secure electronic transaction). SET is a cryptographic protocol developed by Visa, Mastercard, Netscape, and Microsoft. It is used for credit card transactions on the Web and provides the following:

Authentication: All parties to a transaction are identified.

Confidentiality: A transaction is encrypted to foil eavesdroppers.

Message integrity: It is not possible to alter an account number or transaction amount.

Linkage: Attachments can only be read by a third party if necessary.

In addition, the SET protocol supports all features of a credit card system: cardholder registration, merchant registration, purchase requests, payment authorizations, funds transfer (payment capture), chargebacks (refunds), credits, credit reversals, and debit card transactions. Furthermore, SET can manage real-time and batch transactions and installment payments. In addition, because SET is used for financial transactions only, it can be exported and hence can be a global solution for e-commerce. The details of SET are discussed in another chapter.

In the area of providing a secure channel for messages, there are alternatives to SSL/TLS. One is IPsec (IP security), which is a set of open standards designed by IETF and specified in RFC 2401 (2002). IPsec provides for end-to-end encryption and authentication at the IP layer. IPsec is supported in Ipv4 and mandatory in Ipv6. Another alternative to SSL/TLS is SSH (secure shell). SSH is an application and protocol suite that allows a secure connection to be established between two computers that are using a public network. The SSH protocol architecture has three components:

1. Transport layer protocol, which provides server authentication, confidentiality, and data integrity
2. Authentication protocol, which provides user authentication
3. Connection protocol, which provides multiple data channels in a single encrypted tunnel

These protocols run on top of the TCP layer in the TCP/IP protocol suite, which is similar to SSL and TLS.

GLOSSARY

Advanced Encryption Standard (AES) A cipher that encrypts blocks of data of a variable size. In addition, it uses keys of 128, 192, or 256 bits.

Asymmetric Encryption A cryptographic algorithm that uses separate but related keys for encryption and decryption. If one key of the pair is used for encryption, the other key of the pair must be used for decryption. This is sometimes referred to as a public-key algorithm.

Authentication The process of verifying that a particular client or server is who it claims to be.

Block Cipher A cipher that encrypts blocks of data of a fixed size.

Certificate, Public Key A specified, formatted block of data that contains the name of the owner of a public key as well as the public key. In addition, the certificate contains the digital signature of a CA. This digital signature authenticates the CA.

Certification Authority (CA) A trusted entity that signs public key certificates.

Ciphertext The result of encrypting plaintext.

Confidentiality A condition in which information exchanged between a client and server is disclosed only to those intended to receive it.

Data Encryption Standard (DES) A widely commercially used block cipher.

Diffie-Hellman (DH) An asymmetric algorithm that generates a secret shared between a client and server on the basis of some shared, public, and randomly generated data.

Digital Envelope Used to send a symmetric key to recipient for use in future communications. It is created by the sender encrypting the symmetric key using the recipient's public key.

Digital Signature A data value computed using a public key algorithm. A data block is encrypted with the sender's private key. This ciphertext is not confidential but the message cannot be altered without using the sender's private key.

Digital Signature Standard (DSS) A digital signature algorithm developed by the National Security Agency (NSA) and endorsed by the National Institute of Standards and Technology.

Hash Function A function that maps a variable-length message into a value of a specified bit length. This value is the hash code. There is no known method that will produce the original message using the hash value of the message. There is no known way of creating two messages that hash to the same value.

Integrity Being able to ensure that data are transmitted from source to destination without unauthorized modification.

Internet Protocol A protocol that allows packets of data to be sent between hosts in a network or hosts in connected networks.

Message Digest #5 (MD5) A one-way hash algorithm.

Nonrepudiation Being able to ensure the receiver that the sender of a message did indeed send that message even if the sender denies sending it.

Rivest Cipher #2 (RC2) A block cipher sold by RSA data security. This is a 40-bit key cipher.

Rivest Cipher #4 (RC4) A stream cipher used in commercial products

Rivest, Shamir, Adelman (RSA) An asymmetric cipher (public-key cipher) that can encrypt and decrypt. It is also used to create digital signatures.

Secret Key A cryptographic key that is used with a symmetric algorithm.

Session Key A secret key that is used for a limited period of time. This time period covers the length of time there is communication between a client and a server.

Symmetric Algorithm A cipher that requires one shared key for both encryption and decryption. This

shared key is a secret key, and the strength of the ciphertext depends on keeping the shared key secret.

Transmission Control Protocol (TCP) The Internet protocol that provides reliable communication between client and a server.

Triple DES (3DES) A cipher that uses DES three times with either two or three DES keys.

X.509 A public-key certificate standard.

INTRODUCTION

Public key cryptography is based on asymmetric cryptographic algorithms that use two related keys, a public key and a private key. Given the public key, it is computationally infeasible to derive the private key. Users publish their public keys in a public directory, such as an lightweight directory access protocol (LDAP) directory and keep their private keys to themselves.

According to the purpose of the algorithm, there are public key encryption–decryption algorithms and signature algorithms. An encryption algorithm could be used to encrypt a data (for example, a symmetric key) using the public key so that only the recipient who has the corresponding private key could decrypt the data. Typical public key encryption algorithms are rivest-shamir-adleman (RSA) and (elliptic curve integrated encryption scheme; ECIES Standards for efficient cryptography group, 2000). A signature algorithm together with a message digest algorithm could be used to transform a message of any length using the private key to a *signature* in such a way that, without the knowledge of the private key, it is computationally infeasible to find two messages with the same signature, to find a message for a predetermined signature, or to find a signature for a given message. Anyone who has the corresponding public key could verify the validity of the signature. Typical public key digital signature algorithms are RSA, digital signature algorithm (DSA), and elliptic curve digital signature algorithm (ECDSA).

There have been extensive standardization efforts for public key cryptographic techniques. The major standards organizations that have been involved in public key cryptographic techniques are the following:

- **The International Organization for Standardization (ISO) and the International Electrotechnical**

Commission (IEC) individually and jointly, have been developing a series of standards for application-independent cryptographic techniques. ISO has also been developing bank security standards under the ISO technical committee TC86–Banking and Related Financial Services.

- **The American National Standards Institute (ANSI)** has been developing public key cryptographic technique standards for financial services under Accredited Standards Committee (ASC) X9. For example, it has developed the standards ANSI X9.42 (key management using Diffie–Hellman), ANSI X9.44 (key establishment using factoring-based public key cryptography), and ANSI X9.63 (key agreement and key management using ECC).
- **The National Institute of Standards and Technology (NIST)** has been developing public key cryptography standards for use by U.S. federal government departments. These standards are released in Federal Information Processing Standards publications.
- **The Internet Engineering Task Force** has been developing public key cryptography standards for use by the Internet community. These standards are published in Requests for Comments (RFCs).
- **The (Institute of Electrical and Electronics Engineers) IEEE 1363 working group** has been publishing standards for public key cryptography, including IEEE 1363–2000, IEEE 1363a, IEEE P1363.1, and IEEE P1363.2.
- **Vendor-specific standards** This category includes PKCS standards described in this chapter, standards for efficient cryptography (SEC) standards, and others. SEC 1 and 2 are ECPK cryptography standards that have been developed by Certicom in cooperation with secure systems developers world-wide.

Table 1 Public Key Cryptography Standards (PKCS) Specifications

No.	PKCS Title	Comments
1	RSA Cryptography Standard	
2,4		Incorporated into PKCS 1
3	Diffie–Hellman Key Agreement Standard	Superseded by IEEE 1363a etc.
5	Password-Based Cryptography Standard	
6	Extended-Certificate Syntax Standard	Never adopted
7	Cryptographic Message Syntax Standard	Superseded by RFC 3369 (CMS)
8	Private-Key Information Syntax Standard	
9	Selected Object Classes and Attribute Types	
10	Certification Request Syntax Standard	
11	Cryptographic Token Interface Standard	Referred to as CRYPTOKI
12	Personal Information Exchange Syntax Standard	
13	(reserved for ECC)	Never published
14	(reserved for pseudo random number generation)	Never published
15	Cryptographic Token Information Syntax Standard	

IEEE = Institute of Electrical and Electronics Engineers; RFC = Request for Comment.

The PKCS standards, developed by RSA Laboratories (a Division of RSA Data Security) in cooperation with secure systems developers worldwide for the purpose of accelerating the deployment of public key cryptography, are widely implemented in practice and periodically updated. Contributions from the PKCS standards have become part of many formal and de facto standards, including ANSI X9 documents, IETF documents, and SSL/TLS (secure socket layer/transport layer security). The parts and status of PKCS standards are listed in Table 1 and are discussed in detail in the following sections. The descriptions are largely adapted from the PKCS documents. This chapter concludes with an example application that uses all these PKCS standards.

PKCS 1: RSA CRYPTOGRAPHY STANDARD

PKCS 1 v2.1, provides standards for implementing RSA algorithm-based public key cryptographic encryption schemes and digital signature schemes with appendix. It also defines corresponding ASN.1 syntax for representing keys and for identifying the schemes.

RSA is a public key algorithm invented by Rivest, Shamir, and Adleman (1978) that is based on the exponentiation modulo the product of two large prime numbers. The security of RSA algorithm is believed to be based on the hardness of factoring the product of large prime numbers. In PKCS 1 v2.1, the multiprime RSA scheme is introduced. Multiprime RSA means that the modulus isn't the product of two primes but of more than two primes. This is used to increase performance of RSA cryptographic primitives. In particular, in multiprocessor environments, one can exponentiate modulo each prime and then apply the Chinese remainder theorem to get the final results. However, one should be aware that the security strength of multiprime RSA is a different from the original RSA scheme. Assuming that the best way to attack multiprime RSA is to factorize the modulus and the best

factorization algorithm is the number field sieve (NFS) algorithm, we can compute the approximate strength of some multiprime RSA schemes as listed in Table 2, where u is the number of primes. Similar tables for two primes RSA can be found in literature (e.g., Lenstra and Verheul, 2001).

RSA Keys

Let $n = r_1 \cdots r_u$ be the product of $u \geq 2$ distinct prime numbers of approximately the same size ($|n|/u$ bits each), where $|n|$ denotes the number of bits in n . For the case of $u = 2$, one normally uses p and q to denote the two prime numbers, that is, $n = pq$. A typical size for n is 1,024 bits, and $u = 2$. Let e, d be two integers satisfying $e \cdot d \equiv 1 \pmod{\chi(n)}$, where $\chi(n)$ is the least common multiple of $r_1 - 1, r_2 - 1, \dots, r_u - 1$. We call n the *RSA modulus*, e the *encryption exponent*, and d the *decryption exponent*. The pair (n, e) is the *public key*, and the pair (n, d) is called the *secret key* or *private key*. The public key is public, and one can use it to encrypt messages or to verify digital signatures. The private key is known only to the owner of the private key and can be used to decrypt ciphertexts or to digitally sign messages.

To decrypt ciphertexts efficiently and generate digital signatures efficiently, the private key may include further information such as the first two prime factors and CRT exponents and CRT coefficients of each prime factor. For a prime factor r_i , its CRT exponent is a number d_i satisfying $e \cdot d_i \equiv 1 \pmod{(r_i - 1)}$, and its CRT coefficient t_i is a positive integer less than r_i satisfying $R_i \cdot t_i \equiv 1 \pmod{r_i}$, where $R_i = r_1 \cdot r_2 \cdots r_{i-1}$. PKCS 1 v2.1 specifies the format for such kind of enhanced private keys.

RSA Encryption Schemes

This section begins by describing a basic version of RSA encryption scheme. A message is an integer $m < n$. To encrypt m , one computes $c \equiv m^e \pmod{n}$. To decrypt the ciphertext c , the legitimate receiver computes $c^d \pmod{n}$.

Table 2 Security Strength of Multiprime RSA Schemes

Symmetric Key Size	RSA Modulus Size	u	Symmetric Key Size	RSA Modulus Size	u
80^a	1,024	2	192^d	7,680	4
73	1,024	3	175	7,680	5
112^b	2,335	3	158	7,680	6
100	2,335	4	144	7,680	7
88	2,335	5	125	7,680	9
128^c	3,072	3	256^e	15,360	5
117	3,072	4	235	15,360	6
103	3,072	5	215	15,360	7
93	3,072	6	199	15,360	8

^a Corresponding to the security level of symmetric key cipher Skipjack that is contained in the clipper chip, designed by National Security Agency (NSA)

^b Corresponding to the security level of symmetric key cipher triple-DES, where DES is the Data Encryption Standards

^c Corresponding to the security level of symmetric key cipher AES 128

^d Corresponding to the security level of symmetric key cipher AES 192

^e Corresponding to the security level of symmetric key cipher AES 256

Indeed,

$$c^d \equiv m^{ed} \equiv m \pmod{n},$$

where the last equality follows by Euler's theorem.

For performance reasons, RSA is generally not used to encrypt long data messages directly. Typically, RSA is used to encrypt a secret key, and the data are encrypted with the secret key using a secret key cryptography scheme such as DES or AES. Thus, the actual data to be encrypted by RSA scheme are generally much smaller than the modulus, and the message (secret key) needs to be padded to the same length of the modulus before encryption. For example, if AES-128 is used, then an AES key is 128 bits. Another reason for a standardized padding before encryption using some randomness is that the basic version of RSA encryption scheme is not secure and is vulnerable to many attacks. PKCS 1 v2.1 provides two message padding methods: EME-PKCS1-v1_5 and EME-OAEP.

RSAES-PKCS1-v1_5 Padding

After EME-PKCS1-v1_5 padding to M , the padded message EM appears as follows:

$$EM = \boxed{0 \times 00 \mid 0 \times 02 \mid \text{random octets} \mid 0 \times 00 \mid M},$$

where "random octets" consists of pseudo-randomly generated nonzero octets and 0×00 octet is used to delimit the padding from the actual data. The length of "random octets" is at least eight octets. The top octet 0×00 guarantees that the padded message is smaller than the modulus n (PKCS 1 v2.1 specifies that the high-order octet of the modulus must be nonzero). If the padded message EM were larger than n , decryption would produce $EM \pmod{n}$ instead of EM . The next octet 0×02 is the format type. The value 0×02 is used to encryption and the value 0×01 is used for signature padding format RSASSA-PKCS1-v1_5 (RSASSA-PKCS1-v1_5 is no longer recommended by RSA Lab). The resulting padded message EM is $|n|$ bits and is directly encrypted using the basic version of RSA.

Bleichenbacher (1998) pointed out that improper implementation of this padding method can lead to disastrous consequences. When the encrypted message arrives at the receiver's computer, an application decrypts it, checks the initial block, and strips off the random pad. However, some applications check for the two initial blocks $0 \times 00 02$, and if it is incorrect, they send the error message saying "invalid ciphertext." These error messages can help the attacker to decrypt ciphertext of his choice. PKCS 1 v2.1 recommends certain easily implemented countermeasures to thwart this attack. Typical examples include the addition of structure to the data to be encoded, rigorous checking of PKCS 1 v1.5 conformance in decrypted messages, and the consolidation of error messages in a client-server protocol based on PKCS 1 v1.5.

RSAES-OAEP Padding

EME-OAEP is based on Bellare and Rogaway's (1995) optimal asymmetric encryption scheme. Assuming that it is difficult to inverse the RSA function and the mask generation function in the OAEP padding has appropriate properties, RSAES-OAEP is proven to be secure in a stronger sense. The reader is referred to Bellare and Rogaway (1995) for details.

Let k be the length in octets of the recipient's RSA modulus, $k_0 < k$ be an integer, H be a hash function for which outputs are k_0 -octets, and MGF be the mask generation function. For an input octet string x and an integer i , $\text{MGF}(x, i)$ outputs a string of i octets. Let M be the k_1 -octets message such that $k_1 < k - 2k_0 - 2$, and L be an optional label (could be an empty string) to be associated with the message. EME-OAEP first converts the message M to a $(k - k_0 - 1)$ -octets data block DB that looks as follows:

$$DB = \boxed{H(L) \mid \text{random octets} \mid 0 \times 01 \mid M},$$

where "random octets" consists of pseudo-randomly generated octets. The length of "random octets" could be zero.

EME-OAEP then chooses a random k_0 -octets string r , and generates the OAEP padded message EM as follows:

$$EM = \left[0 \times 00 \mid r \oplus \text{MGF}(DB \oplus \text{MGF}(r, k - k_0 - 1), k_0) \mid DB \oplus \text{MGF}(r, k - k_0 - 1) \right].$$

The resulting padded message EM is k -octets and is directly encrypted using the basic version of RSA. For decryption operations, EME-OAEP decoding method could be constructed directly.

RSA Signature Schemes With Appendix

We begin by describing a basic version of RSA signature scheme with appendix. A message is an integer $m < n$. To sign m , the owner of the private key (n, d) computes the signature $s \equiv m^d \pmod n$. To verify that s is a signature on m from the legitimate owner of the private key (n, d) , one uses the corresponding public key (n, e) to compute $m' \equiv s^e \pmod n$. If $m' = m$, then the signature is valid; otherwise, the signature is invalid.

The basic version of RSA signature scheme can only generate signatures on messages less than $|n|$ bits. In addition, the basic version of RSA signature scheme is not secure. To address these issues, in practice, one first computes a message digest from a given message using a hash function such as message digest 5 (MD5) or secure hash algorithm 1 (SHA-1). The message digest is encoded using an encoding method and the resulting string is converted to an integer and is supplied to the basic RSA signature primitive.

PKCS 1 v2.1 provides two encoding methods for encoding message digests: EMSA-PKCS1-v1.5 encoding and EMSA-PSS encoding. Correspondingly, there are two signature schemes with appendix: RSASSA-PSS and RSASSA-PKCS1-v1.5. Although no attacks are known against RSASSA-PKCS1-v1.5, in the interest of increased robustness, RSASSA-PSS is recommended for eventual adoption in new applications. RSASSA-PKCS1-v1.5 is included in PKCS 1 v2.1 for compatibility with existing applications and is not discussed here. EMSA-PSS is based on the work of Bellare and Rogaway (1996). Assuming that computing e th roots modulo n is infeasible and the hash and mask generation functions in EMSA-PSS have appropriate properties, RSASSA-PSS provides secure signatures. This assurance is provable in the sense that the difficulty of forging signatures can be directly related to the difficulty of inverting the RSA function, provided that the hash and mask generation functions are viewed as black boxes or random oracles. The reader is referred to Bellare and Rogaway (1996) for more details.

Let k be the length in octets of the RSA modulus, H be a hash function for which outputs are k_0 octets ($k_0 < k$), and MGF be the mask generation function. For an input octet string x and an integer i , $\text{MGF}(x, i)$ outputs a string of i octets. Let M be the message to be signed. EMSA-PSS first constructs octet strings M' and DB as follows:

$$M' = \left[0 \times 00 \ 00 \ 00 \ 00 \ 00 \ 00 \ 00 \ 00 \ 00 \ 00 \mid H(M) \mid \text{salt} \right], \quad DB = \left[\text{PS} \mid 0 \times 01 \mid \text{salt} \right],$$

where “salt” and “PS” consist of pseudo-randomly generated octets. The lengths of “salt” and “PS” could be zero, and the length of DB is $k - k_0 - 1$ octets.

EMSA-PSS then constructs the octet string EM' as follows:

$$EM' = \left[DB \oplus \text{MGF}(H(M'), k - k_0 - 1) \mid H(M') \mid 0 \times \text{bc} \right].$$

Assume that the RSA modulus has $|n|$ bits, then the encoded string EM is obtained by setting the leftmost $8k - |n| + 1$ bits of the leftmost octet in EM' to zero. The resulting encoded string EM is k octets and is directly signed using the basic version of RSA signature scheme. The EMSA-PSS decoding process could be constructed directly.

PKCS 3: DIFFIE-HELLMAN KEY AGREEMENT STANDARD (OUTDATED)

PKCS 3 v1.4 describes a method for implementing Diffie-Hellman key agreement, whereby two parties can agree on a secret key that is known only to them. PKCS 3 is superseded by modern treatment of key establishment schemes specified in IEEE 1363a (2003), ANSI 9.42, ANSI X9.44, ANSI X9.63, and so on. Basically, there are two types of key establishment schemes:

1. Key agreement scheme: a key establishment scheme in which the keying data established is a function of contributions provided by both entities in such a way that neither party can predetermine the value of the keying data. Diffie-Hellman key agreement scheme is an example of this category.
2. Key transport scheme: a key establishment scheme in which the keying data established is determined entirely by one entity. For example, one party chooses a random session key, encrypts it with the other party's public key, and sends the encrypted session key to the other party. The other party can then decrypt the session key. A special case of key transport scheme is the key wrap scheme in which the session key is encrypted with a preshared secret using a secret key cipher such as DES or AES.

PKCS 5: PASSWORD-BASED CRYPTOGRAPHY STANDARD

In many applications of public key cryptography, user security is ultimately dependent on one or more secret text values or passwords. For example, user's private key is usually encrypted with a password and the encrypted private key is kept in storage devices (see the section “Private Key Information Syntax Standard”). There are two essential problems with regard to password application, however: (a) A password is not directly applicable as a key to any conventional cryptosystem; (2) passwords are often chosen from a relatively small space.

Thus, special care is required to defend against search attacks. PKCS 5 provides a general mechanism to achieve an enhanced security for password-based cryptographic primitives, covering key derivation functions, encryption schemes, message-authentication schemes, and ASN.1 syntax identifying the techniques. It should be noted that other password-based cryptographic techniques are currently under standardization process in IEEE 1363.2.

Key Derivation Functions

A password-based key derivation function produces a key from a password, a random salt value, and an iteration count. The salt is not secret and serves the purpose of producing a large set of keys for one given password, among which one is selected at random according to the salt. An iteration count serves the purpose of increasing the cost of producing keys from a password, thereby also increasing the difficulty of attack. PKCS 5 v2.0 specifies two password-based key derivation functions PBKDF1 and PBKDF2. PBKDF1 is included in PKCS # 5 v2.0 only for compatibility with existing applications following PKCS 5 v1.5 and is not recommended for new applications.

PBKDF2 applies a pseudo-random function to derive keys. The length of the derived key is essentially unbounded. However, the maximum length for the derived key may be limited by the structure of the underlying pseudorandom function. Let H be a pseudo-random function with the outputs $hLen$ octets, $dkLen \leq (2^{32} - 1) \times hLen$ the intended length in octets for the derived key, P the password (an octet string), S an eight-octet salt string, and c an iterating count. For each integer i , by repeatedly hashing the password, salts, and so on, one gets a sequence of $hLen$ -octets strings:

$$U_1^i = H(P, S || \text{INT}(i)), U_2^i = H(P, U_1^i), \dots, U_c^i = H(P, U_{c-1}^i),$$

where $\text{INT}(i)$ is a four-octet encoding of the integer i , most significant octet first. Then one computes the $hLen$ -octet strings $T_i = U_1^i \oplus U_2^i \oplus \dots \oplus U_c^i$ for each i . The derived key is the first $dkLen$ -octet of the string $T_1 || T_2 || T_3 || \dots$. In other words, let $l = \lceil dkLen / hLen \rceil$ be the number of $hLen$ -octet blocks in the derived key, rounding up, and $r = dkLen - (l - 1) \times hLen$ be the number of octets in the last block. Then the $dkLen$ -octet-derived key $DK = \text{PBKDF2}(P, S, c, dkLen)$ appears as follows:

$$DK = \boxed{T_1 \quad T_2 \quad \dots \quad T_l[0 \dots r - 1]}.$$

Encryption Schemes

PKCS 5 v2.0 specifies two encryption schemes password based encryption scheme 1 (PBES1) and PBES2. PBES1 is included in PKCS 5 v2.0 only for compatibility with PKCS 5 v1.5, and is not recommended for new applications. PBES2 combines the password-based key derivation function PBKDF2 with an underlying encryption scheme \mathcal{E} . Let M be the message to be encrypted, P be the password, k be the key length in octets for \mathcal{E} . For the PBES2 encryption, one first selects a salt S and an iteration count c , then one computes the derived k octets key $DK = \text{PBKDF2}(P, S, c, k)$. The ciphertext C for M

is: $C = \mathcal{E}_{DK}(M)$. The decryption operation for PBES2 can be done similarly.

Message Authentication Schemes

In a *password-based message authentication scheme*, the message authentication code (MAC) generation operation produces a message authentication code from a message under a password, and the MAC verification operation verifies the message authentication code under the same password. PKCS 5 v2.0 defines the password-based message authentication scheme PBMAC1 that combines the password-based key derivation function PBKDF2 with an underlying message authentication scheme \mathcal{A} .

Let M be the message to be authenticated, P be the password, and k be the key length in octets for \mathcal{A} . For PBMAC1, one first selects a salt S and an iteration count c , and then computes the derived k octets key $DK = \text{PBKDF2}(P, S, c, k)$. The message authentication code T can be computed as $T = \mathcal{A}(M, DK)$. The MAC verification operation for PBMAC1 can be done similarly.

PKCS 6: EXTENDED-CERTIFICATE SYNTAX STANDARD (HISTORIC)

When PKCS 6 was drafted, X.509 was in version 1.0 and no `extensions` component was defined in the certificate. An X.509 v3 certificate can contain information about a given entity in the `extensions` component. Since the introduction of X.509 v3, the status of PKCS 6 is historic.

PKCS 7 AND RFC 3369: CRYPTOGRAPHIC MESSAGE SYNTAX (CMS)

PKCS 7 has been superseded by IETF RFC 3369 (Housley, 2002): cryptographic message syntax (CMS), which is the basis for the secure multipurpose internet mail extension (S/MIME) specification. CMS defines the syntax that is used to digitally sign, digest, authenticate, or encrypt arbitrary message content. In particular, CMS describes an encapsulation syntax for data protection. The syntax allows multiple encapsulations; one encapsulation envelope can be nested inside another. Likewise, one party can digitally sign previously encapsulated data. In the CMS syntax, arbitrary attributes, such as signing time, can be signed along with the message content, and other attributes, such as countersignatures, can be associated with a signature. A variety of architectures for certificate-based key management (e.g., the one defined by the IETF Public Key Infrastructure (PKIX) working group) are supported in CMS.

The CMS values are generated using ASN.1 with BER-encoding and are typically represented as octet strings. When transmitting CMS values in systems (e.g., e-mail systems) that do not support reliable octet strings transmission, one should use additional encoding mechanisms that are not addressed in CMS.

CMS defines one protection content type, `ContentInfo`, as the object syntax for documents exchanged between entities. `ContentInfo` encapsulates a single identified content

Figure 1: Cryptographic message syntax content types and their fields.

type and the identified type may provide further encapsulation. A ContentInfo object contains two fields: contentType (object identifier) and content. CMS defines six contentTypes: data, signed-data, enveloped-data, digested-data, encrypted-data, and authenticated-data. Additional content types can be defined outside the CMS document. The type of content can be determined uniquely by contentType. Figure 1 lists the value types in the content field for each CMS defined content type.

In Figure 1, digestAlgorithms is collection of message digest algorithm identifiers. encapContentInfo is the signed content, consisting of a content type identifier and the content itself. signedAttrs, unsignedAttrs, unprotectedAttrs, authAttrs, and unauthAttrs are sets of Attribute objects. An Attribute object is a sequence of two fields: attrType (object identifier) and attrValues (set of values).

PKCS 8: PRIVATE KEY INFORMATION SYNTAX STANDARD

The security of the public key cryptosystem is entirely dependent on the protection of the private keys. Generally, the private keys are encrypted with password and stored in some storage medium. It is important to have a standard to store private keys so that one can move private keys from one system to another system without any trouble. PKCS 8 v1.2 describes a syntax for private key information, which includes a private key for some public key algorithm and a set of attributes, and a syntax for encrypted private key information. A password-based encryption algorithm (e.g., one of those described in PKCS 5) could be used to encrypt the private key information.

Two objects, PrivateKeyInfo and EncryptedPrivateKeyInfo, are defined in this standard. A PrivateKeyInfo

object contains the fields: version, privateKeyAlgorithm, privateKey, and attributes (optional), where privateKeyAlgorithm is the identifier of the private key algorithm, privateKey is the octet string representing the private key, and attributes is a collection of attributes that are encrypted along with the private key. An EncryptedPrivateKeyInfo object contains two fields: encryptionAlgorithm and encryptedData, where encryptionAlgorithm identifies the algorithm under which the private key information is encrypted, and encryptedData is the octet string representing the result of encrypting the private key information.

In practice, the PrivateKeyInfo object is BER encoded into an octet string, which is encrypted with the secret key to give the encryptedData field of the EncryptedPrivateKeyInfo object.

PKCS 9: SELECTED OBJECT CLASSES AND ATTRIBUTE TYPES

To support PKCS-defined attributes (e.g., to store PKCS attributes in a directory service) in directory systems based on lightweight directory access protocol (LDAP) and the X.500 family of protocols, PKCS 9 v2.0 defines two auxiliary object classes, pkcsEntity and naturalPerson. PKCS attributes could be packaged into these two object classes and be exported to other environments such as LDAP directory systems. PKCS 9 v2.0 also defines some new attribute types and matching rules that could be used in other PKCS standards. For example, it defines challengePassword and extensionRequest attribute types to be used in PKCS 10 attribute field, and it defines some attribute types to be used in PKCS 7 (CMS) signedAttrs, unsignedAttrs, unprotectedAttrs, authAttrs, and unauthAttrs fields, as noted earlier. All ASN.1 object classes, attributes,

Table 3 PKCS 9 Attribute Types for Use in Other Standards

Standard Name	Attribute Types
PKCS 7 and CMS	contentType, messageDigest, signingTime, sequenceNumber, randomNonce, and counterSignature (with syntax SignerInfo)
PKCS 10	challengePassword (with syntax DirectoryString) and extensionRequest (imported from ISO/IEC 9594-8 (1997))
PKCS 12 and 15	(user) friendlyName and localKeyld

CMS = Cryptographic message syntax.

matching rules, and types defined in PKCS 9 v2.0 are exported for use in other environments.

The `pkcsEntity` object class is a general-purpose auxiliary object class that is intended to hold attributes about PKCS-related entities. A `pkcsEntity` object class contains these fields:

`pkcsEntity` =

KIND (auxiliary type)	PKCSEntityAttributeSet (optional)	ID
-----------------------	-----------------------------------	----

.

The `PKCSEntityAttributeSet` may contain any of the following attributes: `pKCS7PDU` (with syntax `ContentInfo`), `userPKCS12` (with syntax `PFX`), `pKCS15Token` (PKCS 15), `encryptedPrivateKeyInfo` (PKCS #8), and future extensions. These attributes should be used when the corresponding PKCS data (e.g., CMS signed or enveloped data; PKCS 12 personal identity information data; PKCS 8 encrypted private key data, etc.) are stored in a directory service.

The `naturalPerson` object class is a general-purpose auxiliary object class that is intended to hold attributes about human beings. A `naturalPerson` object class contains these fields:

`naturalPerson` =

KIND (auxiliary type)	NaturalPersonAttributeSet (optional)	ID
-----------------------	--------------------------------------	----

.

The `NaturalPersonAttributeSet` may contain any of the following (or future extensions) attributes:

emailAddress	countryOfCitizenship	countryOfResidence	pseudonym	placeOfBirth
serialNumber	unstructuredAddress	unstructuredName	gender	dateOfBirth

PKCS 9 also defines two matching rules, `pkcs9-CaseIgnoreMatch` and `signingTimeMatch`, which are used to determine whether two PKCS 9 attribute values are the same. Attribute types defined in PKCS 9 that are useful in other standards are listed in Table 3.

PKCS 10: CERTIFICATION REQUEST SYNTAX STANDARD

PKCS 10 v1.7 specifies syntax for certificate request. When one entity wants to get a public key certificate, the entity constructs a certificate request and sends it a certification authority, which transforms the request into an X.509 public key certificate. A certification authority fulfills the request by authenticating the requesting entity and verifying the entity's signature, and, if the request is valid, constructing an X.509 certificate from the distinguished name and public key, the issuer name, and the certification

authority's choice of serial number, validity period, and signature algorithm. If the certification request contains any PKCS 9 attributes, the certification authority may also use the values in these attributes as well as other information known to the certification authority to construct

X.509 certificate extensions. PKCS 10 does not specify the forms that the certification authority returns the new certificate. A certificate request is constructed with the following steps:

1. Construct a `CertificationRequestInfo` object containing fields "version," "subject," "subjectPKInfo," and "attributes," where "subject" contains the entity's distinguished name and "subjectPKInfo" contains the entity's public key. Some attribute types that might be useful here are defined in PKCS 9. An example is the `challengePassword` attribute, which specifies a

password by which the entity may request certificate revocation. Another example is information to appear in X.509 certificate extensions.

2. Sign the `CertificationRequestInfo` object with the subject entity's private key.
3. Construct a `CertificationRequest` object containing fields "CertificationRequestInfo," "signatureAlgorithm," and "signature," where "signatureAlgorithm" contains the signature algorithm identifier, and "signature" contains the entity's signature.

PKCS 11: CRYPTOGRAPHIC TOKEN INTERFACE STANDARD

PKCS 11 v2.20 specifies an application programming interface (API), called "Cryptoki," to devices which hold cryptographic information and perform cryptographic

functions. Cryptoki, pronounced “crypto-key” and short for “cryptographic token interface,” follows a simple object-based approach, addressing the goals of technology independence (any kind of device) and resource sharing (multiple applications accessing multiple devices), presenting to applications a common, logical view of the device called a “cryptographic token.” Cryptoki was intended from the beginning to be an interface between applications and all kinds of portable cryptographic devices, such as those based on smart cards, personal computer memory card international association (PCMCIA) cards, and smart diskettes. The primary goal of Cryptoki was a lower level programming interface that abstracts the details of the devices, and presents to the application a common model of the cryptographic device, called a “cryptographic token” (or simply “token”).

PKCS 11 v2.20 specifies the data types and functions available to an application requiring cryptographic services using the ANSI C (1990) programming language. These data types and functions will typically be provided via C header files by the supplier of a Cryptoki library. Generic ANSI C header files for Cryptoki are available from the PKCS Web page.

Cryptoki isolates an application from the details of the cryptographic device. The application does not have to change to interface to a different type of device or to run in a different environment; thus, the application is portable.

Cryptoki is intended for cryptographic devices associated with a single user, so some features that might be included in a general-purpose interface are omitted. For example, Cryptoki does not have a means of distinguishing multiple users. The focus is on a single user’s keys and perhaps a small number of certificates related to them. Moreover, the emphasis is on cryptography. Although the device can perform useful non-cryptographic functions, such functions are left to other interfaces.

Cryptoki is likely to be implemented as a library supporting the functions in the interface, and applications will be linked to the library. An application may be linked to Cryptoki directly; alternatively, Cryptoki can be a so-called shared library (or dynamic link library), in which

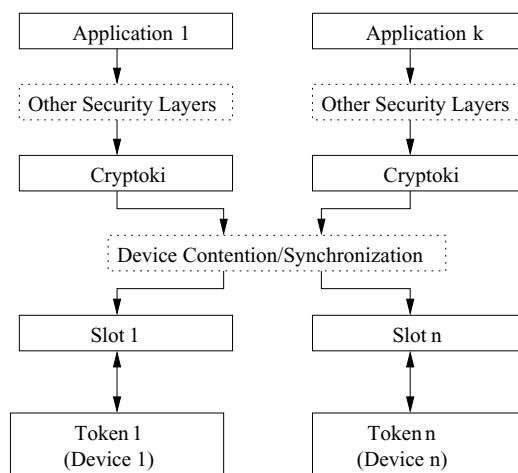

Figure 2: General Cryptoki model.

remains the same. Figure 2 describes the general cryptoki model.

Cryptoki defines general data types, objects, and functions. The general data types include general information data types (e.g., CK_VERSION and CK_INFO), slot and token types (e.g., CK_SLOT_ID), session types (e.g., CK_SESSION_HANDLE), object types (e.g., CK_OBJECT_CLASS), data types for mechanisms (e.g., CK_MECHANISM_INFO), function types (e.g., CK_FUNCTION_LIST), and locking-related types (e.g., CK_CREATEMUTEX).

Cryptoki’s logical view of a token is a device that stores objects and can perform cryptographic functions. Cryptoki recognizes three classes of objects, as defined in the CK_OBJECT_CLASS data type: data, certificates, and keys. An object consists of a set of attributes, each of which has a given value. A key object stores a cryptographic key. The key may be a public key, a private key, or a secret key; each of these types of keys has subtypes for use in specific mechanisms (cryptographic algorithms). For example, public key objects (object class CKO_PUBLIC_KEY) hold public keys and contains the following common attributes:

CKA_ID	CKA_KEY_TYPE	CKA_DERIVE	CKA_KEY_GEN_MECHANISM
CKA_WRAP	CKA_END_DATE	CKA_LOCAL	CKA_KEY_ALLOWED_MECHANISM
CKA_VERIFY	CKA_SUBJECT	CKA_TRUSTED	CKA_WRAP_TEMPLATE
CKA_ENCRYPT	CKA_START_DATE	CKA_CHECK_VALUE	CKA_VERIFY_RECOVER

case the application would link the library dynamically. The dynamic approach certainly has advantages as new libraries are made available, but from a security perspective, there are drawbacks. In particular, if a library is easily replaced, then there is the possibility that an attacker can substitute a rogue library that intercepts a user’s personal identification number (PIN). From a security perspective, therefore, direct linking is preferable, although code-signing techniques can prevent many of the security risks of dynamic linking. In any case, whether the linking is direct or dynamic, the programming interface between the application and a Cryptoki library

According to their lifetime, objects are classified as “token objects” and “session objects.” Further classification defines access requirements. “PIN” or token-dependent methods are required to access “private token” whereas no restriction is put on “public tokens.”

In addition to the PIN protection to private objects on a token, protection to private keys and secret keys can be given by marking them as sensitive or unextractable. Sensitive keys cannot be revealed in plaintext off the token, and unextractable keys cannot be revealed off the token even when encrypted (although they can still be used as keys). It is expected that access to private, sensitive, or unextractable objects by means

Table 4 Session Events

Event	Occurs When
Log In SO	the SO is authenticated to the token.
Log In User	the normal user is authenticated to the token.
Log Out	the application logs out the current user (SO or normal user).
Close Session	the application closes the session or closes all sessions.
Device Removed	the device underlying the token has been removed from its slot.

other than Cryptoki (e.g., other programming interfaces or reverse engineering of the device) would be difficult. Cryptoki does not consider the security of the operating system by which the application interfaces to it. For example, because the PIN may be passed through the operating system, a rogue application on the operating system may be able to obtain the PIN.

Cryptoki provides functions for creating, destroying, and copying objects in general and for obtaining and modifying the values of their attributes. Objects are always well formed in Cryptoki. That is, an object always contains all required attributes, and the attributes are always consistent with the one from the time the object is created. This contrasts with some object-based paradigms in which an object has no attributes other than perhaps a class when it is created and is uninitialized for some time. In Cryptoki, objects are always initialized.

Cryptoki defines thirteen categories of functions: general-purpose functions (four functions including `C_Initialize` and `C_Finalize`), slot and token management functions (nine functions), session management functions (eight functions), object management functions (nine functions), encryption functions (four functions), decryption functions (four functions), message digesting functions (five functions), signing and MACing functions (six functions), functions for verifying signatures and MACs (six functions), dual-purpose cryptographic functions (four functions), key management functions (five functions), random number generation functions (two functions), and parallel function management functions (two functions). In addition to these functions, Cryptoki can use application-supplied callback functions to notify an application of certain events and can also use application-supplied functions to handle mutex objects for safe multithreaded library access.

Cryptoki has two user types: security officer (SO) and normal user. The function of SO is to initiate a token and to set the PIN for the normal user. Only the normal user has access to private objects in the token.

A mechanism specifies precisely how a certain cryptographic process is to be performed (e.g., a digital signature process or a hashing process). Cryptoki defines mechanisms for almost all available cryptographic operations that are currently used in the industry.

An application in a single address space becomes a "Cryptoki application" when one of its running threads calls the Cryptoki function `C_Initialize` and it ceases to be the "Cryptoki application" by calling the Cryptoki function `C_Finalize`. Cryptoki has support mechanisms for multithreading access.

Cryptoki requires that an application open one or more sessions with a token to gain access to the token's objects and functions. A session can be a read/write (R/W) session or a read-only (R/O) session. R/W and R/O refer to the access to token objects, not to session objects. In both session types, an application can create, read, write, and destroy session objects and read token objects. Table 4 lists session events.

Cryptoki header files define a large array of data types. Certain packing- and pointer-related aspects of these types are platform- and compiler-dependent; these aspects are therefore resolved on a platform-by-platform (or compiler-by-compiler) basis outside of the Cryptoki header files by means of preprocessor directives. These directives are described in the Cryptoki also.

PKCS 12: PERSONAL INFORMATION EXCHANGE SYNTAX STANDARD

PKCS 12 v1.0 describes a transfer syntax for personal identity information, including private keys, certificates, miscellaneous secrets, and extensions. Machines, applications, browsers, Internet kiosks, and so on that support this standard will allow a user to import, export, and exercise a single set of personal identity information. PKCS 12 can be viewed as building on PKCS 8 by including essential but ancillary identity information along with private keys and by instituting higher security through public key privacy and integrity modes.

There are four combinations of *privacy modes* and *integrity modes*. The privacy modes use encryption (public key-based or password-based) to protect personal information from exposure and the integrity modes (public key digital signature-based or password message authentication code-based) protect personal information from tampering. For example, in public key privacy mode, personal information on the source platform is enveloped using the trusted encryption public key of a known destination platform and the envelop is opened using the corresponding private key.

Although all combinations of privacy and integrity modes are permitted, certain practices should still be avoided. For example, it is unwise to transport private keys without physical protection when using password privacy mode. In general, it is preferred that the source and destination platforms have trusted public and private key pairs usable for digital signatures and encryption, respectively. When trusted public and private key pairs are not available, password modes for privacy and integrity could be used.

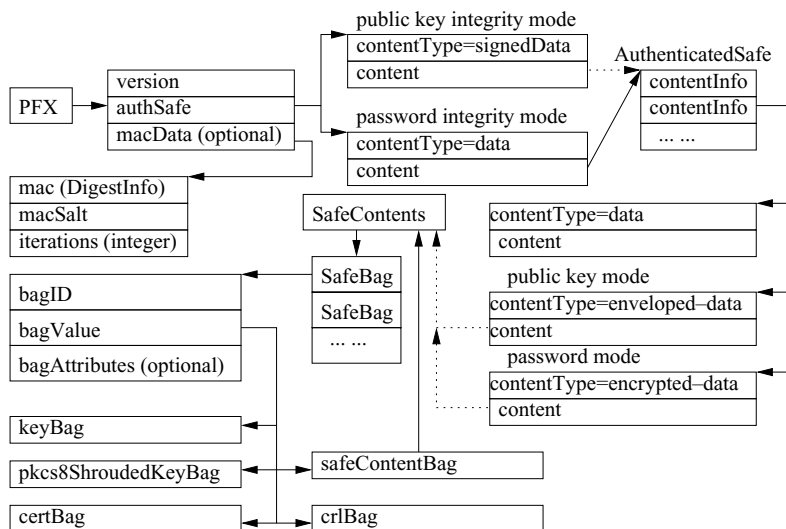

Figure 3: PFX object structure.

The top-level exchange PDU (protocol data unit) in PKCS 12 is called PFX. A PFX has three fields: version, authSafe, and macData (optional), where authSafe is a PKCS 7 ContentInfo. Figure 3 describes the structure of the PFX object.

It is straightforward to create PFX PDUs from the structure described in Figure 3. The data wrapped in the PFX could be imported by reversing the procedure for creating a PFX.

PKCS 15: CRYPTOGRAPHIC TOKEN INFORMATION SYNTAX STANDARD

Cryptographic tokens, such as Integrated Circuit Cards (or IC cards) are intrinsically secure computing platforms ideally suited to providing enhanced security and privacy functionality to applications. They can handle authentication information such as digital certificates and capabilities, authorizations, and cryptographic keys. Furthermore, they are capable of providing secure storage and computational facilities for sensitive information such as private keys and key fragments. At the same time, many of these tokens provide an isolated processing facility capable of using this information without exposing it within the host environment where it is at potential risk from hostile code (viruses, Trojan horses, and so on). Unfortunately, the use of these tokens for authentication and authorization purposes has been hampered by the lack of interoperability. First, the industry lacks standards for storing a common format of digital credentials (keys, certificates, etc.) on them. This has made it difficult to create applications that can work with credentials from a variety of technology providers. Second, mechanisms to allow multiple applications to share digital credentials effectively have not yet reached maturity.

PKCS 15 is a standard intended to enable interoperability among components running on various platforms (platform neutral), to enable applications to take advantage of products and components from multiple manufacturers (vendor neutral), to enable the use of advances in technology without rewriting application-level software

(application neutral), and to maintain consistency with existing, related standards while expanding on them only where necessary and practical. As an example, the holder of an integrated circuit (IC) card containing a digital certificate should be able to present the card to any application running on any host and successfully use the card to present the contained certificate to the application. As a first step to achieve these objectives, PKCS 15 v1.1 specifies a file and directory format for storing security-related information on cryptographic tokens.

The PKCS 15 token information may be read when a token is presented and is used by a PKCS 15 interpreter which is part of the software environment (e.g., as shown in the Figure 4).

PKCS 15 v1.1 defines four general classes of objects: keys, certificates, authentication objects, and data objects. All these object classes have subclasses (e.g., private keys, secret keys, and public keys) for which instantiations become objects actually stored on cards. Objects can be private, meaning that they are protected against unauthorized access, or public. In the IC card case, access (read, write, etc.) to private objects is defined by authentication objects (which also includes authentication procedures). Conditional access (from a cardholder's perspective) is achieved with knowledge-based or biometric user information. In other cases, such as when PKCS 15 is implemented in software, private objects may be protected against unauthorized access by cryptographic means. Public objects are not protected from read-access.

Figure 4: Embedding of a PKCS 15 interpreter (example).

Figure 5: Typical PKCS 15 card layout and contents of DF(PKCS 15).

Whether or not they are protected against modifications depends on the particular implementation.

In general, an IC card file format specifies how certain abstract, higher level elements such as keys and certificates are to be represented in terms of more lower level elements such as IC card files and directory structures. A typical IC card supporting PKCS 15 has the file structure layout as in Figure 5, where the following abbreviations are used: MF (master file), DF(x) (dedicated file x), and EF(x) (elementary file x).

PKCS 15 defines syntax for application directory contents as in Table 5. PKCS 15-compliant IC cards should support direct application selection as defined in ISO/IEC 7816-4 Section 9 and ISO-IEC 7816-5 Section 6 (the full application identifier [AID] is to be used as parameter for a “SELECT FILE” command). The operating system of the card must keep track of the currently selected application and only allow the commands applicable to that particular application while it is selected. The AID data element consists of 12 bytes, and its contents are defined in PKCS 15.

Objects could be created, modified, and removed from the object directory file on a card. ASN.1 syntax for these objects have also been specified in PKCS 15.

AN EXAMPLE

This chapter concludes with an example application of different PKCS standards. Assume that we want to implement a smart card authentication system based on public key cryptography technology. Each user will be issued a smart card containing users’ private key, public key certificate, and other personal information. Users can authenticate themselves to different computing systems (or banking systems) by inserting their smart cards into card readers attached to these computing systems and typing the password (or PIN).

RSA cryptographic primitives specified in PKCS 1 could be chosen as the underlying cryptographic mechanisms. First, user Alice needs to register herself to the system to get her smart card. In the registration process, the system first generates a public key/private key pair for Alice. Using PKCS 9, the system may create a naturalPerson object or a few attributes containing Alice’s personal information. This information can then be used to generate a CertificateRequest object according to PKCS 10. The system can then send the CertificateRequest object to the certificate authorities (CAs) enveloped using CMS (PKCS 7). After the identity information verification, the CA signs Alice’s public key to generate a certificate for Alice and sends it back to the system. After receiving Alice’s certificate from the CA, the system can build a smart card for Alice. Using Alice’s password (PIN) the system generates an EncryptedPrivateKeyInfo object for Alice according to PKCS 8 and PKCS 9 (PKCS 5 is also used in this procedure). PKCS 12 may then be used to transfer Alice’s encrypted private key and personal information from one computer to another computer (e.g., from a server machine to the smart card making machine). Using the dedicated file format DF (PKCS 15), Alice’s encrypted private key object EncryptedPrivateKeyInfo, certificate, and other personal information could be stored on the smart card. The card is now ready for Alice to use. At the same

Table 5 Application Directory Contents

EF(ODF)	An object directory file (ODF) contains pointers to other EFs (PrKDFs, PuKDFs, SKDFs, CDFs, DODFs, and AODFs)
EF(PrKDF)	A private key directory file (PrKDF) contains (references to) private keys
EF(PuKDF)	A public key directory file (PuKDF) contains (references to) public keys
EF(SKDF)	A secret key directory file (SKDF) contains (references to) secret keys
EF(CDF)	A certificate directory file (CDF) contains (references to) certificates
EF(DODF)	A data object directory file (DODF) is for data objects other than keys or certificate
EF(AODF)	An authentication object directory file (AODF) is for authentication objects such as personal identification numbers passwords, and biometric data
EF(TokenInfo)	A mandatory TokenInfo with transparent structure contains generic information about the card (e.g., card serial number, supported file types, algorithms implemented on the card) and its capabilities
EF(UnusedSpace)	An UnusedSpace file with transparent structure is used to keep track of unused space in already created elementary files
	Other EFs in the PKCS #15 directory contains the actual values of objects (such as private keys, public keys, secret keys, certificates and application specific data) referenced from within PrKDFs, SKDFs, PuKDFs, CDFs or DODFs

EF = Elementary file.

time, Alice may also get a copy of these private information on a universal serial bus (USB) memory stick. This personal information is stored on the memory stick according to PKCS 12.

Because all computing systems (e.g., different platforms from different vendors) support PKCS 11 API, when Alice inserts her card into an attached card reader, applications on these computing systems can communicate smoothly with Alice's smart card. In particular, after typing her password (PIN), Alice's smart card can digitally sign challenges from these computing systems and these computing systems can verify Alice's signature using the certificate presented by Alice's smart card. Thus, Alice can authenticate herself to these systems.

ACKNOWLEDGMENTS

The author thanks anonymous referees for the constructive comments on improving the presentation of this chapter. The author also thanks Dennis Hamilton (UoL KIT eLearning Division) for comments on PKCS 5 v2.0.

GLOSSARY

Abstract Syntax notation one (ASN.1) Defined in ISO/IEC 8824-1-4 (1995).

Advanced Encryption Algorithm (AES) A secret key cipher, as defined in FIPS PUB 197 (2001).

Attribute An ASN.1 type that identifies an attribute type (by an object identifier) and an associated attribute value.

Basic Encoding Rules (BER) Defined in X.690 (1994), is the set of rules for encoding ASN.1 defined data into a particular representation for transmitting to another system.

Cryptoki cryptographic token interface.

Data Encryption Standard (DES), Triple DES Secret key ciphers, as defined in FIPS PUB 46-3 (1999).

Key Derivation Function A function that produces a derived key from a base key and other parameters.

Lightweight directory access protocol (LDAP) Defined in Hodges and Morgan (2002).

MD5 A cryptographic hash function, as defined in Rivest (1992). MD5 reduces messages of any length to message digests of 128 bits.

Message Authentication Code (MAC) Scheme A cryptographic scheme consisting of a message tagging operation and a tag checking operation that is capable of providing data origin authentication and data integrity.

Octet An octet is a bit string of length 8. An octet is represented by a hexadecimal string of length 2. For example 0x9D represents the bit string 10011101.

Octet String An ordered sequence of octets.

Personal Identity Information Personal information such as private keys, certificates, and miscellaneous secrets.

PKCS 11 Token The logical view of a cryptographic device defined by Cryptoki.

PKCS 15 Elementary File Set of data units or records that share the same file identifier and that cannot be a parent of another file.

PKCS 15 Directory (DIR) File An elementary file containing a list of applications supported by the card and optional related data elements.

Protocol Data Unit (PDU) A sequence of bits in machine-independent format constituting a message in a protocol.

SHA-1, SHA-256, SHA-384, and SHA-512 Cryptographic hash function functions, as defined in FIPS PUB 180-2, (2002). SHA-1 (SHA-256, SHA-384, and SHA-512, respectively) reduces messages of any length to message digests of 160 bits (256 bits, 384 bits, and 512 bits, respectively).

SSH INTRODUCTION AND ITS HISTORY

The advent of the Internet and its rapid spread around the world have changed the way we look at communication. It is no longer restricted to telephones, couriers, or fax. Instead, in the present age of digital revolution, it is almost impossible to think of a world without the Internet. One of the often overlooked problems that arise with the use of the Internet for communication is security. Communication over the Internet often takes place in the form of a local workstation (client) making use of the services offered by a more powerful remote machine (server). Securing this transfer of data is one of the biggest challenges we face today.

This chapter is intended to give the reader an overview of a widely used security protocol called secure shell (SSH). It begins with a brief discussion about the history and the reason for the development of the protocol. The various services such as confidentiality, integrity and authentication and functionalities like secure command shell and secure file transfer are presented. The discussion then turns to the various data types and message formats used by SSH. The next section talks about the layered protocol architecture of SSH and details each of the layers. The discussion then moves to a protocol specifically developed for the purpose of secure file transfer, the secure file transfer protocol (SFTP). Next the focus is on

SSH tunneling, TCP/IP port forwarding, and X forwarding. Key management in SSH is discussed thereafter, followed by consideration of the security aspects associated with SSH, such as the man-in-the-middle and denial of service attacks. The section also gives a comparison between the two versions of SSH. The chapter closes with discussion of SSH in the real world and takes a look at some practical implementations.

Conventional Ways of Remote Access and Problems

The traditional means of remote access are the following services under the UNIX environment:

- **rlogin**: a remote login program. It connects a user to the remote system and usually provides the user with a shell.
- **rsh (remote shell)**: it executes a noninteractive command on the remote system.
- **rcp**: a remote copy program that can be used to transfer files to and from the remote machine.
- **telnet**: a terminal emulation program for TCP/IP networks. It is used to connect to servers on the Internet.

Unfortunately, these commands, often called the “r commands,” are insecure. They make use of the concept of trusted hosts, which makes their use convenient, but the

price that one has to pay for this convenience comes in the form of security risks. The concept used in these commands is that each remote machine has a file named `/etc/hosts.equiv` that contains the names of the trusted hosts. If any client is listed, the user is not asked for any password for authentication. This makes these commands insecure. While using the `rlogin` command, if the local host name is not found in the file on the remote machine, the client is prompted for a password. Similarly, `telnet` requires a user to log on first by providing user name and password, but even this does not make the communication secure because the password is transferred unencrypted over the network.

What Is the Secure Shell?

Secure shell is a protocol that provides secure network communication. It provides authentication, encryption, and data integrity. A more detailed definition for Secure Shell is the following (Van Dyke Software, 2003a): Secure Shell (SSH) provides an open protocol for securing network communications that is less complex and expensive than hardware-based VPN solutions. SSH secures the remote network connections by encrypting all the transmitted data, which include user names and passwords. This encryption saves the SSH session from vulnerabilities such as eavesdropping, hijacking, and IP spoofing.

History of SSH

SSH was developed with the view of making remote login and other remote network services secure. The main idea was to replace the existing, insecure commands such as `rlogin` and `rsh` and provide secure encrypted communications between untrusted hosts over an insecure network. The work on the first version, SSH1, began in the early 1990s. Secure Shell version 2 (SSH2) was submitted as an Internet Engineering Task Force (IETF) draft in 1997. The second version was developed to overcome some vulnerabilities which existed in SSH1.

SSH FUNCTIONALITY AND SERVICES

SSH was designed to replace `telnet`, FTP (file transfer protocol), and Berkeley Unix `r` commands. SSH attempts to offer a solution to the problem of securing data over insecure public networks.

Services

SSH addresses the three core security services that are important to maintain adequate security (Van Dyke Software, 2003a):

1. **Confidentiality:** This means that the transmitted data must be recognizable only to the authorized party. If someone steals the data during transmission, he or she should not be able to understand it. Confidentiality is achieved through encryption.
2. **Integrity:** This means that data should not be changed during transmission, and if it is changed, the authorized party receiving it should be able to notice that.

Integrity is achieved by computing checksum or MAC (message authentication code) of the data being sent. This allows detecting any changes made during transmission.

3. **Authentication:** This means that both parties communicating should be able to identify each other. It is required to prevent identity spoofing by malicious people. Authentication is provided by using challenge passwords or public key cryptography and digital signatures.

Functionality

SSH is a protocol for secure remote logins and encrypted file transfer. It is now a de facto standard and can also tunnel arbitrary TCP/IP sessions over a single encrypted secure shell connection. Thus, the basic functionalities are as follows:

1. **Secure Command Shell:** Users of UNIX and DOS are familiar with the command shell known as a “command prompt” in the Windows environment. The SSH allows a user to run commands over a remote machine. It is also known as remote logon.

SSH or remote logon allows the user to view and edit files and directories and access custom database applications. Administrators can start, view, or stop jobs remotely. They can view, create, or delete user profiles over the secure command shell. SSH command shell allows a user or administrator to do all the things remotely that he or she could do by logging on to a particular system.

2. **Secure File Transfer:** Conventional ways of data transfer include the `RCP` and `FTP` commands in UNIX and Windows. The problem with these commands is that they are not secure because the data are sent unencrypted and the passwords are sent in clear. Besides that, `FTP` uses two connections, one for control and one for data.

Secure file transfer protocol (SFTP) is a separate protocol over the SSH protocol to handle file transfers. It encrypts user names, passwords, and data. Its advantage over `FTP` is that it uses the same port as the secure shell server. Another important function of SFTP is that it can be used to create a secure extranet (Van Dyke Software, 2003b). An extranet is a private network used by business firms to share securely part of their business information with vendors and perhaps other business partners. The term extranet arrives from the concept that it can also be viewed as an extension to the local intranet of any firm for some authorized users outside the company. This extranet can be used for uploading files and reports, making archives of data files, and remotely administering file oriented tasks.

3. **Data Tunneling for TCP/IP Applications:** Data tunneling, also known as port forwarding, allows securing data from normally insecure TCP/IP applications. Once it is set up, the SSH client sends data across an encrypted tunnel. The advantage of tunneling is that multiple applications can send data over a single encrypted tunnel. This eliminates the need to open additional vulnerable ports on a firewall or router.

Figure 1: Representation of an array of n bytes -byte[n].

SSH DATA TYPES, MESSAGE FORMATS AND ALGORITHM NAMING

Data Types and Their Representation

The various data types that are used in the implementation of SSH are described in the following list.

1. **byte:** A byte represents 8 bits of data. Fixed length data can also be represented as an array of bytes. For example, an array consisting of n bytes is represented as byte[n] (Figure 1).
2. **Boolean:** A boolean value can either be true or false. A boolean value is stored as one byte. The value 0 represents false, and the value 1 represents true.
3. **uint32:** This represents a 32-bit unsigned integer and is stored as 4 bytes in order of decreasing significance (also known as the network byte order).
Example: The number 699921578, in hex 0x29b7f4aa, is stored as 29 b7 f4 aa.
4. **uint64:** This represents a 64-bit unsigned integer. It is stored as 8 bytes in the order of decreasing significance.
5. **String:** This is used to represent binary strings of arbitrary length. The binary strings can contain arbitrary binary data that include null characters. They are also used to store text in which case US-ASCII is used for internal names. The representation is shown in Figure 2.
Example: The string *security* would be stored as 00 00 00 08 s e c u r i t y. The uint32 represents the length of the string, which is 8 in this case.
6. **mpint:** This format is used to represent multiple precision numbers in two's complement. It is stored as a string with 8 bits per byte with the *most significant bit* (MSB) first. A negative number has the value 1 as the most significant bit of the first byte of the data partition. The representation for number 0xab169fa637 is shown in Figure 3.
Similarly, the representation for value -deadbeef (in hex) is 00 00 00 05 ff 21 52 41 11 (in hex).
7. **name-list:** This is used to represent a string containing a list of names separated by a comma. A list may be empty (containing zero names). However, a name must be non-zero length and contain no comma. According to the earlier string representation, name-list is represented as a uint32 followed by comma-separated names, as shown by the following examples:

Figure 2: Internal representation of a string.

Figure 3: Internal Representation of 0xab169fa637.

Value	Representation (hex)
() , the empty list	00 00 00 00
("mlib")	00 00 00 04 6d 6c 69 62
("mlib", "zero")	00 00 00 09 6d 6c 69 62 2c 7a 65 72 6f

Message Numbers

SSH packets have message numbers attached that lie in the range of 1 to 255. The numbers have been allocated in the following manner:

Transport Layer Protocol:

1 to 19 Generic transport layer messages such as "connect," "disconnect," and "ignore"

20 to 29 Algorithm negotiation

30 to 49 Specific to the key exchange method used

User Authentication Protocol:

50 to 59 Generic authentication layer messages

60 to 79 Specific to the user authentication method used

Connection Protocol:

80 to 89 Generic connection layer protocol messages

90 to 127 Channel-related messages

Reserved for client protocols:

128 to 191 Reserved

Local Extensions:

192 to 255 Local extensions

Algorithm Naming

SSH uses names to refer to specific hash, encryption, and compression algorithms (e.g. sha-1 etc.). There are two formats in which these names can be associated with the algorithms:

1. There are certain names that have been reserved to be assigned by IETF. These names do not contain an at-sign (@). Examples include names like 3des-cbc, zlib etc.
2. There are additional names that can be defined by anyone. These names usually have the format yourciphername@yourcorporatename.com.

SSH PROTOCOL ARCHITECTURE

The SSH protocol runs on top of the TCP/IP protocol (Ylonen, Kivinen, Saarinen, Rinne, & Lehtinen, 2003b). It is composed of three layers (see Figure 4).

Figure 4: Protocol architecture.

1. Transport layer protocol (SSH-TRANS): Provides server authentication, confidentiality, and integrity. It runs on top of TCP/IP.
2. User authentication protocol (SSH-USERAUTH): Authenticates a client side user to the server. It runs on top of SSH-TRANS.
3. Connection protocol (SSH-CONNECT): Multiplexes an encrypted tunnel into several logical channels. It runs on top of SSH-USERAUTH.

The Transport Layer Protocol (SSH-TRANS)

The SSH Transport Layer is a low-level transport protocol that provides strong encryption, cryptographic host authentication, and integrity protection (Ylonen, Kivinen, Saarinen, Rinne, & Lehtinen, 2003c).

1. **Functions and position:** This protocol runs on top of TCP/IP and is at the bottom of the SSH protocol architecture. It has been designed to be simple and flexible to allow parameter negotiations and to minimize number of round trips. This protocol negotiates key exchange methods, public key algorithms, symmetric encryption algorithms, message authentication algorithms, and hash algorithms.

2. **Identification string exchange:** SSH works over any 8-bit clean, binary, transparent transport. When used over TCP/IP the server listens for connections over port 22. Once the connection is established, both parties must exchange the SSH protocol version number.

The server may send other lines of data before the version string, but each should be ended by a carriage return and newline must be encoded in ISO-10646 UTF-8. The primary use of this feature is to allow TCP wrappers to display error messages before disconnecting.

3. **Host keys and fingerprints:** Every SSH server host should have a host key and may have multiple host keys. A *host key* is a private key and public key pair, but in general, it means the public key of a host. The SSH client will base on the host (public) key of a SSH server host to authenticate the host from the beginning. Thus ensuring the authenticity of a host key for a host is absolutely necessary to guarantee the security of SSH sessions and to prevent the man-in-the-middle attack.

Nowadays, because of lack of public key infrastructure (PKI) and public key certificates, the verification of the host key for a SSH server host is left to the SSH users. Additional methods should be provided to verify the correctness of host keys. One of these methods is called a *fingerprint*, which in SSH is a hexadecimal value derived from the SHA-1 hash of a public key and is much shorter than the public key. The fingerprint of a host key should be made available for checking. The users of SSH client should verify the fingerprint of a host key by some means for which security does not rely on the integrity of the actual host key, such as by using a telephone or other external communication channel.

4. **Server authentication:** The authentication in this protocol is host based. There are two trust models that are widely employed for server authentication:

- **Local Database:** Under this method, each client maintains a local database that stores the servers names and the corresponding host keys. The database gets filled in whenever the client connects to new servers. The first time the client connects to the server, the server sends its host key to the client and gives it an option of storing it in its local database. This method has an inherent flaw, which can lead to the man-in-the-middle attack, discussed in detail in the later section, “SSH Security.”

- **Employing a Certification Authority:** The other trust model employs a certification authority that stores the host key, and the authentication for the host is routed through this third party. This method has the advantage that the host key has to be stored securely only at one location, that is, the certification authority.

5. **Binary packet protocol:** All packets transmitted between the SSH client and the SSH server follow the binary packet protocol format, which is as follows:

```
uint32    packet_length
byte      padding_length
byte[n1]  payload; n1 = packet_length - padding_
           length-1
byte[n2]  random padding; n2 = padding_length
byte[m]   MAC (Message Authentication Code);
           m = MAC_length
```

The length is measured in bytes. The `packet_length` does not include the MAC or the `padding_length` field itself. The random padding field is used for making the total length of (`packet_length` || `padding_length` || `payload` || `padding`) a multiple of the cipher block size or 8, whichever is higher. The padding should be random bytes. The amount of padding is between 4 and 255 bytes. The client and the server may negotiate the MAC algorithm; however, it must be “none” initially. Once the MAC algorithm has been negotiated, the MAC field contains the MAC bytes and the length of the MAC depends on the MAC algorithm.

6. **Encryption algorithm:** An encryption algorithm and a key will be negotiated during the key exchange. When encryption is in effect, all the fields of the packet are encrypted by the algorithm chosen. The ciphers in each direction must run independently and implementations should allow choosing different ciphers in each direction.
7. **Data integrity:** Data integrity is protected by including a message authentication code in each packet. This MAC is computed from a shared secret packet sequence number and the contents of the packet.
8. **Key exchange:** Key exchange begins immediately after version string exchange by each side sending a list of supported algorithms. Each side may guess which algorithm the other side is using and may send an initial key exchange packet. The packet format is as follows:

byte	SSH_MSG_KEXINIT
byte[16]	cookie (random bytes)
string	kex_algorithms
string	server_host_key_algorithms
string	encryption_algorithms_client_to_server
string	encryption_algorithms_server_to_client
string	mac_algorithms_client_to_server
string	mac_algorithms_server_to_client
string	compression_algorithms_client_to_server
string	compression_algorithms_server_to_client
string	languages_client_to_server
string	languages_server_to_client
boolean	first_kex_packet_follows
uint32	0 (reserved for future extension)

Each algorithm list must be a comma separated list of algorithm names. The list must be sorted in order of preference with preferred (guessed) algorithm first.

The initial key exchange produces shared secret K and exchange hash H . The exchange hash H from the first key exchange is used as the unique session identifier (`session_id`). This `session_id` remains the same even if the keys are later exchanged again. K and H and the `session_id` are used by the client and the server to derive six keys as follows (three keys in each direction):

For client to server:

Initial IV = hash ($K\|H\|A$ || `session_id`).

Encryption Key = hash ($K\|H\|B$ || `session_id`).

Integrity Key = hash ($K\|H\|C$ || `session_id`).

For server to client:

Initial IV = hash ($K\|H\|D$ || `session_id`).

Encryption Key = hash ($K\|H\|E$ || `session_id`).

Integrity Key = hash ($K\|H\|F$ || `session_id`).

In these derivations, hash is the same hash algorithm that is used in initial key exchange methods. “A”, “B” ... are single characters ASCII 65, 66, ...

Keys with required length are derived from the above keys using the following process: If the above hash has more bits than the required key-length, key data are taken from the beginning of the hash. If the required key-length is longer than the output of the hash, the key is extended by computing hash of the concatenation of K , H , and the key so far, and appending the resulting bytes to the key. This can be summarized as follows:

$K_1 = \text{hash}(K\|H\|X\|\text{session_id})$ // X can be “A”, “B”, etc.

$K_2 = \text{hash}(K\|H\|K_1)$

$K_3 = \text{hash}(K\|H\|K_2)$

...

$\text{KEY} = K_1\|K_2\|K_3\dots$

The basic steps in transport layer protocol are as follows (see also Figure 5):

- The SSH client initiates communication with the SSH server by connecting to the host and port number (22). If the server is up, a TCP connection between the server and client will be established by the underlying TCP/IP protocol.

- The server sends its version string to the client.
- The client sends its version string to the server.
- The server sends SSH_MSG_KEXINIT containing supported algorithms in the order of preference to the client.
- The client sends SSH_MSG_KEXINIT containing selected or supported algorithms in order of preference to the server.
- The server and client then will determine the same algorithms such as the host key algorithm, encryption algorithm, MAC algorithm, and compression algorithm. Then the server and client will begin the concrete key exchange based on the selected host key algorithm. The server host key will be sent to the client for authentication during the key exchange. Only one key exchange method is specified as required in the standard, that is, diffiehellman-group1-sha1. The key exchange for this method is discussed in detail in the section “Diffie–Hellman Key Exchange.”

User Authentication Protocol (SSH-USERAUTH)

The SSH authentication protocol is a general purpose user authentication protocol that assumes the underlying protocols provide integrity and confidentiality, protection (Ylonen, Kivinen, Saarinen, Rinne, & Lehtinen, 2003a).

1. **Function and position:** This protocol runs on top of SSH-TRANS and provides a single authenticated tunnel for the SSH Connection Protocol. When this protocol starts, it receives a session identifier from SSH-TRANS. This identifier is the exchange hash in the first key exchange. It uniquely identifies a session and is used for signing to prove ownership of private key.

2. **Authentication protocol framework:** The server drives authentication at any given time by telling the client which authentication methods can continue the exchange. The client has the freedom to try the listed methods in any order, and thus the server has control over the authentication process, but the authentication process remains flexible for the client. It is recommended that the server has a timeout for authentication and should disconnect if the time period or the maximum number of attempts runs out.

3. **Authentication requests and message formats:** All the authentication requests must follow the following message format:

byte	SSH_MSG_USERAUTH_REQUEST
string	user name (in ISO-10646 UTF-8 encoding [RFC 2279])
string	service name (in US-ASCII)
string	method name (US-ASCII)

The rest of the packet is method-specific. The server must ensure the user name specified in the request is valid. If not, it can send a false list of services to avoid disclosing user account information. If the server does not support the requested service, it should send a proper failure message.

Figure 5: Transport layer protocol.

4. **Responses to authentication requests:** If the server rejects the authentication request for some reason, it should send the following message:

```
byte      SSH_MSG_USERAUTH_FAILURE
string    authentications that can continue
boolean   partial success
```

Authentications that can continue is a comma-separated list of authentication method names that can be used to carry out the process. If partial success is true, it means that the last authentication method was successful, but still some more methods are required to complete authentication process. After it completes all the required authentication methods successfully, the server sends a success message as follows:

```
byte      SSH_MSG_USERAUTH_SUCCESS
```

5. **Authentication procedure:**

- The client sends an authentication request with requested method as none.
- Upon receiving this request, the server checks to determine whether the user name is valid.
- If the user name is valid, it must reject the “none” request with a failure message. Otherwise, the server rejects the client.

- The failure message contains a list of authentication methods the server supports.
- Then the client fulfills all the required authentications in the order it finds suitable.
- Upon completing all the authentication methods successfully, the server sends the success message.
- Any authentication request after the success message is ignored.

The authentication protocol message numbers range from 50 to 79.

6. **Authentication methods:** There are three basic authentication methods: public key based, password based, and host based. Out of the three only Public Key Method is REQUIRED and all implementations must support it.

- **Public Key-Based Method:** This method works by sending a signature created with a private key of the user. The server checks that the key used indeed belongs to the user and the signature computed is correct. If both are valid, the request gets accepted. Otherwise (i.e., just one or neither of them is valid), the request is rejected.

Private keys are generally stored in an encrypted form at the client machine. The user must supply a pass-phrase to generate a signature. To avoid unnecessary processing and user interaction the following message is provided:

```

byte      SSH_MSG_USERAUTH_REQUEST
string    user name
string    service
string    "publickey"
boolean   FALSE
string    public key algorithm name
string    public key blob

```

The algorithm name is from the list provided by transport layer protocol. The public key blob may contain certificates. The client can use this message to determine the algorithm or send a signature with the preferred algorithm. It is then the server's duty to check for validity of key and signature.

- **Password-Based Method:** All implementations should support password-based authentication. It uses the following packet format:

```

byte      SSH_MSG_USERAUTH_REQUEST
string    user name
string    service
string    "password"
boolean   FALSE
string    plaintext password (ISO-10646 UTF-8)

```

Note that even though a plaintext password is sent in the packet, the transport layer encrypts the entire packet. The implementations generally prompt the user to change a password on first logon and possibly again after some time when the password has expired.

- **Host-Based Method:** Some sites wish to allow authentication based on the host where the user is coming from. This form of authentication is optional and should be used carefully to prevent a regular user from obtaining the host's private key.

The Connection Protocol (SSH-CONNECT)

1. **Functions and Position:** This protocol has been designed to run on top of transport and user-authentication protocol. It provides interactive login sessions for the remote execution of commands, forwarded TCP/IP connections, and forwarded X11 connections (Ylonen, Kivinen, Rinne, & Lehtinen, 2003).
2. **Channel Mechanism:** All terminal sessions, forwarded connections, and other connection types are defined as channels. Multiple channels are multiplexed into a single connection. Channels are identified by numbers at each end of the connection. A request to open a channel contains the sender's channel number. Any other channel-related messages will contain the recipient's channel number for the channel. Channels are flow-controlled. Data may not be sent to a channel until a message is received to indicate that the window space is available.

Opening a Channel

If either side wishes to open a new channel, it can do so by sending the following message to the other side. It must include the local channel number and initial window size in the message.

```

byte      SSH_MSG_CHANNEL_OPEN
string    channel type (restricted to US-ASCII)

```

```

uint32    sender channel
uint32    initial window size
uint32    maximum packet size
channel type specific data follows

```

The remote side decides whether it wants to open the channel or not and sends a confirmation or failure message accordingly. The client may return some failure codes to indicate reasons.

Data Transfer

The window size specifies how many bytes the other party can send before it must wait for the window to be adjusted. Both parties use the following message to adjust the window:

```

byte      SSH_MSG_CHANNEL_WINDOW_ADJUST
uint32    recipient channel
uint32    bytes to add

```

After receiving this message, the recipient may send the given number of bytes more than it was previously allowed to send; the window size is incremented. Data transfer is done with messages of the following type:

```

byte      SSH_MSG_CHANNEL_DATA
uint32    recipient channel
string    data

```

The maximum amount of data allowed is the current window size. The window size is decremented by the amount of data sent. Both sides usually ignore all extra data sent after the allowed window is empty.

Closing a Channel

When either side no longer wishes to send more data to a channel, it sends the following message:

```

byte      SSH_MSG_CHANNEL_EOF
uint32    recipient_channel

```

No explicit response is sent to this message; however, the application may send end of the EOF to whatever is at the other end of the channel. Note that the channel remains open after this message, and more data may still be sent in the other direction. This message does not consume window space and can be sent even if no window space is available.

When either side wishes to terminate the channel, it sends

```

byte      SSH_MSG_CHANNEL_CLOSE
uint32    recipient_channel

```

Upon receiving this message, the party must send back a `SSH_MSG_CHANNEL_CLOSE` unless it has already sent this message for the channel. The channel is considered closed for a party when it has both sent and received `SSH_MSG_CHANNEL_CLOSE`, and the side may then reuse the channel number. Any side may send `SSH_MSG_CHANNEL_CLOSE` without having sent or received `SSH_MSG_CHANNEL_EOF`.

This message does not consume window space and can be sent even if no window space is available. The standard recommends that any data sent before this message be delivered to the actual destination, if possible.

Connection, (Interactive) Sessions, and Channels

In SSH specification, various terms are used to denote different concepts and operations. Once the SSH client and SSH server complete the transport layer protocol and user authentication protocol, there is a secure connection established between the client and the server. The connection is identified by a connection identifier, which is the *exchange hash H* from the first key exchange, also called *session identifier*. Then the connection protocol is executed to open one or multiple channels and multiplex them into the single connection. The channels may be in the form of a remote shell (i.e., an interactive session for remote execution of commands), a tunnel such as TCP/IP port forwarding and X11 forwarding, or a secure subsystem such as SFTP. In general, the first channel is automatically opened after successful user authentication and is an interactive session. The interactive session provides an interactive interface for the user of the SSH client to perform various tasks such as SFTP, X11 forwarding, and TCP/IP port forwarding by opening multiple channels. These channels are independent from the first channel (i.e., the initial interactive session) and from each other, and they all run on top of the secure connection.

A secure connection is associated with various parameters such as session keys, encryption algorithms, authentication algorithms, and compression algorithms, which are negotiated during the execution of the transport layer protocol and user authentication protocol. The connection provides necessary security support such as confidentiality and data integrity. The connection exists until either the client or server closes the connection or there is an abnormal termination at either end.

SECURE FILE TRANSFER PROTOCOL

Function and Position

The traditional methods for file transfer over the Internet do not provide adequate security to the data being transmitted. The trouble is that the user names, passwords, and the data are sent in plaintext, which can be easily intercepted.

SFTP is a secure file transfer protocol that makes use of the underlying SSH for authentication and encryption. Although it is a separate protocol by itself, SFTP is integrated with SSH to an extent that it is sometimes called a subsystem of SSH. SFTP is used from the SSH connection protocol when used with SSH (Galbraith, Ylonen, & Lehtinen, 2004).

The protocol follows a request-response model. The user, once authenticated by the SSH server via the user authentication protocol, sends requests to the server. There can be multiple requests pending at a time, and because each request and response transmitted contains a sequence number, the confusion as to which response is for which request is avoided.

General Packet Format

The format for the packets transmitted over the secure connection is as follows:

```
uint32      length
byte        type
byte[length-1] data payload
```

The length field indicates the length of the type and data payload areas. The client generally determines the maximum packet size, which in turn depends on the maximum size of the read or write request it sends. Typically, a few more bytes are added to take care of the packet overheads.

Protocol Initialization

The file transfer protocol is initialized in a specific way, consisting of the following steps (see also Figure 6):

- The client does the first step in the initialization process. It sends an initialization packet (SSH_FXP_INIT, value = 1) to the server. It also includes its version number (SFTP_PROTO_VERSION).

The format of the SSH_FXP_INIT packet sent to the server by the client is

```
unit32 version
```

- The server responds by sending a SSH_FXP_VERSION packet in which it supplies its lowest version and also the client version. Both sides should agree on a particular version of the protocol. The format of the SSH_FXP_VERSION packet sent to the client by the server is

```
unit32 version
< extension data >
```

The extension data in these packets can be empty or can consist of details such as *packet length* or *maximum length of the packet*.

Figure 6: Protocol initialization in SFTP.

File Attributes

The protocol defines a new compound data type for defining file attributes. The data type is basically just a combination of certain flags that indicate the attributes. The encoding used by the server to send the file attributes is the same as used by the client. When the attributes are sent to the server, the flags field specifies which attributes are included and which are not. In the same way, while the attributes are received from the server, the flags specify which attributes are included. The flags specify which of the fields are present. Those fields for which the corresponding flag is not set are not present, that is, they are not included in the packet returned by the server.

A few examples are as follows:

```

unit32  flags
unit32  size present only if flag SSH_FILEXFER_ATTR_
        SIZE is set
unit32  uid present only if flag SSH_FILEXFER_ATTR_
        UIDGID is set
unit32  gid present only if flag SSH_FILEXFER_ATTR_
        UIDGID is set

```

The size field specifies the file size. The identifiers corresponding to the users and groups to which the file belongs to are represented by the uid and gid.

Requests From the Client to the Server

Once a user has been authenticated and is connected to the remote SSH server, the user can perform many functions. Normally the user connects to perform remote file manipulation on the server, which include opening a file, moving a file from one directory to another, or uploading a file to some remote location. There are many examples of this.

In SFTP, the requests from the client to the server represent the various file operations that a user can perform. Each request begins with an id field, which is a 32-bit identifier identifying the request made by the client. An example request is SSH_FXP_OPEN that is used to open a file. The server responds by sending the file handle, which can later be used to access the file.

Request Synchronization and Reordering

While implementing the file transfer protocol, the client may send multiple requests to the server. Ideally, the server should respond to the multiple requests in such a way that the client receives the results in the same way as if it had sent the requests one at a time and waited. If the multiple requests are nonoverlapping in nature, the server can process them in parallel or even reorder them. This cannot be done in cases where the requests for the same files overlap, however.

File Names

The file names are represented as strings and use the / delimiter as the directory separator. The concept is similar to that used in UNIX. File names that begin with the forward slash are relative to the root of the file system. These names are known as *absolute file names*. Other names that

do not have a forward slash at the beginning of the file name refer to the user's home directory.

File Operations

There are a number of operations that can be performed on files using SFTP. Files can be opened and created by using the SSH_FXP_OPEN message. The data part of the message is as follows:

```

uint32  id
string  filename
uint32  pflags
AATTRS  attrs

```

The file is opened in a binary mode. The id field is the request identifier as for all requests. The filename field specifies the file name. The attrs field specifies the initial attributes for the file. The pflags is a bitmask for which, we have the following bits defined:

SSH_FXF_READ: used to open a file for reading.

SSH_FXF_WRITE: used for writing to the file.

SSH_FXF_APPEND: used for appending to a file.

SSH_FXF_CREAT: used to create a new file if the file does not exist

SSH_FXF_TRUNC: used to truncate a file with the same name to zero when creating a new file using SSH_FXF_CREAT

SSH_FXF_EXCL: used to fail the request if the file being created by SSH_FXF_CREAT already exists.

SECURE TUNNELING: TCP PORT FORWARDING AND X FORWARDING TCP/IP Port Forwarding

SSH can be used for more than secure remote logins or secure file transfers. It can be used in a way to provide partial transparency so as to secure otherwise insecure TCP/IP applications and X window applications. SSH maintains the transparency by hiding the secure tunnel created using strong encryption and authentication and providing the user with a terminal session resembling that provided by telnet or rsh.

Port forwarding is a process by which SSH transparently encrypts (tunnels through a secure SSH link) the data stream from any TCP/IP connection that would otherwise be insecure (Barrett & Silverman, 2001). Following is a brief example of port forwarding.

Suppose a user uses his or her home machine, say "M," which runs any internet message access protocol (IMAP) or post office protocol (POP) e-mail client. The e-mail client would connect to a simple mail transfer protocol (SMTP) server running on another machine, say "S," to send his or her e-mails. Normally, this connection would be insecure and the user names and passwords would be transmitted in clear as plaintext over the network. But with the port forwarding service of SSH, the user can route the SMTP connection in such a way that it passes through SSH, which would securely encrypt the data over the connection.

Let us assume the SMTP server running on the server phoenix.cs.iupui.edu SMTP uses TCP port 25, and as such, the SMTP server would be listening to port 25 for incoming connection requests. If we wish to tunnel the SMTP connection through SSH, we would have to forward (i.e., map) the remote socket (phoenix.cs.iupui.edu, 25) to a local port on the home machine (the local host). We can select any port between 1024 and 65535, say 1098, for example.

Now the following command would create the tunnel:

```
$ssh -L1098 : localhost:25 phoenix.cs.iupui.edu
```

By this command, we not only login into phoenix.cs.iupui.edu but also forward the TCP port 1098 on M to port 25 on the server. The last step would be to make the e-mail reader program connect to the socket (localhost, 1098) instead of the socket (phoenix.cs.iupui.edu, 25) on the server to send e-mails. The connection path can be depicted by Figure 7.

The steps to forward the connection are as follows:

- The e-mail reader running on the home machine M sends data (the e-mail) to local port 1098.
- The SSH client running on M reads the data, encrypts it, and sends it through a secure SSH connection to the SSH server running on phoenix.cs.iupui.edu.
- The SSH server on phoenix decrypts the data and forwards it to the SMTP server listening on port 25.

This example assumes that both the SSH client and the e-mail reader application program are running on the same host machine (M). The same also applies with regard to the SSH server and the SMTP server. It is also possible,

however, to have the SSH client and the e-mail reader (similarly, the SSH server and the SMTP server) running on two machines (suppose the two machines are in the same local area network (LAN) or there is no security threat between the two machines) and still use the TCP port forwarding service provided by SSH. The following example illustrates this.

Suppose that the e-mail reader application is running on the host machine M. The SSH client now runs on a different machine (68.1.1.4), and it listens to the interface 0.0.0.0 at port 1098. By listening to this interface, we make the SSH client accept any connection request irrespective of its origin, and the TCP application can reside in a physically different machine than the SSH client. The e-mail reader is configured to connect to the host running the SSH client at port 1098.

The SSH client encrypts the data as in the previous case and sends it through a secure SSH connection to the SSH server running on phoenix.cs.iupui.edu (134.68.140.4). The SSH server decrypts the data and forwards it to the SMTP server running on a different host. The SMTP server is configured to listen to the interface 0.0.0.0 at port 25. Again by making the SMTP server listen to 0.0.0.0, we make it accept any connection requests irrespective of the origin.

Note that the data is transmitted unencrypted between the SSH Server and the SMTP server. We assume that this is secure as they are part of the same LAN or inside the same corporate office. The entire process is shown in Figure 8.

X Forwarding

Having discussed how TCP port forwarding works, this section considers how forwarding can be applied to X

Figure 7: Port forwarding transmission control protocol/internet protocol connections locally. Figure was adapted with permission from Bitwise Software Ltd. (2002).

Figure 8: Remote Forwarding of TCP/IP Connections. Figure was adapted with permission from Bitvise Software (2002).

protocol connections. The X window system was developed at the Massachusetts Institute of Technology in the late 1980s, and it remains a popular window system for Unix workstations. It is freely available and completely transparent to the user. The user can run remote X applications that would open their windows on the user's local display (Barrett & Silverman, 2001).

The X Window System

The X window system, or X, is based on a client-server architecture and consists of two distinct parts—the X server and one or more X clients. X clients are windowing application programs such as paint programs or terminal emulators. The X server invariably runs on the machine to which the display is connected. The clients may run on the same machine, communicating directly with the server, or they might run on stand-alone workstations and communicate over the network using the X protocol.

A key part of X is the concept of display. When an X client is invoked, it needs to know which display to use. The DISPLAY environment variable indicates the location of the X server. Displays are named as strings of the form HOSTNAME:d, where HOSTNAME is the name (IP address) of the machine running the X server and controlling the display and d is the display number. It is an integer that allows a single server to control multiple displays.

Forwarding X Connections

The user is unlikely to be aware of X forwarding, but behind the scenes, the SSH client and server cooperate with each other to securely tunnel the X connection.

The process begins when the SSH client requests for X forwarding while connecting to the SSH server. If the server supports X forwarding, it creates a proxy X server

running on the remote machine and allocates a “fake” display to it. In other words, it sets the DISPLAY environment variable in the user's remote shell to point to the proxy X display.

If the user runs an X client program, he or she is connected to the SSH server, which behaves just like a real X server. Once this connection has been established, the SSH client and server could then send X protocol data back and forth over this secure tunnel created and the whole process remains transparent to the user (Barrett & Silverman, 2001).

SSH KEY MANAGEMENT

Diffie-Hellman Key Exchange for the SSH Transport Layer

The SSH protocol performs the initial key exchange based on the Diffie-Hellman key exchange method. In technical terms, it is known as the diffie-hellman-group1-sha1 method (Friedl, Provos, & Simpson, 2003). The Diffie-Hellman key exchange method provides a mechanism for two parties to obtain a shared secret in such a way that either party alone cannot determine it. In SSH, to avoid a man-in-the-middle attack and provide host authentication, the key exchange is signed with the host key.

The key exchange that takes place is shown in Figure 9 and explained further in the following paragraphs.

The Setup

The server keeps a list of safe primes (a prime p is safe if $p = 2q + 1$, where q is also a prime) and the corresponding generators for the same. Here the client is “C” and the server is “S.” p is a large safe prime and g is a generator for a subgroup of $GF(p)$. min is the minimal size of p (in bits) that the client is ready to accept. n is the size of the

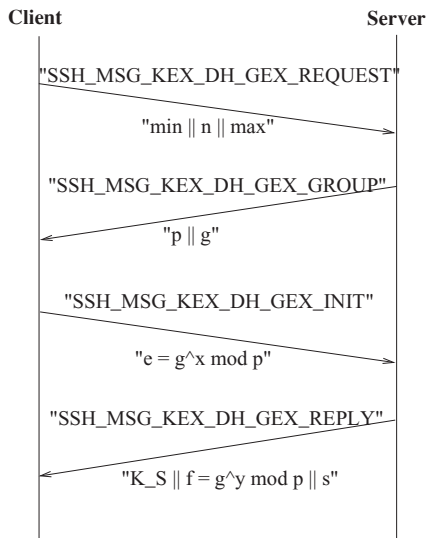

Figure 9: Diffie–Hellman key exchange for SSH transport layer.

modulus p in bits that the client would like to receive from the server. max is the maximum size of p that the client could accept. V_S is the version string of the server and V_C is the version string of the client. K_S is the public host key of the server. I_C is the KEXINIT message of the client and I_S is that of the server. The KEXINIT messages have been exchanged before this part begins. Note that the symbol \parallel implies concatenation or being followed by.

The Working Process

Step 1: Client to Server

C sends “ $min||n||max$ ” to S, indicating the minimal acceptable group size, the preferred size of the group, and the maximal group size in bits the client will accept.

Step 2: Server to Client

S finds a group that best matches the client’s request, and sends “ $p||g$ ” to C.

Step 3: Client to Server

C generates a random number $x(1 < x < (p - 1)/2)$. It computes $e = g^x \bmod p$, and sends “ e ” to S.

Step 4: Server to Client

S generates a random number $y(0 < y < (p - 1)/2)$ and computes $f = g^y \bmod p$. It computes $K = e^y \bmod p$, $H = \text{hash}(V_C||V_S||I_C||I_S||K_S||min||n||max||p||g||e||f||K)$ and signature s on H with its private host key. S sends “ $K_S||f||s$ ” to C.

Step 5: Client to Server

C verifies that K_S really is the host key for S (e.g., using one of the two trusted models described earlier, viz. certificates or a local database). C then computes $K = f^x \bmod p$, and $H = \text{hash}(V_C||V_S||I_C||I_S||K_S||min||n||max||p||g||e||f||K)$ and verifies the signature s on H .

SSH Public Key File Format and Public Key Subsystem

It is important to exchange public keys to be able to use public key authentication. Public keys must follow a public key file format.

File Format: A key file is a text file, containing a sequence of lines. Each line in the file must not be longer than 72 bytes.

Line Termination Characters: To achieve the goal of exchanging public key files between servers, implementations are required to read files using any of the common line termination sequence, $\langle CR \rangle$, $\langle LF \rangle$, or $\langle CR \rangle \langle LF \rangle$.

Begin and End Markers: The first line of a conforming key file must be a begin marker, which is the literal text:

— BEGIN SSH2 PUBLIC KEY —

The last line of a conforming key file **MUST** be an end marker, which is the literal text:

— END SSH2 PUBLIC KEY —

Key File Header: The key file header section consists of multiple RFC822-style header fields. Each field is a line of the following format:

Header-tag ':' 'Header-value

The Header-tag must not be more than 64 bytes. The header-value must not be more than 1,024 bytes. Each line in the header **MUST NOT** be more than 72 bytes.

A line is continued if the last character in the line is a \backslash . If the last character of a line is a \backslash , then the logical content of the line is formed by removing the \backslash and appending the contents of the next line.

The Header-tag must be US-ASCII. The header-value must be encoded in UTF-8 (Friedl et al., 2003).

A line that is not a continuation line and that has no $'$ is assumed to be the first line of the base 64-encoded body. Compliant implementations must ignore unrecognized header fields. Implementations should preserve unrecognized header fields when manipulating the key file.

Existing implementations may not correctly handle unrecognized fields. During a transition period, implementations should generate key file headers that contain only a Subject field followed by a Comment field.

Subject Header: This field currently is used to store the login name that the key was generated under. For example:

Subject: user

Comment Header: This contains a user-specified comment that will be displayed when using the key. It is suggested that this field default to $user@hostname$ for the user and machine used to generate the key. For example:

Comment: user@mycompany.com

Currently, common practice is to quote the Header-value of the Comment, and some existing implementations fail if these quotes are omitted.

Public Key File Body: The body of a public key file consists of the public key blob as described in the SSH transport draft.

“Public Key Algorithms,”-encoded in base 64 as specified in RFC-2045 “Base64 Content-Transfer-Encoding.” As with all other lines, each line in the body must not be longer than 72 bytes. The following example shows a typical public key block.

— BEGIN SSH2 PUBLIC KEY —

```
Comment: "1024-bit RSA, converted from OpenSSH by galb@test1"
AAAAB3NzaC1yc2EAAAABIwAAAIEA1on8gxCGJJWSRT4uOrR13mUaUk0hRf4RzxSZ1
zRbYYFw8pFgesIFoEuVth4HKyF8k1y4mRU nYHP1XNMNMJ1JcEArC2asV8sHf6zSP

```

— END SSH2 PUBLIC KEY —

SECURITY

Comparison of SSH1 and SSH2

The work on secure shell has resulted in two versions of the protocol, which are quite different from but also somewhat incompatible with one another. The two versions are SSH1 and SSH2. SSH1 was developed as a replacement to the existing insecure UNIX commands such as `rlogin`, `rcp`, and `rsh`. SSH1 did not have a separate protocol for file transfer over the Internet, but soon certain vulnerabilities were found, and to overcome them, SSH1 was rewritten with improvements in security, performance, and portability.

The major improvement that was introduced by SSH2 over the first version was the introduction of a new protocol for transferring files (i.e., SFTP). SSH1 used separate TCP connections for control and data. A user could connect to the SSH1 server by sending a request at port 22 on the server (the port used by SSH). This connection was encrypted and hence secure, but FTP uses port 21 for communication. Therefore, the request would be forwarded to this port on the FTP server. Once the connection to the FTP server was established, the data transfer between the client and the server was done in clear, which was insecure. This was a serious vulnerability in SSH1, and FTP servers often became common targets for attacks.

SSH2 introduced the concept of a separate protocol for file transfer via the SFTP, which did not use the concept of port forwarding. Instead, SFTP was developed to work as a subsystem to be integrated with SSH2. Under the new scheme, a single secure connection to the SFTP server is made. The SFTP commands such as `open`, `read`, `write`, and so forth are tunneled through the existing SSH session making such data transmissions more secure. The key points of difference between the two versions are the following:

- SSH2 has a separate protocol for file transfer.
- The number of encryption algorithms supported by SSH2 is larger than SSH1.
- SSH2 is more secure compared with SSH1.
- SSH1 is subject to the man-in-the-middle attacks.
- SSH1 has more diverse authentication support.

The Man-in-the-Middle Attacks

The present implementations of SSH do not provide any mechanism for secure transmission of public keys of hosts. There is no method available for initial authentication of the host unless the client has already securely

been given the public key of the host before, which it had stored in its database and which it can verify every time it needs to connect to the server.

The method followed is something like this. The client makes a request for a connection to a particular server. The server responds to the request by sending its public key. If the client is trying to connect to the host for the first time and does not have the host public key stored in its database, the user is prompted to store the same in its local database. This key is then later used for host authentication every time the client tries to connect to the same host. This method relies on the principle of initial trust, which eliminates the need to securely transmit the host keys prior to the communication between the client and the host. It makes the protocol vulnerable to what is known as the man-in-the-middle attack, however (Saito, Kito, Umesawa, & Mizoguchi, 2002).

In short, the man-in-the-middle attack is when attackers try to modify the transmission between the client and the server in such a way that they masquerade as the client for the server and the server for the client.

Three points of discussion for the man-in-the-middle attack are pertinent to SSH.

First, the attacker intercepts the authentic public key sent by the host and replaces it with its own. Here the attacker is able to mimic the server while communicating with the client. In certain cases, it can also do the same in the other directions (i.e., masquerade as the client to the server). When this happens, both the client and the server are fooled to accept the attacker as an authentic counterpart. This attack can be avoided to a certain extent if the client has been provided with the host key prior to the initial communication and the user decides not to continue with the new key received from the attacker, but instead decides to go with the key stored in the local database at its end.

The second case is similar to the first, although it is related to the secure transmission of the server host key to the client. If the public server keys are not securely distributed, the client cannot know whether it is talking with the intended server. If the attacker can modify this transmission, the client can be fooled into talking with the server. The attacker is able to establish client-attacker session and a corresponding attacker-server session. This can be avoided if the fingerprints of the server public keys are made available in such a way that the client can verify that once it gets the initial public key from the server.

In the third case, the attacker might be able to modify the packets in transit between peers once the connection has been established. This kind of attack is highly improbable under normal circumstances, thanks to the MAC algorithms used. It appears to be difficult, if not impossible, to construct inputs to a MAC algorithm to give a known output. If the MAC algorithm has a vulnerability or is weak enough, the attacker may be able to specify certain inputs to yield a known MAC output, and then the attacker might be able to alter the contents of the packets in transit.

Denial of Service Attacks

Denial of service (DoS) attacks are those in which the attacker bogs down the server by sending a large number of bogus requests, thereby rendering its services unavailable to the legitimate users. The SSH protocol is vulnerable to this type of attack in two ways (Ylonen et al., 2003b). First, because the protocol is designed to run over a reliable transport mechanism, the connection will be closed if there is any form of transmission error or message manipulation. Thus, an attacker can manipulate messages to cause the connection to be closed and the client to lose the services from the server.

The second type of DoS attack is when the connection setup and key exchange occur ahead of the user authentication phase. The attacker can force the server to conduct repeatedly the connection setup and key exchange, which are central processing unit and memory-intensive tasks, without authenticating. This will make the server unable to establish connections with the legitimate users.

SSH IN THE REAL WORLD

Operating Systems Support for SSH

Secure shell was initially introduced as a free open-source package under UNIX. Security firms have introduced various commercial implementations that are not open source. Implementations of SSH are available under UNIX as well as non-UNIX environments. The operating systems supported currently by one or the other implementation of SSH are Unix AIX, HP - UX, Linux, SUN Solaris, Windows 2000/NT/XP, Mac OS X, FreeBSD, and Cygwin.

Current Implementations

One of the leading vendors for the secure shell is SSH Communications, which provides a product called SSH Secure Shell (<http://www.ssh.com>). At present, it is the most widely used implementation of secure shell and has been deployed in many universities across the United States.

Van Dyke software (<http://www.vandyke.com>), another large security firm, offers products such as Secure CRT (terminal emulator) and Secure FX (for secure file transfer). Other vendors are F-Secure (offering F-Secure Tunnel and Terminal) and AppGate (offers AppGate client and server).

The implementations mentioned here are all commercial implementations, but some open-source implementations can be downloaded and used. These may not contain

as many features as the commercial implementations, however. Two of the best known open-source projects that provide support for SSH and SFTP are OpenSSH and WinSCP.

OpenSSH (<http://www.openssh.com>) is a free open-source implementation of the secure shell and has support for SSH1 and SSH2 protocols. It provides the SSH program, used for remote logins; the sftp program, used for secure file transfer; and the scp program, used for secure copy of files. It also includes sshd, which is the server side of the package. OpenSSH is seeing increased use in the open-source world because it is simple and highly portable.

WinSCP (<http://winscp.sourceforge.net/eng/>) is an open-source SSH file transfer protocol and secure file copy client for Windows. The main objective behind the development of WinSCP was for safe copying of files between a local and a remote computer. It does provide some additional features to the user, including operations such as renaming files and folders, creating new folders, and changing folder properties.

Installation and Execution

Describing the procedure for downloading and executing SSH is beyond the scope of this chapter. This section briefly explains the compilation and installation details of OpenSSH, which remains one of the most widely used implementations in the open-source world.

Obtaining the Distribution

OpenSSH is a free implementation available at <http://www.openssh.com>. Developed under the OpenBSD project, the main version of OpenSSH is specifically for the UNIX operating system.

Building and Installing the Distribution

The following steps are required to compile and install SSH. One must log on as the root user to execute the following commands:

- Change the directory to the root directory of the distribution and run the configure script in the distribution by:

```
$ ./configure
```
- Then compile everything by:

```
$ make
```
- Install everything by:

```
$make install
```

Compile-Time Configuration

Building SSH does not appear to be difficult, but when building and installing a new security product, one should not blindly accept the default settings. In other words, system administrators should make sure that they know exactly what kind of settings the installed product will have.

Compile-time configuration can be performed by running the script `configure` before compiling the distribution. There are a set of configure flags that help change the default settings and configure SSH according to user

needs. The complete set of configure flags can be seen with the following command:

```
$. /configure—help
```

The most important compile-time flags associated with OpenSSH are as follows:

- `—without-pam`
Pluggable authentication module (PAM) is an infrastructure developed by Sun Microsystems to support multiple authentication methods. PAM eliminates the hassles that are usually associated with a new authentication method. PAM helps programs perform authentication and authorization tasks using various authentication methods. It uses dynamically loaded libraries.
By default, OpenSSH uses PAM for password authentication. By using the flag, the PAM support could be omitted.
- `—with-md5-passwords`
Enables use of MD5 passwords
- `—with-ssl-dir=PATH`
Sets the path to OpenSSL installation. It should be used only if OpenSSL is installed.
- `—with-kerberos=PATH`
Enables Kerberos.
- `—with-ipv4-default`
This makes OpenSSH use IPv4 unless we specify `-6`.
- `—with-4in6`
OpenSSH supports IPv6 and this option is used to convert IPv4 addresses into IPv6.

Server-Side Configuration

The configuration decisions at the server end includes issues such as which authentication techniques should be used, the number of bits in the server key, and time out for idle connections. The following is an overview of the process.

Server Configuration

The SSH server in OpenSSH is named `sshd`. The SSH server is invoked automatically when the host computer is booted and if the server is running as a daemon. Alternately it could also be invoked manually. The server could be configured in the following ways:

- Using the server configuration file, usually found at `/etc/sshd.config`
- Using command-line options

Using the first method, one could change the configuration file and use that in place of the default configuration file by using the `f` option followed by the path for the alternate file:

```
$sshd f /usr/local/new_sshdconfig
```

Alternatively, we could use the command line options to configure the server. The advantage of this is that it can

be used to debug the server. An example of the command line option would be using the `-p` option to specify the port number to be used by the server:

```
$ sshd p<port number>
```

Host Keys

Each SSH server has a host key that is persistent and uniquely identifies itself to the client. The two parts of the host key, the private key and the public key, are stored as two distinct files. For OpenSSH, the private key is stored in `/etc/ssh/Host_key`. The public key is stored at the same location and as a `.pub` appended to the name. For OpenSSH it is `/etc/ssh/Host_key.pub`.

Encryption Algorithms

The SSH server supports many encryption algorithms for secure transmission of data. The client selects a cipher from the list of algorithms that the corresponding server supports. The keyword `Ciphers`, which is either a comma-separated list of permissible algorithm names or a single string indicating a set of algorithms, serves the purpose.

CONCLUSION

The materials in the article are mainly based on the SSH standard specification from the Internet Society, that is, various IETF Internet Drafts on SSH. These drafts are available online (see the references), and readers are encouraged to refer to these documentation for detail. PuTTY (2004) helps greatly in the analysis of SSH mechanisms.

ACKNOWLEDGMENT

I thank Mr. Amandeep Thukral and Mr. Yogesh Karandikar for their help with the preparation of the chapter.

GLOSSARY

Channel An identified communication session created by SSH-CONNECT between the SSH client and the SSH server. Channels include interactive login sessions, remote execution of commands, forwarded TCP/IP connections, and forwarded X11 connections. All of these channels are multiplexed into a single encrypted tunnel established by SSH-TRANS and SSH-USERAUTH.

Connection Protocol (SSH-CONNECT) The top level of the three-level SSH architecture. SSH-CONNECT multiplexes the encrypted tunnel into several logical channels. It runs on top of SSH-USERAUTH.

Fingerprint A fingerprint in SSH is a hexadecimal value derived from the SHA-1 hash of a public key. It is much shorter (typically 128 bits) than the public key which makes it easy to memorize, store, and transfer. A fingerprint is used to verify the authenticity of a public key.

Hash Function A function that maps a string of random length to a value of fixed length. A hash function should satisfy the following three requirements: one-way, matching resistance, and collision resistance.

Host Key The public and private key pair generated by the SSH system for a host when the SSH system is installed on the host. Typically, the host key means the public key in the key pair. A host key is used to identify or authenticate the host.

Message Authentication Code (MAC) An authenticator that is a hash function of both the data to be authenticated and a secret key. In other words, MAC is a keyed hash function. It is also referred to as a cryptographic checksum.

Port Forwarding A process by which SSH transparently encrypts the data stream from any TCP/IP connection that would otherwise be insecure by means of tunneling through a secure SSH connection.

Public Key Certificate Binding of a public key with the identity of its owner, signed by a trusted certificate authority. It is used to obtain the authentic public key of a user or verify the authenticity of a claimed public key by a user.

(Digital) Signature A value computed for a message based on a user's private key such that a recipient of the message can verify, based on the public key of the user, that the message is really from the user.

Transport Layer Protocol (SSH-TRANS) The lowest level of the three-level SSH architecture. SSH-TRANS provides server authentication, confidentiality, and integrity. It runs on top of TCP/IP.

User Authentication Protocol (SSH-USERAUTH) The middle of the three-level SSH architecture. SSH-USERAUTH authenticates client side user to the server. It runs on top of SSH-TRANS.

THE WIRELESS APPLICATION PROTOCOL

The wireless application protocol (WAP) is a collection of protocol standards whose purpose is to enable communication between handheld wireless devices and Internet-based service providers. Mobile devices vary greatly in capability. Some are compact, but fully powerful, computers. These are not the subjects of this chapter. WAP exists to accommodate the limitations of very small devices, generally mobile phones. Limited amounts of memory, both RAM and ROM, impact the performance characteristics of these devices. Applications and utilities, including security elements, must be optimized for the restricted environment. The service providers include Web servers providing content formatted especially for small wireless devices and other service providers who target the wireless devices exclusively.

This set of standards builds on existing standards, reusing or modifying where necessary to address the special needs of the handheld wireless community. The particular limitations of the wireless world include greatly restricted bandwidth, nonrobust connections, signal security limitations, the small screen on most devices, limited battery life, and restricted input options. Output from the handheld devices is generally limited to the small screen, although some devices can connect to other units, including projectors. Processor power and memory are other limitations for most target devices. Within these constraints, security is a particular challenge.

The Current Situation

The mobile telephone industry is currently suffering from disparity in standards that limit the usefulness of phones as they travel from one location to another. Currently, wireless system providers in the United States adhere to one of four different standards: IS-95 CDMA, TDMA, GSM, and iDEN. CDMA is Code Division Multiple Access and is the basis of the third-generation (3G) wireless transmission technologies WCDMA and CDMA2000. TDMA is Time Division Multiple Access in which each conversation

has access to the carrier frequency only part of the time. There are a number of implementations of TDMA, including the Digital American Mobile System (D-AMPS), the Global System for Mobile communications (GSM), Personal Digital Cellular (PDC), and Integrated Digital Enhanced Network (iDEN). GSM is uniformly used throughout Europe allowing systems to roam and retain service over large areas. GSM is also the standard in use in most African nations (Digital mobile phone networks in Africa). PDC is the standard for cell phone access in Japan, where the widespread use makes it the second most used standard in the world. iDEN is a proprietary standard from Motorola. The lack of interoperability among the various standards is a serious limitation, restricting access as users move about.

An important characteristic of the communication mode is the basic model for connectivity. Connection can be either packet switched or circuit switched. Circuit switched means that a connected user consumes bandwidth for as long as the connection is maintained. Most systems charge by connection time, reflecting the consumption of bandwidth. Packet-switched connectivity means that the device consumes resources only when actually sending or receiving a transmission. There is no reason to disconnect the device from the network. This always-on feature has significant consequences for wireless service providers. As a result, the most actively used wireless services are those in Japan, where cell phone use is pervasive and services are always available, without the need for establishing a connection.

The mobile phone networks are moving toward advanced technologies, which will bring packet-based communication to the systems used outside Japan. Expectations are that the always-on characteristic will drive interest in and use of emerging applications available to the mobile phone users. If the experience in Japan translates into usage patterns in the rest of the world, the demand for applications will grow at a great rate in the near future. Developed to run over any and all of the mobile device transmission methods, the Wireless Application Protocol suite is the common set of standards that

allows these applications to be available to all the wireless devices.

MOBILE ACCESS TO THE WORLD WIDE WEB AND OTHER DATA RESOURCES

The World Wide Web has become a utility, taken for granted as an information and communication resource. Similarly, the mobile communication device—whether phone or personal digital assistant—has become a part of the environment for many people. It is natural to look to combine these two. Access to existing Web pages is one goal of emerging standards and technologies for handheld, mobile, wireless devices. However, these devices offer opportunities to provide services and information feeds beyond what the Web provides. Web pages are dynamic, but they are not very responsive to the location of the visitor. Although there are location-specific services, such as yellow pages, most Web-based information is relatively static. A mobile user has different needs from a stationary browser. A mobile user might want to know what the traffic is just ahead or how to get from here to there. By combining the other features of the mobile device with a GPS system [or mobile positioning system (MPS) technologies], an application could address those questions. When a mobile user asks for information about nearby restaurants, the response needs to be organized for effective viewing on the small screen and must accommodate the limitations of imperfect connections. When a mobile user queries his or her bank balance before making a purchase, strong encryption must protect the data transferred without unduly impacting the amount of time required to get the answer.

One class of applications geared specifically to mobile users is localized data push. Assuming the user gives permission for such intrusion, a store may broadcast notice of a sale or even a special offer to a mobile device user who happens to be driving or walking nearby. Thus, the information obtained will be offered by a company or organization to attract the attention of a potential customer and entice with coupons or other offers. This type of communication depends on short-range data transfer using methods such as WLAN (wireless local area network) or Bluetooth. An example is the Flower framework for local wireless service (Hakkarainen, Lattunen, & Savikko, 2002). Such a service broadcasts to receivers that are in range and provide messages about special offers or just the existence of a business or service the device owner might patronize. Security in such an environment must depend on the ability of the device to reject dangerous files and to decline to submit user information in return.

Designing applications for the mobile device user requires different criteria from designing Web-based applications that will be accessed through large-screen devices with high-speed, reliable connections. When the information is requested by the user, income for the service provider is likely to be in the form of a charge for the amount of data delivered rather than advertising revenue. This means that the information presented to the user must be efficiently designed and delivered. The small screen size of most mobile devices requires

consideration in designing the information presentation. Having to scroll both horizontally and vertically to see the content of a message is difficult with devices typically held and controlled by one hand. User responses must be obtained without the use of a full keyboard and often without an effective pointing device. The design challenges are significant.

Standards

WAP must deal with two sets of constraints: limitations of the wireless data networks and limitations of the handheld devices used to send and receive data. When compared to landline networks, the wireless data networks, regardless of the technology used, are characterized by the following:

- Less bandwidth
- More latency
- Less connection stability
- Nonconsistent availability

These characteristics are factors of the wireless environment independent of the type of device used. Bandwidth limitations and extra latency are characteristics of the wireless service currently available. Connection stability and consistency of service availability result from mobility and the need to move between bases.

The Wireless Application Protocol is motivated by the desire to bring the Internet to small, generally handheld devices (Wireless Application Protocol Specification, 2001). In addition to the limitations of wireless devices of all types, the handheld wireless devices are characterized by the following:

- Small screens
- Limited input options
- Less memory
- Less powerful CPUs

Although technology will improve the situation, some characteristics are inherent to the handheld device class: screen sizes will be small because an important feature of these devices is their small size and light weight. Battery life restrictions will limit CPUs and memory size. Input options include various implementations of a keyboard, none of which are ideal for significant typing. Output is limited to a small screen. Storage includes limited memory and some supplemental storage cards. WAP is a set of standards designed with these restrictions in mind. The WAP protocol stack is similar to the ISO OSI reference model (ISO/IEC, 1994) for the upper layers. Layers below the network layer are implied in the bearer protocols. Figure 1 shows the protocol stack with the WAP standards in place.

Wireless Application Environment

The wireless application environment (WAE) is a framework for the development of applications that can be accessed from many types of wireless devices from a variety of manufacturers. The goal is a structure in which operators and services providers can build their products

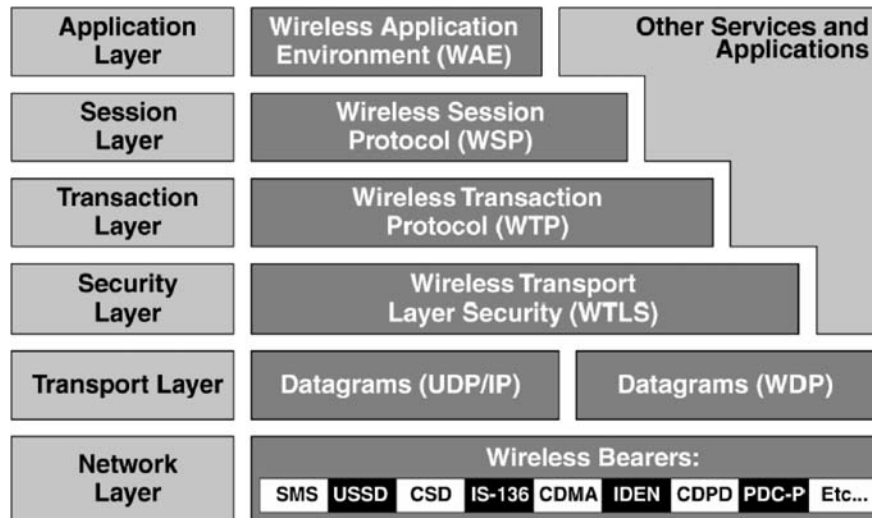

Figure 1: The WAP Stack (WAP Forum, 2002).

with confidence of interoperability with a wide variety of devices and applications. WAE includes XHTML Mobile Profile [HTMLMP], WML, WCSS, WMLScript, WBXML, vCARD, and vCalendar. Each of these is summarized briefly below:

- XHTML Mobile Profile. W3C is migrating HTML to XHTML, making it an XML application, and at the same time making it modular. Applications can be built using just the modules that are appropriate for the target devices. Starting with module XHTML Basic, XHTML Mobile Profile adds extensions suitable for the mobile devices.
- WML is the wireless markup language, an XML based markup language designed for use on devices characterized by low bandwidth connections, limited memory and restricted CPU capacity, a small screen, and limited user input interfaces.
- WCSS is the wireless cascading style sheet. Cascading style sheets are used in Web development to control display without sacrificing device independence. WCSS is specified for the special features of small mobile devices.
- WMLScript is a scripting language, roughly similar to JavaScript, designed to run on small mobile devices.
- WBXML is a compact, binary representation of XML documents intended to reduce the size of the files for transmission without losing semantic information.
- vCARD and vCalendar are industry standards for sharing address and calendar information.

Wireless Session Protocol

The wireless session protocol (WSP) offers the application layer consistent interfaces for session services. Two modes are offered. A connection mode runs over the wireless transaction protocol and a connectionless service runs directly over a datagram transport service. Initial versions of WSP offer browsing capabilities, including the equivalent of HTTP with implementation more suitable for wireless devices, plus facilities for long-lived sessions, session suspend/resume, data push, and capability negotiation.

Wireless Transaction Protocol

The wireless transaction protocol (WTP) provides services to allow browsing; specifically, WTP provides request response interaction between a client and a server. Unlike regular Web surfing with HTTP, WTP runs over a datagram service at the network layer. WTP enhances the service provided by unreliable datagrams to provide appropriate service levels to the higher layers, relieving the wireless device of the need to support all the services of TCP but providing a reliable service to the application. By using a datagram transport service, WTP eliminates the need for connection establishment and connection release activities. The protocol transmits a message as its basic unit, rather than a stream of bytes. WTP defines three classes of service:

1. Class 0: Unreliable invoke message with no result message.
2. Class 1: Reliable invoke message with no result message.
3. Class 2: Reliable invoke message with exactly one reliable result message.

Class 2 is the basic invoke/response service. Class 0 is available for an invoke message that will not be retransmitted if delivery fails and for which no response is expected. Class 1 is used for an invoke message that must be delivered or resent. The variations allow an application to function with a minimum of data transmission required.

Wireless Transport Layer Security

Wireless Transport Layer Security (WTLS) exists to provide privacy and security among communicating entities in a wireless environment. Security includes both data integrity and authentication services. The services of WTLS are optional and their use depends on the nature of the application and the vulnerability of the data it transmits.

Datagrams

Datagrams are transport protocol mechanisms that offer best effort delivery service without the high overhead

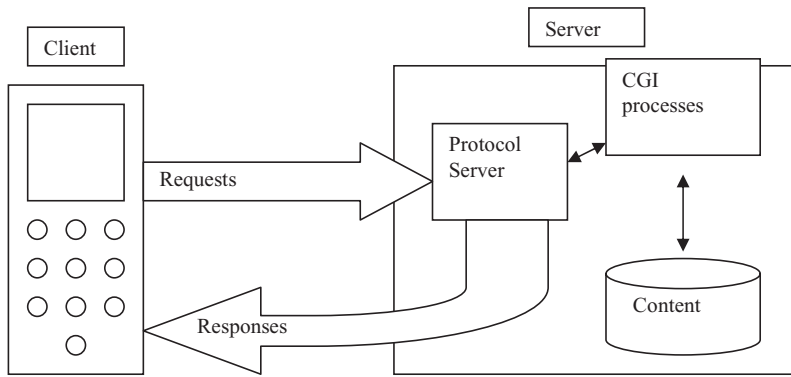

Figure 2: Direct Interaction Between the Wireless Client and Wireless Application Server.

required to provide highly dependable transport. Datagram transport protocols are lightweight, fast, and suitable for situations where the underlying network services are highly reliable or where the application will provide reliability and so services at the transport layer are redundant.

Access to wireless applications can be provided by direct connection to a WAP server that is also a content provider as illustrated in Figure 2. However, because most of the Internet content is present in Web sites designed to respond to HTTP requests and formatted in HTML that is often not suitable for the wireless device, standard access includes a gateway. The gateway receives requests using the WAP protocols and passes those requests to conventional web servers using HTTP. The gateway reformats responses for display on the limited device and encodes the response for transmission using the WAP protocol stack. Figure 3 shows wireless client interaction with a conventional Web server.

SECURITY

There are four aspects to security in general network communications:

1. Privacy. Content is visible only to the intended recipient and both parties have confidence that privacy is

protected. This is addressed with various levels of encryption. The degree of confidence required will be weighed against processing costs to determine the appropriate level of encryption to use.

2. Integrity. Content is not modified between leaving the sender and arriving at the recipient's device. Digital signatures allow documents to be verified as being the same as was transmitted. A hash code is computed over the document and sent as part of the signature. If the hash code check on the recipient side does not produce the correct results, the document has been modified.
3. Authentication. The sender's identity can be verified with a very high degree of confidence. Passwords, authentication, and digital signatures identify the originator.
4. Nonrepudiation. The sender cannot later deny having sent the information. Digital signatures are the primary tools for binding the sender to the document or resource as sent.

The WAP protocol suite includes four standards related to security: (1) the WAP Identity Module (WIM) is a hardware chip used for client side authentication; (2) WML Script Crypto API (WMLSCrypt) provides access to the WML security function library; (3) wireless transport layer security (WTLS) sits above the transport layer

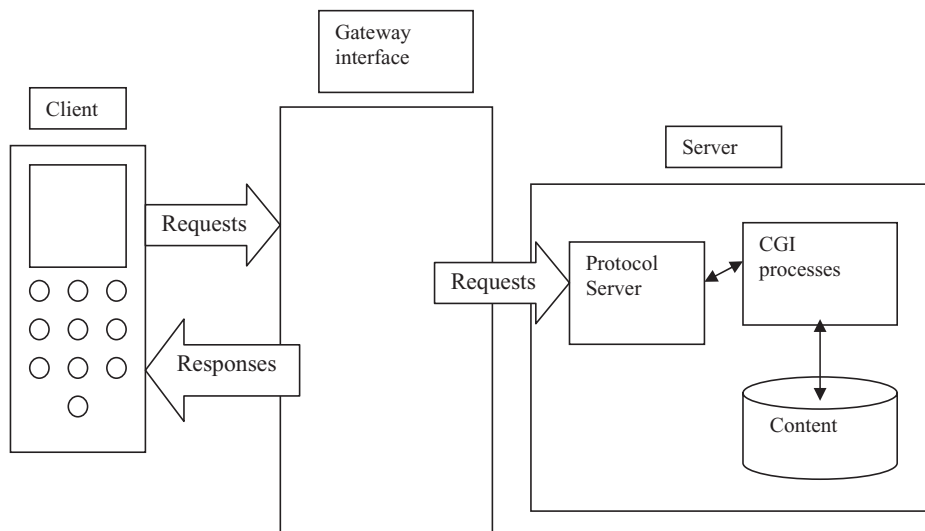

Figure 3: Wireless Application Client Interaction with a Conventional Web Server.

to provide basic security services; and (4) WAP Public Key Infrastructure (WPKI) is a wireless version of the Public Key Infrastructure (PKI). Thus, security in WAP consists of a hardware chip in the client device (WIM), a library of security-related objects and services and an application program interface to that library (WMSSCrypt), protocols for security services built on top of a standard transport layer (WTLS), and infrastructure and procedures for establishing trust relationships between a client and server (WPKI).

WAP Identity Modules

A WAP identity module or WIM, is a chip installed in the WAP-enabled device to facilitate client-side authentication. The chip implements WTLS Class 3 functionality, as described in the section on WTLS. WIMs can store key material such as the PKI root public key and the user's private key (Ashley, Hinton, & Vandenwauver, 2003). They are most commonly implemented using smart card chips. These chips have memory and storage for data and programs (Wireless public-key infrastructure, 2003). The basic requirement of WIMs is that they are tamper-resistant, meaning that certain physical hardware protection must be used. WIMs provide support for public key cryptography with RSA (see chapter 65) being mandatory and elliptic curve cryptography (ECC) (see chapter 113) optional. Each WIM comes configured by the manufacturer with two certificates and two sets of public-private keypairs. One keypair is used for signing and the other for authentication. The certificates bind the manufacturer's name with the public key side of the keypairs and allow for WTLS sessions to be established between the WIM and a WAP gateway before the user establishes an individual registered certificate (WAP Forum, 2001). The initial session is established with the built-in keys and may include a user-specific key.

The storage included in the smartcards used for most WIM implementations allow retention of certificates as well as programs and user data (Ashley et al., 2003). WIMs can store user certificates or user certificate references (e.g., URL-based references). The reference form is practical because of the substantial size of the actual certificates. However, storing the reference only imposes an additional communication requirement in using the certificate. It also requires confidence that the certificate is stored securely and remains valid for later use.

WML Script Crypto API

WML Script Crypto API (WMLSCrypt) is an application programming interface that allows WAP applications to access library items for security functions. The security objects and services are defined by other WAP security standards such as the PKI (see chapter 56). WML Script access the certificates, encryption keys, and other data stored in the embedded WIM chip. Specific functions supported by the WMLSCrypt include the following (Wireless public-key infrastructure, 2003):

- Generation of keypairs
- Store keys and other personal data

- Control access to stored keys and data
- Generate and verify digital signatures
- Encryption and decryption of data

An example WMLSCrypt function use is a call on `Crypto.signText()` to require a user to sign a string of text. The function is invoked by the WAP browser on the client device. The signature prevents the user from later denying having sent the text. This nonrepudiation function is essential to meaningful transactions conducted from easily portable (and easily lost) devices such as phones and PDAs. An application may implement the `signText()` function directly on the client device or invoke a call on a server. The signed text allows a server to validate the identity of the client and to retain the signed information for possible later use if the client denies the transaction (Ashley et al., 2003).

WAP Transport Layer Security

WTLS is based on the Transport Layer Security (TLS) protocol (see chapter 64) a derivative of the Secure Sockets Layer (SSL) protocol (Mikal, 2001). TLS is the de facto security implementation of the Internet. WTLS is used to authenticate communicating parties and encrypt and check the integrity of WML data when it is in transit. WTLS is a cryptography-based, PKI-enabled protocol that operates above the transport layer and addresses issues of authentication, privacy, integrity, and denial of service protection (Howell, 2003; Wireless public-key infrastructure, 2003).

- **Authentication:** WTLS uses digital signatures and public-key certificates to authenticate individuals, servers, or nodes prior to a session.
- **Privacy:** PKI-enabled, WTLS can encrypt data between communicating parties to provide privacy by preventing eavesdropping or unauthorized access. One-to-many communication is supported by using an authenticated and different encryption key for each communicating party.
- **Data integrity:** Hashing a document produces a data fingerprint allowing the detection of data modification.
- **Denial of service attack protection:** WTLS protects against denial of service attacks by detecting and rejecting data that has been replayed or has not been verified.

Unlike TLS, WTLS operates over user datagram protocol (UDP) rather than transmission control protocol (TCP) and also over wireless datagram protocol (WDP) in the absence of UDP [19]. In essence, WTLS takes TLS and tries to add datagram support, optimize the packet size, and select fast algorithms from the algorithm suite.

WTLS is a client/server protocol connecting the client and the WAP gateway. The session includes negotiation of security parameters, including the choice of encryption protocols, signature algorithms, public keys, and certificate exchanges. The choices depend on the capabilities of the cooperating client and server and the level of security needed for a particular application. After the encryption protocols have been selected during session established, communication is encrypted and should be safe

from eavesdroppers. WTLS options include both a full handshake, with complete negotiation of security parameters, and a lightweight handshake in which security parameters of another session are reused.

WTLS also supports session suspend and resume. This allows sessions that last for extended periods, even for days at a time. This possibility represents a security risk in WTLS. A very long session represents a large number of messages exchanged with the same keys. This risk is managed by requiring keys to be renegotiated periodically during a session. Renegotiating keys is not as computationally expensive as establishing the keys in the first place, so renegotiation is more efficient than tearing down and reestablishing the session.

The WAP specification (Howell, 2003) defines three implementation classes. The first class provides support for anonymous key exchange with no authentication using Diffie–Hellman (Ashley et al., 2003) key exchange. The key exchange establishes an encrypted channel between the server and client (WAP Forum, 2001). The second class of WTLS provides support for certificate-based server authentication in which the server key is either anonymous or authenticated and the client key is anonymous. This class uses public key certificates with the WAP gateway using a WTLS certificate. The server provides a certificate mapping back to an entity trusted by the client. The third and final class uses certificate-based authentication of both client and server. Both the client and server keys are anonymous (using the manufacturer installed keys in the WIM) or authenticated. The client may possess a private key and public key certificate enabling it to identify itself to other entities in the network (WAP Forum, 2001). All classes of WTLS allow a username/password identification and authentication using WML forms sent between the server and the mobile devices (Ashley et al., 2003).

WTLS suffers from many security weaknesses. For instance, WTLS allows for weak encryption algorithms (Mikal, 2001). With some WAP clients, users can even disable WTLS encryption entirely. Markku-Juhani Saariinen (2003) introduced seven known security issues in his study, including a chosen plaintext data recovery attack, a datagram truncation attack, a message forgery attack, and a key-search shortcut for some exportable keys.

Certificates

WAP defines a WTLS certificate format, which is optimized for storage on mobile devices and for transmission over constrained networks (Howell, 2003). These certificates rely on the server to perform processing under some circumstances but provide all the functionality of other formats. Bandwidth savings also contribute to efficient operation in the wireless environment (Ashley et al., 2003).

Use of ECC, (see chapter 113) further reduces the size of certificates required. The keys for ECC are typically on the order of six times smaller than equivalent keys (Wireless public-key infrastructure, 2003). The general model is that server certificates will use the WTLS certificate format whereas client certificates will use X.509 format, but as far as possible will not be sent over the air or stored on the client (WAP Forum, 2001).

One security issue with these schemes comes from the very nature of the devices used. Because these devices are mobile, small, and easily mislaid, certificate loss is an issue. Where access to the certificate opens access to data or services that require strict control, the possibility of a lost phone becomes too great a risk. At the simplest level, this risk is addressed by placing a certificate on a certificate revocation list once it has been reported missing. Although that prevents further use of the certificate, it leaves too much vulnerable time for the protected data and services. An application also has options to validate the current user's identity ranging from a simple PIN through a SecureID token (Howell, 2003).

WAP Gateway

The WAP gateway is a form of proxy used to translate between WAP protocols and traditional Internet protocols. WAP gateways were defined in the WAP 1.2 protocol published by the WAP Forum in 2000 (WAP Forum, 2002).

The WAP gateway is a software application typically running on a computer in a building under the control of the mobile service provider (MSP) (Jørgensen & Juul, 2002). Many gateways include a “transcoding” function that will translate an HTML page into a WML page suited to a particular device. The WAP gateway has three main functions (Ashley et al., 2003): (1) DNS services such as resolving domain names used in URLs, (2) a control point for management of fraud and service utilization, and (3) a proxy, translating the WAP protocol stack to the Internet protocol stack.

Most WAP gateways are hosted on the network provider's own local network. If access is required to services hosted on another server somewhere across the network, the WAP gateway will act as a proxy for the client mobile device in establishing the required sessions with the remote host (Howell, 2003).

The WAP gateway has five layers: WDP, WTLS, WTP, WSP, and WAE as pictured in Figure 4 (Wireless Internet Provider, 2004). The WDP is the transport layer and provides adaptation to different types of bearer technologies. The WTLS is used for establishing a secure connection between the phone and the WAP gateway, as described in the previous section. The WTP is the transaction layer and handles the flow control. The WSP provides session management and converts WAP requests to HTTP requests and vice versa. The WAE works as a router between different applications.

The WAP gateway is responsible for providing four services to wireless applications (Jørgensen & Juul, 2002). The first is switching between transport protocols. The gateway in its communication with the mobile phone uses a transport protocol (WDP) that is connectionless and unreliable. In contrast, the transport protocol used by HTTP on the ordinary Internet is the connection-oriented and reliable protocol, TCP. In TCP, there is additional communication to ensure that all data actually gets through, and if not, it is retransmitted. At the risk of possible data loss, omitting the cost of TCP saves significantly on latency and bandwidth.

The second service provided by the gateway is compression. The gateway compresses the WML document

Figure 4: WAP Gateway (Wireless Internet Provider. Technical Description: WIP Mobilis Development Kit (MDK). <http://www.wip.se/MDK/html/index.html>).

before sending it to the mobile phone. The gateway applies lossless data compression so that the same information can be sent in a format that occupies fewer bytes. The compression relies on the predefined translation between the vocabulary of HTTP and WSP.

The third service is compilation. If a WML document contains embedded source code, the gateway compiles the code into a bytecode format, something that relieves the mobile phone of the task of parsing the code. WML documents may contain code written in the scripting language WML script, which is similar to the JavaScript language that may be embedded inside HTML documents. Such code is executed inside the browser.

The final service is decompression. The gateway reads and interprets the original WSP request, the compressed form of which is not understood by the Web server. The Web server expects the comparatively lengthy HTTP requests expressed as ordinary text rather than by greatly abbreviated numerical codes. Also, the gateway also invokes the services of a DNS (domain name server) to translate a symbolic Internet address into an IP number. In addition to reducing the processing that must be done in the restricted environment of the mobile device, these services also reduce the amount of data that must be sent from the mobile phone.

WAP Security Gap

As functional as the gateway is to WAP, it creates a major security gap in wireless applications. If the gateway is acting as a proxy, the mobile device's session is with the WAP gateway instead of the remote host's Web server. At the gateway, the secure session terminates and all encrypted material is decrypted (Howell, 2003). If there is a requirement for a secure session with the Web server, it will be established by the WAP gateway on behalf of the mobile

device with the gateway using TLS to establish the secure session. Thus, the secure session established by the client is not between the mobile device and the Web server. Instead, there are two secure sessions; one between the mobile device and WAP gateway and one between the gateway and the Web server. Within the gateway, data are not encrypted during the translation processing, as illustrated in Figure 5. The Web service host has no control over the security that exists between the mobile device and the WAP gateway. Furthermore, the host has limited control over the TLS session between the gateway and the Web server and will be limited to providing security that does not exceed a level determined by the network operator.

Several solutions have been proposed to fix the gap at the WAP gateway ranging from ensuring that encryption and decryption happens in memory to putting a gateway at the host site (Howell, 2003), the only way to have complete control over security. However, these solutions are extreme and not easily implemented for most users. The WAP 2.0 specification seeks a more convenient solution to the gateway gap.

Transport Layer e2e

The WAP 2.0 specification replaces the WTLS security standard by TLS for secure end-to-end (e2e) data transport. This allows direct and secure connection between the phone-based client and the data serving site (Getgen, 2002). The TLS specification uses similar security mechanisms/algorithms to those of WTLS, including integrity confirmation, public key-based authentication of client and server either through use of certificates or anonymously, and message protection through secret key cryptography (Jeffer, 2001).

The process of communication in the e2e scheme is similar to the previous WAP gateway model as illustrated

Figure 5: Gateway Problem[19]

in Figure 6. The WAP client tries to send a request through its default gateway to a secure domain (Ashley et al., 2003). The secure content server determines the need for security that requires use of its local WAP gateway. It responds to the initial client request with an HTTP redirect message. The redirect passes back to the client through the default gateway, which validates the redirect and sends it to the client. The client caches the new connection and uses the subordinate WAP gateway for further communication with the data server. After the connection is terminated the default gateway is reselected and used for subsequent communications.

e2e security changes the role of the WAP gateway to more of a smart router (Getgen, 2002). The gateway continues to be used for services such as performing server-initiated push of data, offering location-based services, and performing data compression to the message body

Figure 6: WAP e2e Security[16]

(unencrypted text only) before it is transmitted over the air (Durham & Getgen, 2001). However, the gateway still has support for the previous architecture. Put simply, the role of the gateway changes from translator to an intelligent router reformatting data bits without reading the traffic.

Although there is still a role for the gateway in the e2e scheme, some of its functionality is lost (Jørgensen & Juul, 2002). If code written in WML script is encrypted, it cannot be compiled, unless the gateway can first decrypt the script, thus breaking the end-to-end encryption. For the same reason, it would not be possible for the gateway to understand (decompress) the encrypted WSP requests, so the mobile phone has to use the much higher latency-incurring and more bandwidth-consuming HTTP requests. The gateways can no longer compress ordinary WML documents; because the gateway can no longer recognize WML tags, it cannot replace full tags with the shortened numeric representations.

The new e2e scheme is not without drawbacks. Some of the weaknesses in WTLS are also present in the current TLS/SSL used over the Internet, and will therefore also apply to the "profiled" TLS used by WAP 2.0 (Jeffer, 2001). Although opportunities for security enhancement are provided, there is no obligation to exchange certificates or to verify certificates and authenticate owners. If the application does not invoke these functions, no security enhancement is possible. Also, TLS allows anonymous Diffie-Hellman mode where exchanges are not supported by public key certificates. Finally, with TLS an active intruder is able to substitute a different public key for the requested public key and can then participate in the communication without the awareness of the client or server.

WAP PUBLIC KEY INFRASTRUCTURE

E-commerce depends on reliable communication between mobile devices and service providers. Reliability includes four basic components: Communication must be confidential. That means that no eavesdroppers can intercept and understand the communication. Communication must be authenticated. That means the user must be confident about the identity of the service provider.

Communication integrity must be provided. That means that the user must be able to sign the transaction and the server can know the identity of the user. Finally, the transaction must be safe from repudiation. Once the user has committed to the transaction, no later denial can occur.

These assurances are provided in the stationary, wired world through the Public Key Infrastructure. WPKI is an optimized extension of traditional PKI for the wireless environment (Wireless public-key infrastructure, 2003; Open Mobile Alliance, 2004). WPKIs manage relationships, keys, and certificates to enforce business policies. Current functionality in WPKI manages the security requirements of WAP 1.2. This includes CA Public Key Certificates for WTLS class 2 (client capability to authenticate the identity of a gateway), Client Public Key Certificates for WTLS class 3 (client private key is used to sign text) and Client Public Key Certificates used with WMLScript signText (Open Mobile Alliance, 2004). Future versions are intended to add security services, including application level end-to-end confidentiality and integrity.

WPKI uses the same four components as traditional PKI: an end-entity application (EE), the registration authority (RA), a certification authority (CA), and a PKI directory. An additional component, the PKI portal, interacts with the wireless device and the CA; it will include the functionality of the RA (Wireless public-key infrastructure, 2003). The CAs issue and revoke certificates; RAs confirm the validity of a public key with respect to a specific person or device. Certificates are issued to people, applications, and devices. The certificates are stored and used to sign digital documents or transactions.

WTLS Security Classes

There are three classes of WTLS security for wireless devices communicating with an application or information server. Class 1 provides no authentication. The wireless device uses WTLS to communicate with a WAP gateway. The WAP gateway communicates with the server with SSL. The encryption used to protect the communication must be undone within the gateway for the gateway to do the translation between the two security protocols. No authentication of the server or the user occurs (Nardone, 2004).

WTLS class 2 security allows the WAP device to authenticate the identity of the WAP gateway through which it communicates with the service provider. Both a two phase security and an end-to-end security model are defined. Both require an initial setup stage. In the two-phase model, the WAP device again uses WTLS to communicate with a WAP gateway and the WAP gateway uses SSL to communicate with the application or information server. Prior to this communication request, the WAP gateway generates a pair of keys, the public and private key. The WAP gateway requests a certificate through the WPKI portal. The WPKI portal confirms the identification of the gateway and forwards the certificate request to the certificate authority. The CA sends the gateway public certificate to the WAP gateway and stores the WAP gateway certificate in the online repository. With this phase complete, the WAP device establishes a WTLS session with the WAP gateway and the WAP gateway establishes a SSL/TLS

session with the server. In future communications of this device through this gateway, the sessions can be established based on certificate information available between the WAP gateway and the device. This does not provide end-to-end security but does allow the device to authenticate the gateway that purports to provide a secure link to the desired server (Nordone, 2004).

End-to-end security eliminates the use of the WAP gateway and supports direct communication between the wireless device and the WAP server. The WAP server resembles a Web server but is able to communicate directly to wireless devices with WTLS. In this model, the initial setup consists of the same steps as before, but the WAP server takes the role of the gateway as well as the information or application server. The WAP server generates a pair of keys, a private key and a public key, and sends the certificate request to the WPKI portal. The WPKI portal confirms the identity of the WAP server and passes on the certificate request to the CA. The CA sends the Server Public Certificate to the WAP Server and stores the certificate in its on-line repository.

WTLS class 3 authentication extends the identity confirmation to include server authentication of the WAP Device. Cryptographic functionality for signing messages comes with the WMLScript Crypto Library. The function Crypto.sign.Text presents the user with a request to sign a body of text using an authenticated certificate. This facility adds to the basic authentication of SSL by providing persistence. The user connection to the text is stored for as long as that association is needed.

Class 3 authentication also requires an initial setup and then steps related to the authentication used in a session. The setup is similar to that in class 2 authentications but now is focused on the WAP Device. The WAP device requests a certificate through a WPKI portal. The request will travel through the WAP gateway unless the portal is acting as both portal and gateway (i.e., the portal is a WAP server offering certification). The WPKI portal confirms the identity of the WAP device, which is stored in its WIM, and forwards the request to the CA. The CA generates the user certificate and sends either the certificate or a certificate URL to the WAP device. The CA may store the certificate in its database. In future interactions between the gateway and this WAP device, the user signs the transaction and sends the transaction, the signature and the certificate (or certificate URL) to the application or information server. If the server receives a certificate URL, it retrieves the certificate from the CA database; that step is not needed if the user sends the actual certificate. The server verifies the signed transaction from the user and proceeds with the service. The user's certificates and keys are stored in the device's WAP identity module (WIM), which may be separate from or combined with the subscriber identity module (SIM). When these are combined, the card is called SWIM (subscriber WAP identity module). Implementation recommendations include minimization of the amount of user input from clients and of the persistent information about each PKI that any client should have to store.

The WTLS certificate format includes a validity period, which necessitates a provision of updates over the air before existing settings expire. Several different schemes

Figure 7: WTLS Class 2 Authentication.

were defined by the WAP Security Group (WSG) (Farrell, 2000):

- **Out-of-band distribution:** The user downloads the root CA information without regard to security in the channel but then must activate the CA by entering a 30-decimal digit value, which was received out of band. Although not attractive to the end user, this approach allows introduction of new CAs into the device without the user control.
- **CA introduction:** An existing CA digitally signs (validates) new CA information. Although much more attractive to the user, this scheme requires confidence on the part of one CA that the policies of the CA being introduced are appropriate. In some cases, liability issues may hinder this type of CA cooperation.
- **Rollover:** A variation on the CA introduction scheme allows the new CA to be identical to the old one.
- **Other:** The specification allows other mechanisms to be used when appropriately secure facilities are available.

Although WPKI can be looked at as an optimization of the traditional IETF PKIX standards for the wireless environment, a number of special features have been found necessary as a result of the wireless environment. Particularly WPKI optimizes the PKI protocols, certificate formats, and cryptographic algorithms and keys.

WPKI uses the ASN.1 Basic Encoding Rules (BER) and Distinguished Encoding Rules (DER) used to handle PKI services for WML and WMLSCrypt (Wireless public-key infrastructure, 2003). WML and the signText function in WMLSCrypt provide significant savings when encoding and submitting PKI service requests compared to traditional PKI methods.

Functioning of the WAP PKI

The capability established in WTLS class 2 establishes the authentic identity of the gateway with which a client is communicating. Early implementations allow communication between the phone and a gateway and between the gateway and a server. In this model the client (phone) depends on the gateway to establish the identity of the server. A later version of the protocol implementation allows the server to obtain its certificate directly from the certificate authority and the ensuing session with the user is between the phone and the server (Open Mobile Alliance, 2004). The gateway remains in use for routing, but the session is between the client and the server with no

role for the gateway in authentication. Figure 7 illustrates both types of connection. First, the gateway communicates with CA through the PKI portal (solid lines in the figure). The CA provides the gateway public certificate to the gateway. Subsequently, the client communicates through the gateway to the server (dotted lines). Only the gateway has been authenticated. Later versions provide for end-to-end authentication: The gateway still obtains a certificate. However, the server also obtains a certificate from the CA (server public certificate) (dashed lines). The session proceeds between the client and the server with the gateway providing routing (dotted lines). The role of the gateway could be eliminated under this model.

LOOKING AHEAD

Expectations for Mobile Computing

It is hard not to think back to 1993 or 1994 when early Web pages were available and only a few people knew the basics of producing and deploying them. In the early years of the 2000s, the wireless Web is in a similar situation. Application development is necessary to drive demand which in turn will drive more development. E-commerce applications are core elements of the Web today and the security services that support them must be available on small handheld devices in addition to desktop and powerful portable computers. This is an area of active development with strong motivation for the service providers.

The Role of the Wireless Application Protocol

In June 2002, the WAP Forum became part of a larger collaboration of industries and standards bodies called the Open Mobile Alliance. They describe the formation as follows:

The foundation of the Open Mobile Alliance was created by consolidating the efforts of the supporters of the Open Mobile Architecture initiative and the WAP Forum. In addition, the Location Interoperability Forum (LIF), SyncML, MMS Interoperability Group (MMS-IOP), and Wireless Village, each focusing on mobile service enabler specifications, announced that they have signed a Memorandum of Understanding of their intent to consolidate with the Open Mobile Alliance.

Thus, the work of the WAP Forum continues with a larger context and a much larger degree of commitment from

the related industries. The role of these protocol efforts to join the industries that produce the client devices and those who produce the services and information sources will be crucial to the kind of open connectivity and roaming accessibility necessary to make the wireless Web as pervasive and important as the wired Web is today.

GLOSSARY

- Code Division Multiple Access** The basis of third-generation wireless transmission technologies.
- Datagram** A communication technique in which messages are broken into independent units that travel separately through network connections.
- Data Push** Access to the data is initiated by the provider, which pushes it toward the consumer.
- D-AMPS** Digital Advanced Mobile Phone Systems
- Gateway** An intermediate device that links incompatible communication systems.
- GSM** Global System for Mobile Communications
- iDEN** Integrated Dispatch Enhanced Network
- PDC** Personal Digital Cellular

INTRODUCTION

Wireless networks can be classified in many ways—based on mobility, topology, application, or coverage. For example, based on mobility, we may classify wireless networks as fixed, stationary, portable, or mobile. If we consider applications, we may look at wireless data networks and cellular voice networks. The topology of a wireless network may be based on a fixed infrastructure that enables mobile stations (MSs) to connect to the rest of the network or the topology may be ad hoc where MSs connect to one another in a peer-to-peer manner without assistance from a fixed infrastructure. The most popular classification is based on coverage—whether the wireless network provides service over a local area or a larger geographical region. *Wireless local area networks* (WLANs) typically cover areas ranging anywhere between parts of a building to a campus of an organization. *Wireless wide area networks* (WWANs) cover entire cities and even parts of a nation. Usually, WWANs provide lower data rates compared to WLANs and are more complex in architecture. The spectrum allocated to WWANs is typically licensed spectrum and there needs to be careful planning and deployment of WWANs. WLANs mostly form extensions to existing local area network (LAN) segments in organizations. They typically use unlicensed spectrum and as long as the interference is reasonable, they can be deployed by anyone, anywhere. Recently, WLANs are also being used to provide broadband Internet access in hotspots such as airports, cafes, and hotels.

There are several standards for WWANs and WLANs and they are primarily dependent on geography. The European Telecommunications Standards Institute (ETSI), based in France, is responsible for the standards activities in the European Union (EU) although these standards have been sometimes adopted in other parts of the world. In the United States, standards activities are

less centralized. There are many organizations involved in standards activities such as the Institute for Electrical and Electronic Engineers (IEEE), American National Standards Institute (ANSI), the Telecommunications Industry Association (TIA), and so on. Typically, a standard is created based on input from several industry groups and once such standards are approved, the International Standards Organization (ISO) often adopts these standards (see list of URLs for standards bodies). Many of the details in this article are derived from the IEEE 802.11 standards and information available on the IEEE 802.11 Web site.

Standards for wireless technologies have to deal with a gamut of different issues starting from the spectrum that can be used by this technology going up to defining entities in the system and the detailed protocols between them. In this article, we briefly look at wireless network standards in general and focus on one particular WLAN standard—namely the IEEE 802.11 standard.

Wireless Wide Area Network Standards

Standards for WWANs focus on cellular telephone systems and wireless data services as overlays on top of the cellular systems. It is common to consider generations of wireless systems each spanning approximately a decade. The first generation of WWANs (spanning the 1980s) employed analog modulation schemes and a common example that is still deployed in the United States is the *Advanced Mobile Phone System* (AMPS) (Pahlavan, 2002). The capacity limitations of the first generation WWANs resulted in development of digital alternatives in the late 1980s. During the 1990s, digital cellular systems (called the second generation) were deployed based on standards developed by ETSI in Europe and TIA in the United States. The standards based on time division multiple access (TDMA) were the global system for mobile (GSM)

Table 1 Summary of Some WWAN Standards¹

Standard	Standard Body	Spectrum (MHz)	Multiple Access	Primary Region
AMPS	TIA	824–849, Uplink 869–894, Downlink	FDMA	United States, Canada
IS-136	TIA	824–849, Uplink 869–894, Downlink	TDMA/FDMA	United States
IS-95	TIA	824–849, Uplink 869–894, Downlink	CDMA/FDMA	United States, Latin America, Asia
GSM	ETSI	890–915, Uplink 935–960, Downlink	TDMA/FDMA	Europe, Africa
CDPD	TIA	824–849, Uplink 869–894, Downlink	DSMA/TDMA	United States
GPRS	ETSI	890–915, Uplink 935–960, Downlink	Reservation/TDMA	Europe
cdma2000	3GPP2	824–849, Uplink 869–894, Downlink	CDMA	United States, Asia-Pacific
UMTS	3GPP	Varies	CDMA	Europe

¹Spectra allocated to different standards are only representative and are different in different countries.

communications and the TIA interim standard 136 (IS-136). The former is widely deployed in Europe and other parts of the world. The latter, also called the North American TDMA or digital AMPS, is deployed primarily in North America. The standard based on code division multiple access (CDMA) was designed by Qualcomm and standardized later by TIA and ANSI. It is commonly called the IS-95 standard although there are several modifications that have followed. CDMA has better robustness under harsh wireless conditions and interference and has the potential to offer a larger capacity. The third generation of cellular telephone systems is thus based on CDMA. There are two competing paths—one that is a migration from IS-95, called cdma2000, and another that is a migration from GSM, called Universal Mobile Telecommunications System (UMTS). The former is being standardized by a consortium of standards bodies called 3GPP2 and the latter by a second consortium called 3GPP. 3GPP stands for Third Generation Partnership Project.

Wireless data services were typically overlaid on the cellular systems already in place during the 1990s. There are several proprietary wireless data services. Two open standardized common data overlays are the Cellular Digital Packet Data (CDPD) that is overlaid on AMPS and the General Packet Radio Service (GPRS) that is overlaid on GSM. The former was standardized by the CDPD forum in 1995 and the latter by ETSI. CDPD standardization is now handled by the TIA. Wireless data services use different multiple access mechanisms over the air compared to voice services that are circuit switched (Salkintzis, 1999). CDPD makes use of a technique called digital sense multiple access (DSMA) on the uplink and TDMA on the downlink. GPRS makes use of reservation of time slots for multiple access. In the third-generation, packet data services are integrated with the cellular telephone service in the standard. Table 1 summarizes some of these WWAN standards.

Wireless Local Area Network Standards

Like WWANs, standards activities for WLANs have also evolved geographically with the ETSI's Broadband Radio Access Network (BRAN) working on High Performance Radio LAN or HIPERLAN standards in Europe and the IEEE on the 802.11 series in the United States. In Japan, the Multimedia Mobile Access Communications (MMAC) working group under the Association of Radio Industries and Businesses (ARIB) works on WLAN standards. The spectrum used by WLANs is mostly unlicensed spectrum although some systems use licensed spectrum as well. Unlike WWANs, the only commercially successful WLAN standard has been the IEEE 802.11. HIPERLAN/1 was standardized in the mid-1990s and supported complex multihop ad hoc networking. The medium access mechanism in HIPERLAN/1 (Wilkinson, 1995) was based on a form of carrier sense multiple access called Elimination-Yield Non-Preemptive Multiple Access (EY-NPMA). HIPERLAN/2 has adopted a physical layer that is very similar to IEEE 802.11a and a medium access mechanism based on reservation and TDMA. However, both these standards have not been adopted successfully in commercial products. Recently, there have been efforts to harmonize the standards activities of ETSI, IEEE 802.11, and MMAC. Table 2 summarizes some of the 802.11, HIPERLAN, and MMAC standards.

In the rest of this article, we consider primarily the IEEE 802.11 standard in some detail and also look at some related protocols for security.

INTRODUCTION TO THE IEEE 802.11 STANDARD

Within the IEEE, there are several standards activities carried on by different groups. The IEEE 802 LAN/MAN Standards Committee is responsible for local

Table 2 Summary of Some WLAN Standards

Standard	Standard Body	Spectrum	Data Rate	Primary Medium Access	Primary Region
IEEE 802.11, b, g	IEEE	2.4-GHz ISM bands	1, 2, 5.5, 11, up to Mbps	CSMA/CA ¹	North America
IEEE 802.11a	IEEE	5-GHz U-NII and ISM bands	Up to 54 Mbps	CSMA/CA	North America
HIPERLAN/1	ETSI	5-GHz bands	23 Mbps	EY/NPMA ²	Europe
HIPERLAN/2	ETSI	5-GHz bands	Up to 54 Mbps	TDMA Reservation	Europe
Wireless Access and WLAN	MMAC	5-GHz bands	20–25 Mbps	Wireless ATM	Japan

¹CSMA/CA, Carrier Sense Multiple Access with Collision Avoidance.

²EY-NPMA, Elimination Yield Non-Preemptive Multiple Access.

area network (LAN) standards and metropolitan area network (MAN) standards. Individual working groups are in charge of a variety of LAN/MAN standards of which the 802.11 working group is responsible for *wireless local area networking (WLAN) standards*.

The 802.11 standard (Crow, 1997), like most LAN standards, is concerned only with the lower two layers of the OSI stack, namely the physical (PHY) and medium access control (MAC) layers. The MAC and PHY layers operate under the IEEE 802.2 logical link control (LLC) layer that supports many other LAN protocols. In the case of wired LAN standards such as 802.3, there are several physical layers that correspond to the same MAC specifications. A good example is IEEE 802.3, which was originally designed for thick coaxial cable but was subsequently revised to include thin coaxial cable, a variety of twisted pair cables, and even fiber optic links. In the same way, the IEEE 802.11 standard specifies a common MAC protocol that is used over many different PHY standards. The PHY standards are the “base” IEEE 802.11 standard, the 802.11b and g standards and the 802.11a standard. The MAC protocol is based on carrier sense multiple access with collision avoidance (CSMA/CA). An optional polling mechanism called point coordination function (PCF) is also specified. In addition to the MAC and PHY layers, the IEEE 802.11 standard also specifies a *management plane* that transmits management messages over the medium and can be used by an administrator to tune the MAC and PHY layers. The MAC layer management entity (MLME) deals with management issues such as roaming and power conservation. The PHY layer management entity (PLME) assists in channel selection and interacts with the MLME. A station management entity (SME) handles the

**Figure 1:** Protocol stack of IEEE 802.11.

interaction between these management layers. Figure 1 shows the protocol stack associated with IEEE 802.11.

The base IEEE 802.11 standard specifies three different PHY layers—two using radio-frequency (RF) and one using infrared (IR) communications. The RF PHY layers are based on spread spectrum (SS), either direct sequence (DS) or frequency hopping (FH), whereas the IR PHY layer is based on pulse position modulation (PPM). Two different data rates are specified—1 and 2 Mbps for each of the three PHY layers. The RF physical layers are specified in the 2.4-GHz industrial, scientific, and medical (ISM) unlicensed frequency bands.

The IEEE 802.11b standard specifies the physical layer at 2.4 GHz for higher data rates—5.5 Mbps and 11 Mbps. The PHY layer makes use of a modulation scheme called complementary code keying (CCK). The transmission rate depends on the quality of the signal and it is backwards compatible with the DSSS based base-802.11 standard. Depending on the signal quality, the transmission rates could fall back to lower values. The 802.11g standard further increases the data rates to up to 54 Mbps in the 2.4-GHz ISM bands using orthogonal frequency division multiplexing (OFDM). The IEEE 802.11a standard (Kapp, 2002) deals with the PHY layer in the 5 GHz unlicensed national information infrastructure (U-NII) bands. Once again data rates up to 54 Mbps are specified in these bands with OFDM as the modulation technique. Depending on the PHY layer alternative, the frequency band is divided into several channels. Each channel supports the maximum data rate allowed by that PHY layer alternative.

In the next few sections, we discuss the IEEE 802.11 standard in a top-down manner. We first look at the topologies possible in IEEE 802.11 and also understand some of the management functions. We then take a detailed look at the MAC layer of 802.11 and discuss the different PHY layer alternatives. Once the basic operation of the 802.11 WLAN has been considered, it will be easier to delve into security issues in IEEE 802.11 and the recent ongoing activities to extend the standard further.

IEEE 802.11 WLAN OPERATIONS

The topology of an IEEE 802.11 WLAN can be one of two types—infrastructure or ad hoc (see Figure 2). In the infrastructure topology, an access point (AP) covers

Figure 2: Topologies in IEEE 802.11

a particular area called the basic service area (BSA) and mobile stations (MSs) communicate with each other or with the Internet through the AP (Crow, 1997). The AP is connected to a LAN segment and forms the *point of access* to the network. All communications go through the AP. So a MS that wants to communicate with another MS first sends the message to the AP. The AP looks at the destination and sends it to the second MS. The AP along with all the MSs associated with it is called a basic service set (BSS). In the ad hoc topology (also called independent BSS or IBSS), MSs that are in range of each other can communicate directly with one another without a wired infrastructure. However, it is not possible for a MS to forward packets meant for another MS not in the range of the source MS. Figure 2 shows schematics of both topologies. MSs and APs are identified by a 48-bit MAC address that is similar to other MAC addresses at the link layer. In an infrastructure topology, the MAC address of the AP also forms the BSSID, a unique identifier of the BSS.

If we assume that the range of communication of any WLAN device, be it a MS or an AP is a region of radius R , we can look at the comparative advantages of the two topologies. A MS can communicate with another MS that is up to $2R$ away using an AP provided both MSs are within a distance R of the AP. The cost here is the additional transmission from the AP to the destination. In the ad hoc topology, a destination MS cannot be more than a distance R from the source MS. The advantage is that the information can be received in one hop.

Extending the Coverage in Infrastructure Topology

Depending on the environment in which it is deployed and the transmit powers that are used, an AP can cover a region with a radius anywhere between 30 and 250 feet. To cover a building or a campus, it often becomes necessary to deploy multiple APs that are connected to the same LAN. A group of such APs and the member mobile stations is called an *extended service set* (ESS). The coverage area is called the extended service area (ESA). The wired backbone that connects the different APs along with services that enable the ESS is called the *distribution system*. The distribution system, for example, supports roaming between APs so that MSs can access the network over a wider coverage area than before. This is similar to cellular telephone systems where multiple base stations provide coverage to a region, each base station covering only a cell.

Network Operations in an Infrastructure Topology

When a MS is powered up and configured to operate in an infrastructure topology, it can perform a passive scan or an active scan. In the case of a passive scan, the MS simply scans the different channels to detect the existence of a BSS. The existence of a BSS can be detected through *beacon* frames that are broadcast by APs pseudoperiodically. The reason why it is called pseudoperiodic is that the beacon is supposed to be transmitted regularly at certain intervals. However, the AP cannot preempt an ongoing transmission to transmit a beacon. When we discuss the MAC layer, we will see that any device has to wait for the medium to be free before transmitting a frame. If the medium is busy, the AP will transmit the beacon after the medium becomes free in which case, the beacon may not be precisely periodic. The beacon is a management frame that announces the existence of a network. It contains information about the network—the BSSID and the capabilities of the network (the PHY alternatives it supports, if security is mandatory, whether the MAC layer supports polling, the interval at which beacons are transmitted, timing parameters, and so on). The beacon is similar to certain control channels in cellular telephone systems (for instance, the Broadcast Control Channel—BCCH in GSM). The MS also performs signal strength measurements on the beacon frame. In the case of an active scan, the MS already knows the ID of the network that it wants to connect to. In this case, the MS sends a *probe request* frame on each channel. APs that hear the probe request respond with a *probe response* frame that is similar in nature to the beacon. In either case, the MS can create a scan report that provides it with information about the available BSSs, their capabilities, their channels, timing parameters, and other information. The MS makes use of this information to determine a compatible network that it can associate itself with.

To associate itself with an AP, the MS must authenticate itself if this is part of the capability of the network and we will look at this in a later section. Otherwise, as long as the MS satisfies the announced capabilities of the network, it can send an *association request* frame to the AP. The association request informs the AP of the intention of the MS to join the network and it also provides additional information about the MS such as its MAC address, how often it will listen to the beacon (called the *listen interval*), the supported data rates and so on. If the AP is satisfied with the capabilities of the MS, it will reply with

an *association response* frame. In this message, the MS is given an association ID and this frame confirms that the MS is now able to access the network.

If a MS moves across BSSs or if it moves out of coverage and returns to the BSA of an AP, it will have to reassociate itself with the AP. For this purpose, it will use a *reassociation request* frame similar in form to the association request frame, except that the MAC address of the old AP will be included in the frame. The AP will respond with a *reassociation response* frame. A MS moving from one BSS to another will have to detect the drop in signal strength from the old AP and detect the beacon of the new AP before the reassociation request. It could also use a probe request message instead of detecting the beacon from the new AP.

Power management is an important component of network operations in an IEEE 802.11 WLAN. When MSs have no frames to send, they can enter a sleep mode to conserve power. If a MS is sleeping when frames arrive at an AP for it, the AP will buffer such frames. A sleeping MS wakes up periodically and listens to the beacon frames. How often it wakes up is specified by the listen interval mentioned earlier. The beacon frame also contains a field called the traffic indication map (TIM). This field contains information about whether packets are buffered in the AP for a given MS. If a MS detects that it has some frames waiting for it, it can wake up from the sleep mode and receive those frames before going back to sleep. The MS uses a *power-save poll* frame to indicate to the AP that it is ready to receive buffered frames.

If the MS chooses to leave the network or shutdown, it will send a *dissociation* frame to the AP. This frame will terminate the association between the MS and the network enabling the network to free resources that were previously reserved for the MS (such as the association ID, buffer space, etc.).

Network Operations in an Ad Hoc Topology

In an ad hoc topology, there is no fixed AP to coordinate transmissions and define the BSS. A MS that operates in ad hoc mode will power up and scan the channels to detect beacons from other MSs that may be in the vicinity and that may have set up an IBSS. If it does detect

beacons, it may declare its own network. If it detects a beacon, then the MS can join the IBSS in a manner similar to the process in the infrastructure topology. MSs in an IBSS may choose to rotate the responsibility of transmitting a beacon. Power management works in a similar way, except that the source MS itself has to send an announcement traffic indication map (ATIM) frame to the recipient MS.

THE IEEE 802.11 MAC LAYER

MSs in an IEEE 802.11 network have to share the transmission medium, which is air. If two MSs transmit at the same time and the transmissions are both in range of the destination, they may collide resulting in the frames being lost. The MAC layer is responsible for controlling access to the medium and ensuring that MSs can access the medium in a fair manner with minimal collisions. The medium access mechanism is based on carrier sense multiple access but there is no collision detection like the wired equivalent LAN standard (IEEE 802.3). Collisions are extremely hard to detect in RF because of the dynamic nature of the channel. Detecting collisions also incurs difficulties in hardware implementation because an MS has to be transmitting and receiving at the same time. Instead, the strategy adopted is to avoid collisions to the extent possible. In IEEE 802.11, there are two types of carrier sensing—physical sensing of energy in the medium and virtual sensing. Virtual sensing is implemented by decoding a duration field in the 802.11 frame that allows a MS to know the time for which a frame will last. This time is stored in a *network allocation vector* (NAV) that counts down to zero to indicate when the medium is free again. To illustrate the IEEE 802.11 MAC layer, we use the ad hoc topology as an example. However, the procedures are identical in an infrastructure topology as well.

The Distributed Coordination Function

We first describe the basic medium access process in IEEE 802.11 called the distributed coordination function (DCF). Consider Figure 3 that shows the basic method for accessing the medium in IEEE 802.11. A MS will initially sense the channel before transmission. If the medium is

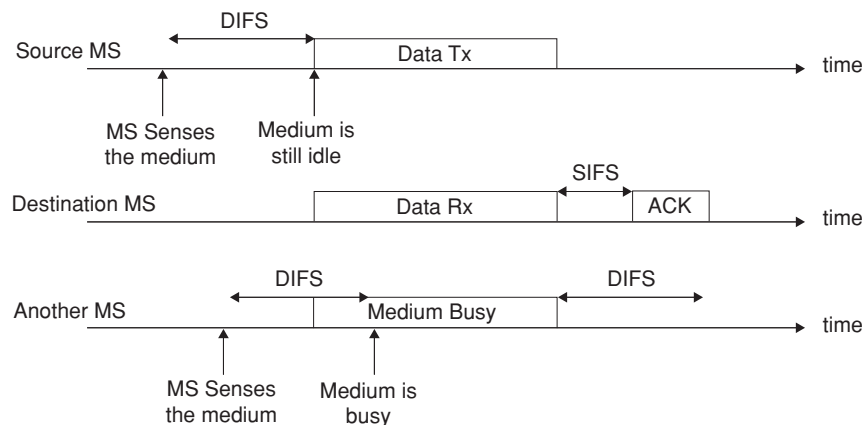

Figure 3: Basic medium access in IEEE 802.11.

Figure 4: Backoff process in IEEE 802.11.

free, the MS will continuously monitor the medium for a period of time called the *distributed coordination function* (DCF) *interframe space* (IFS) or DIFS. If the medium is still idle after DIFS, then the MS can transmit its frame without waiting. Otherwise, the MS will enter a back off process. The rationale is that if another MS senses the medium after the first MS, it will also wait for DIFS. However, before a time DIFS expires, the first MS would have started its transmission. Upon hearing the transmission, the second MS will have to back off. The wireless medium is harsh and unreliable and hence all transmissions are acknowledged. The destination of the frame will send an acknowledgement (ACK) back to the source if the frame is successfully received as follows. It will wait for a time called the *short interframe space* (SIFS) and transmits the ACK. The SIFS value is smaller than the DIFS value. All IFS values depend on the physical layer alternative. Thus, any other MS that senses the channel as idle after the original frame was transmitted will still be waiting and ACK frames have priority over their transmissions. To maintain fairness and avoid collisions, the MS that senses the medium as free for a time DIFS and transmits a frame will have to enter the backoff process if it wants to transmit another frame immediately. The exception is when it is transmitting one frame in many fragments. In such a case, the MS can indicate the number of fragments in the first frame to be transmitted and occupy the channel till the frame is completely transmitted.

The backoff process works as follows. Once an MS enters the backoff process, it picks a value called the *backoff interval* (BI) that is a random value uniformly distributed between zero and a number called the *contention window* (CW). The MS will then monitor the medium. When the medium is free for at least a time DIFS, the MS will start counting down from the BI value as long as the medium is free. The counter is decremented every so often (called a slot). If the medium is sensed as occupied before the counter goes down to zero, the MS will freeze the counter and continue to monitor the medium. As soon the counter becomes zero, the MS can transmit its frame. This process is shown in Figure 4.

The IEEE 802.11 MAC supports *binary exponential backoff* as in IEEE 802.3. Initially, the CW is maintained at a value called CW_{min} , which is typically $2^5 - 1 = 31$ slots. So the BI will be uniformly distributed between 0 and 31 slots. If a packet is not successfully transmitted (this could be because of collisions or a channel error), the value of CW is essentially doubled. The MS will now pick a BI value that is uniformly distributed between 0 and $2^6 - 1 = 63$ slots. This process can be continued till CW reaches a value that is CW_{max} (usually 1023 slots). The

rationale behind this approach is as follows. If there are many MSs contending for the medium, it is likely that one or more MSs may pick the same BI value. Their transmissions will then collide. By increasing the value of CW, it is likely that this probability will go down, thereby reducing collisions.

Frames may be lost because of channel errors or collisions. A positive ACK from the destination is necessary to ensure that the frame has been successfully received. In IEEE 802.11, each MS maintains retry counters that are incremented if no ACKs are received. After a retry threshold is reached, the frame is discarded as being undeliverable.

The Hidden Terminal Problem and Optional Mechanism

In wireless networks that use carrier sensing, there is a unique problem called the hidden terminal problem. Suppose all MSs are identical and have a transmission and reception range of R as shown in Figure 5.

The transmission from MS-A can be heard by MS-C but not MS-B. So when MS-A is transmitting a frame to MS-C, MS-B will not sense the channel as busy and MS-A is *hidden* from MS-B. If both MS-A and MS-B transmit frames to MS-C at the same time, the frames will collide. This problem is called the hidden terminal problem. There is a dual problem called the exposed terminal problem. In this case, MS-A is transmitting a frame to MS-D. This transmission is heard by MS-C, which then backs off. However, MS-C could have transmitted a frame to MS-B and the two transmissions would not interfere or collide. In this case, MS-A is called an *exposed terminal*. Both hidden and exposed terminals cause a loss of throughput.

Figure 5: Illustrating the hidden and exposed terminal problems.

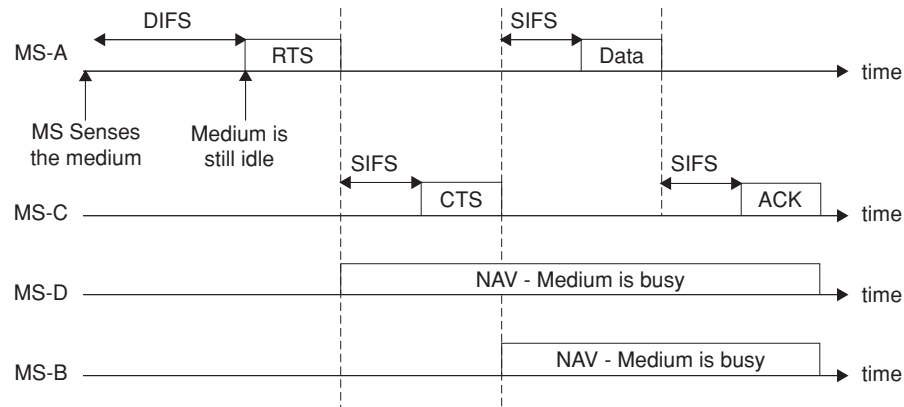

Figure 6: Operation of the RTS-CTS mechanism.

To reduce the possibility of collisions because of the hidden terminal problem, the IEEE 802.11 MAC has an optional mechanism at the MAC layer shown in Figure 6. Suppose MS-A wants to transmit a frame to MS-C. It will first transmit a short frame called the *Request-to-Send* (RTS) frame. The RTS frame is heard in the transmission range of MS-A and includes MS-C and MS-D but not MS-B. Both MS-C and MS-D are alerted to the fact that MS-A intends to transmit a frame and they will not attempt to simultaneously use the medium. This is achieved by the virtual carrier sensing process that sets the NAV to a value equal to the time it will take to successfully complete the exchange of frames. In response to the RTS frame, MS-C will send a *Clear-to-Send* (CTS) frame that will be heard by all MSs in its transmission range. This includes MS-B and MS-A but not MS-D. The CTS frame lets MS-A know that MS-C is ready to receive the data frame. It also alerts MS-B to the fact that there will be a transmission from some MS to MS-C. Consequently, MS-B will defer any frames that it wishes to transmit in anticipation of the completion of the communication to MS-C. This way, even though MS-B is outside the transmission range of MS-A, the CTS message can be used to *extend* the carrier sensing range thereby reducing the hidden terminal problem. Of course, it is quite possible that the RTS frame itself collided with a transmission from MS-B. In such a case, both MS-A and MS-B will have to enter the backoff process and retransmit their frames.

The RTS-CTS mechanism can be controlled in IEEE 802.11 by using an RTS threshold. All unicast and management frames larger than this threshold will always be transmitted using RTS-CTS. By setting this value to 0, all frames will use RTS-CTS. The default value that disables RTS-CTS for all packets is 2347. When RTS-CTS signals are used, the CTS frame is transmitted by the destination MS after waiting simply for a time equal to SIFS. This way, the CTS frame has priority compared to all other transmissions that have to wait for at least a time DIFS and perhaps an additional waiting time in backoff. Using the RTS-CTS signals reduces the throughput of a WLAN, but it may be essential to use this in dense environments.

The Point Coordination Function

One consequence of using CSMA/CA as described above with DCF is that it is impossible to have any bounds

on the delay or jitter suffered by frames. Depending on the traffic load and the BI values that are picked, a frame may be transmitted instantaneously or it may have to be buffered until the medium becomes free. For real-time applications such as voice or multimedia, this can result in performance degradation especially when strict delay bounds are necessary. To provide some bounds on the delay, an optional MAC mechanism called the *point coordination function* (PCF) is part of the IEEE 802.11 standard (Crow, 1997). PCF provides contention-free access to frames using a polling mechanism described below.

The process starts when the AP captures the medium by sending a beacon frame after it is idle for a time called the *PCF interframe space* (PIFS). The PIFS is smaller than the DIFS and larger than SIFS. In the beacon frame, the AP, also called the point coordinator, announces a *contention-free period* (CFP), where the usual DCF operation will be preempted. All MSs that use only DCF will set a NAV to indicate that the medium will be busy for the duration of the CFP. The AP maintains a list of MSs that need to be polled during the CFP. MSs get onto the polling list when they first associate with the AP using the association request. The AP then polls each MS on the list for data. The polls are sent after a time SIFS and the ACKs on the poll and any associated data will be transmitted by the corresponding MS also after a time SIFS. If there is no response from a MS to a poll, the AP waits for a time PIFS before it sends the next poll frame or data. The AP can also send management frames whenever it chooses within the CFP. An example of PCF operations is shown in Figure 7.

The AP indicates the culmination of the CFP via a message called CFP-End. This is a broadcast frame to all MSs and frees the NAV in MSs that are only DCF based. Following the CFP, a contention period starts. In this period, it must be possible for a MS to transmit at least one maximum-length frame using DCF and receive an ACK. The CFP can be resumed after completion of the contention period. The PCF mechanism is optional in IEEE 802.11. Most commercial systems deployed today do not support PCF and real-time services do not have very good support in WLANs today. Note that polling has a lot of overhead especially if MSs do not have any frames to send when they are polled.

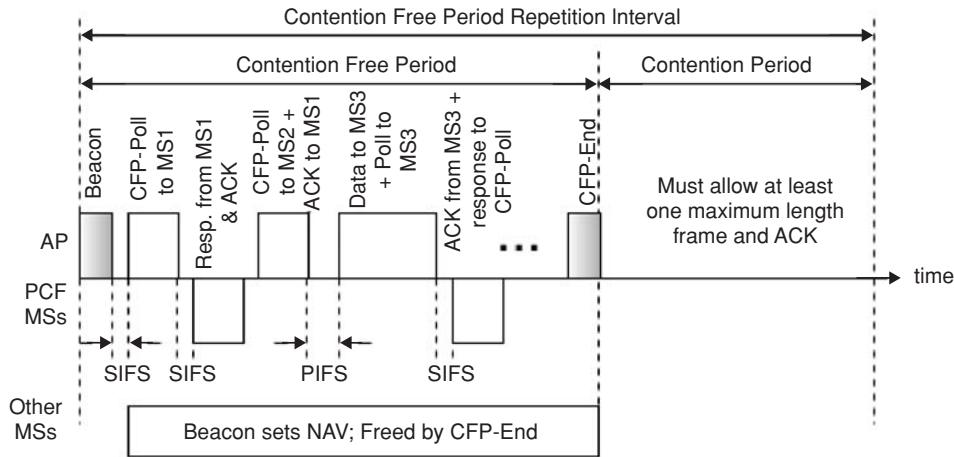

Figure 7: Operation of the PCF.

MAC Frame Formats

It is not the goal of this chapter to define the different frame formats of an IEEE 802.11 MAC frame and discuss the fields in great detail. However, some examples to illustrate the MAC frame formats are shown. Figure 8 shows the general format of a MAC frame. The most significant bit is last (right-most) and the bits are transmitted from left to right. The *frame control* field has two bytes and is composed of many fields. It carries information such as the protocol version, the type of frame [management (probe request, association, authentication, and so on), control (RTS, CTS, and so on), or data (pure data, CFP poll and data, null, and so on)], the number of retries, and whether the frame is encrypted (discussed later). The duration field is important to set the NAV during virtual carrier sensing.

There can be up to four address fields in the frame (Gast, 2002). The addresses can be different depending on the type of frame. Common addresses used are the source and destination addresses, the receiver address if the destination is different from the receiver (e.g., the receiver is the AP, but the destination is a wired node on the LAN segment), the transmitter address (once again, if the transmitter is different from the source, it is the AP), and the BSSID. The sequence control field is used in case there is fragmentation of frames. The frame body carries the payload from upper layers and the frame check sequence is a 32-bit cyclic redundancy check used to verify the integrity of the frame at the receiver. The frame format

in Figure 8 is used in an infrastructure topology. In an IBSS, only three address fields are used.

The RTS and CTS frames are very short frames (20 and 14 bytes, respectively) and are shown in Figure 9. The ACK frames are very similar to the CTS frame.

Figure 10 illustrates the frame body of the beacon frame. The time stamp allows MSs to synchronize to a BSS. The beacon interval says how often the beacon can be expected to be heard. It is typically 100 ms but could be changed by an administrator. The capability information (2 bytes) provides information about the topology (whether infrastructure or ad hoc), whether encryption is mandatory, and whether additional features are supported. One such feature is *channel agility*, whereby the AP hops to different channels after a predetermined amount of time.

We have not yet discussed PHY layer alternatives. The parameter sets in the beacon provide information about the PHY layer parameters that are necessary to join the network. For instance, if frequency hopping (FH) is used, the FH parameter set will specify the hopping pattern. The traffic indication map (TIM) field is used to support MSs that may be sleeping as described earlier.

THE IEEE 802.11 PHYSICAL LAYER ALTERNATIVES

The IEEE 802.11 standards body has standardized several different PHY layer alternatives. When it was first

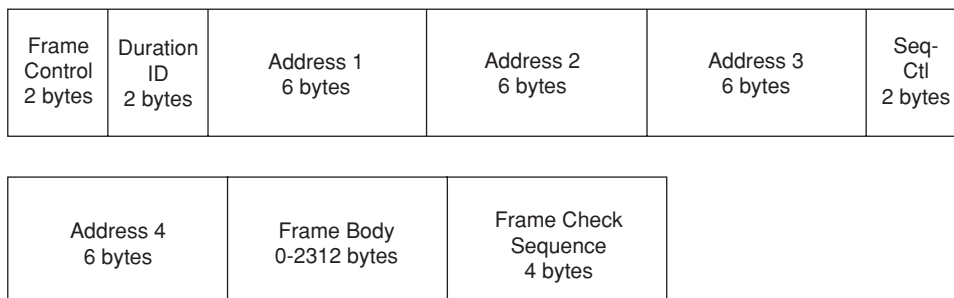

Figure 8: General format of a MAC frame.

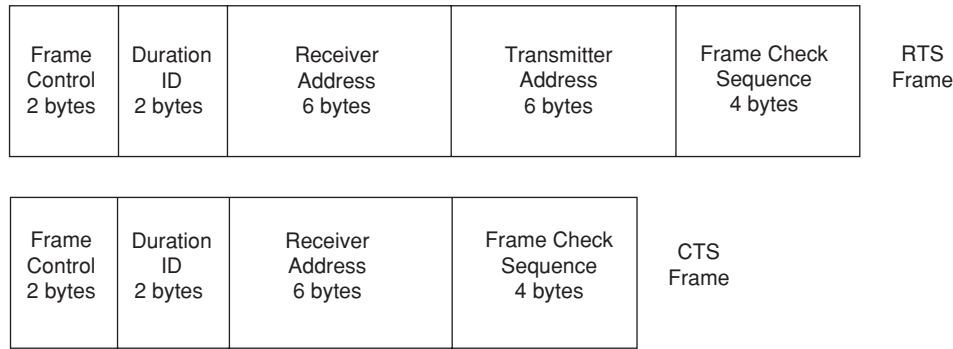

Figure 9: RTS and CTS frame formats.

standardized in 1997, there were three PHY layer options. We will call these options as the “base” IEEE 802.11 PHY layer alternatives. The IEEE 802.11b supports up to 11 Mbps in the 2.4-GHz ISM bands, the IEEE 802.11g standard supports up to 54 Mbps in the 2.4-GHz ISM bands and the IEEE 802.11a standard supports up to 54 Mbps in the 5-GHz U-NII bands. Before we discuss these alternatives, let us look at the PHY layer in IEEE 802.11.

The PHY layer in IEEE 802.11 is broken up into two sublayers—the *physical layer convergence protocol (PLCP)* and the *physical medium dependent (PMD)* layers. The PLCP includes a function that adapts the underlying medium dependent capabilities to the MAC level requirements. The PLCP would, for instance, add some additional fields to the frame to enable synchronization at the physical layer. The PMD actually determines how information bits are transmitted over the medium.

The Base IEEE 802.11 Standard

The base IEEE 802.11 standard specifies three different PHY layer alternatives. Two of these use RF transmissions in the 2.4-GHz ISM bands and one uses IR.

The FH Option

The first option for transmission in the 2.4-GHz ISM bands makes use of frequency hopping spread spectrum (FHSS) (Pahlavan, 2002). The entire band is divided into 1-MHz-wide channels and the specification makes it important to confine 99% of the energy to one such channel during transmission to reduce interference to the other channels. These restrictions are also because of the rules imposed by the Federal Communications Commission (FCC) in the United States. The standard specifies 95 such 1-MHz-wide channels and they are numbered accordingly. In the United States, only 79 of these channels are allowed. Devices that use the FH option hop between these channels when transmitting frames. The dwell time in each channel is approximately 0.4 s. The

hop sequences (the channel hopping pattern) depends on mathematical functions. An example hopping pattern is {3, 26, 65, 11, 46, 19, 74, ...}. In the United States, each set of hopping patterns can have at most 26 different channels. This means that it is possible to create three *orthogonal* hopping sets (because there are 79 channels in the United States). If three APs use these three orthogonal hopping sets, there will be no interference between these networks. The modulation scheme used with FHSS is called *Gaussian frequency shift keying (GFSK)*. This modulation scheme makes use of the frequency information to encode data. It is possible to use either two frequencies within the channel or four frequencies within the channel. In the former case, the data rate will be 1 Mbps and in the latter case, the data rate will be 2 Mbps. The advantage of the FHSS system is that the receivers are less complex to implement. The PLCP for the FHSS PMD introduces an 80-bit field for synchronization, a frame delimiter, and some fields to indicate the data rate. Depending on this field, the data rate can be modified in steps of 500 kbps from 1 to 4.5 Mbps. However, the standard supports only 1 and 2 Mbps. The values of SIFS and the slot for backoff in this option are 28 and 50 μs respectively.

The DS Option

The direct sequence spread spectrum (DSSS) modulation technique has been the most popular commercial implementation of IEEE 802.11. DSSS has some inherent advantages in multipath channels and can increase the coverage of an AP for this reason (Tuch, 1991). We briefly discuss the features of this PMD layer.

In a DSSS system, the data stream is “chipped” into several narrower pulses (chips), thereby increasing the occupied spectrum of the transmitted signal. One common way of doing this is to multiply the data stream (typically a series of positive and negative rectangular pulses) by a spreading signal (typically another series of positive and negative rectangular pulses, but with much narrower

Time Stamp 8 bytes	Beacon Interval 2 bytes	Capab. Info. 2 bytes	SSID Variable	FH Parameter Set 7 bytes	DS Param Set 2 bytes	CF Parameter Set 8 bytes	IBSS Parameter Set 4 bytes	TIM Var.
-----------------------	----------------------------	-------------------------	------------------	-----------------------------	-------------------------	-----------------------------	-------------------------------	-------------

Figure 11: (a) Direct sequence spread spectrum; (b) autocorrelation of the Barker pulse.

pulses than the data stream). Whereas the data stream is random and depends on what needs to be transmitted, the spreading signal is deterministic. Figure 11(a) shows an example where the data stream $d(t)$ is multiplied by a spreading signal $a(t)$ to produce a signal $s(t)$ that is then modulated over an RF carrier. In this figure, 11 narrow pulses are contained within one broad data pulse. The pulses could have a positive (+) or negative (−) amplitude. This results in the bandwidth expanding by a factor of 11 and this is also called as the *processing gain*. The pattern of pulses in the spreading signal is $\{+, +, +, -, -, -, +, -, -, +, -\}$. This pattern is used in the IEEE 802.11 standard and it is called as a Barker sequence. The interesting property of the Barker sequence is that its autocorrelation has a very sharp peak and very narrow sidelobes as shown in Figure 11(b). Because of this property, it is possible for a receiver to reject interference from multipath signals and recover information robustly in a harsh wireless environment. The Barker sequence with differential binary phase shift keying (DBPSK) is used for data rates of 1 Mbps and the Barker sequence with differential quadrature phase shift keying (DQPSK) is used for data rates of 2 Mbps. In either case, the chip rate is 11 Mcps.

Unlike FHSS, a signal carrying 2 Mbps now occupies a bandwidth that is as large as 25 MHz. In the IEEE 802.11 standard, 14 channels are specified for the DSSS PMD. Channel 1 is at 2.412 GHz, channel 2 at 2.417 GHz, and so on. Only the first 11 channels are available for use in the United States. Figure 12 shows the channelization in the United States. Because each channel occupies roughly a 25-MHz bandwidth and the channel separation is only 5 MHz, there is significant overlap between channels. If two WLANs in the same vicinity were to use adjacent channels, there would be severe interference and throughput degradation. In the United States there are three *orthogonal* channels—channels 1, 6, and 11—that can be deployed without interference.

The PLCP sublayer once again introduces some fields for synchronization (128 bits), frame delimiting, and error checking. The PLCP header and preamble are always transmitted at 1 Mbps using DBPSK. The rest of the packet is transmitted using either DBPSK or DQPSK, depending on the data rate. The values of SIFS and the slot for backoff in this option are 10 and 20 μs respectively.

The IR Option

The third option in IEEE 802.11 is to use IR for transmission (Valadas, 1998). The spectrum occupied by the IR transmission is at wavelengths between 850 and 950 nm. The technique used for transmission is diffused infrared; that is, communications are omnidirectional. The range specified is around 20 m, but the transmissions cannot cross through physical obstacles. The modulation scheme used is pulse position modulation (PPM). A data rate of 1 Mbps is supported using 16-PPM and a data rate of 2 Mbps is supported using 4-PPM.

The IEEE 802.11b and 802.11g Standards

The DS option for IEEE 802.11, although successful, consumed a lot of bandwidth for the given data rate. The chip rate is 11 Mcps, but the maximum data rate is 2 Mbps. That is, one Barker sequence of 11 chips, transmitted every microsecond, can at most carry 2 bits of information. To increase the data rate, the IEEE 802.11b standard adopted a slightly different method. Instead of transmitting one 11-chip sequence every microsecond, with IEEE 802.11b, the device transmits one 8-chip codeword every 0.727 μs . Each 8-chip codeword can carry up to 8 bits of information for a maximum data rate of $8/(0.727 \times 10^{-6}) = 11 \text{ Mbps}$. If the codeword carries only 4 bits of information, the data rate will be 5.5 Mbps. The codewords are derived from a technique called *complementary code keying* (CCK) (Halford, 1999).

CCK works as follows for the case when 8 bits are mapped into an 8-chip codeword. The incoming data

Figure 12: Channelization for IEEE 802.11 DS option.

stream is broken up into units of 8 bits. Suppose the least significant bit is d_0 and the most significant bit is d_7 . Then, four phases are defined for each pair of bits as shown in the first two columns of Table 3. Depending on what the bits are, the phases then take on a value as shown in the third and fourth columns in Table 3. For example, if $d_5 = 0$ and $d_4 = 1$, then the phase $\varphi_3 = \pi$. Once the phases are determined, the 8-chip codeword is given by the following vector:

$$C = \left\{ \begin{matrix} e^{j(\varphi_1+\varphi_2+\varphi_3+\varphi_4)}, e^{j(\varphi_1+\varphi_3+\varphi_4)}, e^{j(\varphi_1+\varphi_2+\varphi_4)}, -e^{j(\varphi_1+\varphi_4)}, \\ e^{j(\varphi_1+\varphi_2+\varphi_3)}, e^{j(\varphi_1+\varphi_3)}, -e^{j(\varphi_1+\varphi_2)}, e^{j(\varphi_1)} \end{matrix} \right\}.$$

This vector has elements that belong to the set $\{+1, -1, +j, -j\}$, where j is the square root of -1 . These four elements can be mapped in RF to the phase of the carrier and the receiver can decode this phase information to recover the data bits (Pahlavan, 2002).

The advantage of CCK is that it maintains the channelization of IEEE 802.11b while increasing the data rate by a factor of 5. CCK is also fairly robust to the degradations caused by multipath in the wireless environment. The values of SIFS and the slot for backoff in this option are 10 and 20 μ s respectively. IEEE 802.11b also has an optional modulation method called packet binary convolutional coding (PBCC) that is not widely implemented.

The IEEE 802.11g standard maintains backwards compatibility with IEEE 802.11b and IEEE 802.11 DS options by including some mandatory and optional components. It specifies OFDM and CCK as the mandatory modulation schemes with a data rate of 24 Mbps as the maximum mandatory data rate. It also provides for optional higher data rates of 36, 48, and 54 Mbps. OFDM is the same

modulation scheme that is used in IEEE 802.11a and we discuss it below.

The IEEE 802.11a Standard

One of the primary problems for huge data rates in wireless channels is what is called the coherence bandwidth of the wireless channel caused by multipath dispersion. The coherence bandwidth limits the maximum data rate of the channel to that which can be supported within this bandwidth. To overcome this limitation, we can send data in several subchannels so that many of them will get through correctly. Using several subchannels and reducing the data rate on each channel increases the symbol duration in each channel. If the symbol duration in each channel is larger than the multipath dispersion, errors will be smaller and it will be possible to support larger data rates. This principle can be exploited while maintaining bandwidth efficiency using a fairly old technique called OFDM. OFDM has been used in digital subscriber lines (DSL) as well to overcome the frequency variations over copper. OFDM enables spacing carriers (subchannels) as closely as possible and implementing the system completely in digital eliminating analog components to the extent possible. OFDM (Kapp, 2002) is used as the physical layer in IEEE 802.11a, HIPERLAN/2, and IEEE 802.11g.

IEEE 802.11a specifies eight 20-MHz channels (van Nee, 1999). As shown in Figure 13, several subchannels are created in OFDM using orthogonal carriers in each channel. Fifty-two subchannels are specified for each channel with a bandwidth of approximately 300 kHz each. Forty-eight subchannels are used for data transmission and four are used as pilot channels for synchronization. One OFDM symbol (consisting of the sum of the symbols on all carriers) lasts for 4 μ s and carries anywhere between 48 and 288 coded bits. For example, at 54 Mbps, the OFDM symbol has 216 data symbols. With a code rate of 3/4, the number of coded bits per symbol will be $4 \times 216/3 = 288$. This is possible by using different modulation schemes—ranging from binary phase shift keying, where we have 1 bit per subchannel, to more complex modulation schemes, such as quadrature amplitude

Table 3 Mapping for CCK

Dibit	Phase Parameter	Dibit (d_{i+1}, d_i)	Phase
(d_1, d_0)	φ_1	(0,0)	0
(d_3, d_2)	φ_2	(0,1)	π
(d_5, d_4)	φ_3	(1,0)	$\pi/2$
(d_7, d_6)	φ_4	(1,1)	$-\pi/2$

Figure 13: Orthogonal carriers in OFDM.

modulation (QAM). Error control coding also plays an important role in determining the data rate. Table 4 summarizes some features of the different supported data rates.

The PLCP in the case of 802.11a is a bit different in that there is no synchronization field. A rate field with 4 bits indicates the data rate that is being transmitted. This field is shown in Table 4 for different data rates. The preamble and header are always modulated using BPSK (lower data rates). The values of SIFS and the slot for backoff in this option are 16 and 9 μ s respectively.

Summary of Physical Layer Alternatives

Table 5 summarizes the different PHY layer alternatives in IEEE 802.11.

SECURITY ISSUES AND IMPLEMENTATION IN IEEE 802.11

Security in wireless networks is an important problem, especially because it is extremely difficult to contain radio signals within a protected perimeter (Edney, 2004). Anyone can listen to radio signals and anyone can also potentially inject signals into the network. Typically, in any network wireless or wired, it is common to deploy security features or services such as confidentiality, entity authentication, data authentication and integrity and

so on to protect against security threats (Stinson, 2002). The IEEE 802.11 standard has some mechanisms to provide confidentiality, integrity, and authentication at the link level. All data that leave the 802.11 link will not be protected. For instance, a MS communicating with an AP can have all its IEEE 802.11 frames that are on the air protected. Once the AP receives the frame, all protection is removed before it is transmitted on the distribution system. So additional security at the higher layers [such as IPSec or the Secure Sockets Layer (SSL)] may be required for some applications if the payload needs to be secure.

The original mechanism for providing confidentiality and authentication in IEEE 802.11 is called *wired equivalent privacy* (WEP) (Gast, 2002). Over the past few years, several attacks on WEP have been published in the literature. WEP makes use of the RC4 stream cipher with 40-bit keys (although there are options to use 128-bit keys in most commercial products today). Both the implementation of WEP and the RC4 algorithm itself have vulnerabilities that have rendered WEP nonsecure for today's applications. WEP was initially proposed in the standard as a self-synchronizing, exportable, efficient option. Although it does satisfy these three properties, its security has left much to be desired.

In what follows we discuss the original implementation of security in IEEE 802.11 and discuss enhancements that have been recently proposed.

Table 4 Data Rates and Associated Parameters in IEEE 802.11a

Data Rate (Mbps)	Modulation	Code Rate	Data Bits/Symbol	Coded Bits/Subchannel	PLCP Rate Field
6	BPSK	1/2	24	1	1101
9	BPSK	3/4	36	1	1111
12	QPSK	1/2	48	2	0101
18	QPSK	3/4	72	2	0111
24	16-QAM	1/2	96	4	1001
36	16-QAM	3/4	144	4	1011
48	64-QAM	2/3	192	6	0001
54	64-QAM	3/4	216	6	0011

Table 5 Summary of PHY Alternatives in IEEE 802.11

Standard	U.S. Spectrum (GHz)	Data Rates	Modulation Scheme
Base IEEE 802.11	2.402–2.479	1, 2 Mbps	GFSK, FHSS
	2.402–2.479	1, 2 Mbps	B/QPSK, DSSS
	850–950 nm	1, 2 Mbps	PPM, IR
802.11a	5.15–5.35,	6–54 Mbps	OFDM
	5.725–5.825		
802.11b	2.402–2.479	1, 2, 5.5, 11 Mbps	CCK
802.11g	2.402–2.479	1–54 Mbps	OFDM, CCK

Entity Authentication in IEEE 802.11

The mandatory entity authentication mechanism in IEEE 802.11 is called *open system authentication*. In this case, there is no real authentication. If one IEEE 802.11 device sends a frame to another, it is implicitly accepted. For example, a MS may simply send a frame to the AP choosing “open system” as the authentication algorithm (authentication algorithm = 0). The AP will simply accept it if open system access is allowed and send a response. From this transaction, the AP will obtain the MAC address of the MS for communication purposes.

A better authentication procedure is called *shared key authentication* where WEP is implemented (Gast, 2002). If the network is using WEP, shared key authentication is mandatory. The assumption is that all devices in the network share a secret key. A MS will send a frame for authentication with sequence number 0, the authentication algorithm set to 1 (to indicate shared key authentication). The AP will then send a challenge message (128 bits) in clear text to the MS along with its response. The MS will respond with an encrypted version of the challenge text. If the AP is able to verify the integrity of the reply, the MS is authenticated and it has the shared WEP key configured in it. Sometimes a MS will authenticate itself with several APs before associating itself with one of them. This process is called preauthentication. This authentication scheme is still not very secure, however, and also creates weaknesses in the protocol because of the way in which it is employed with a stream cipher.

Several commercial products also implement address filtering where only certain MAC addresses are allowed access to the network. This is not part of the standard and it is also possible for malicious users to spoof MAC addresses easily. However, address filtering is an additional security measure that is available for IEEE 802.11 networks.

Confidentiality and Integrity in IEEE 802.11

Confidentiality is simply provided in IEEE 802.11 by encrypting all packets using the RC4 stream cipher. Stream ciphers operate as follows. Using a secret key, a pseudorandom sequence of bits (called the key stream) is generated. If this sequence has a very long period and the algorithm is strong, it will be computationally impossible for someone to generate the sequence without knowing the secret key. The pseudorandom sequence thus generated will be XOR-ed with the MAC frame to make the

contents of the frame secure from interception. RC-4 is one algorithm to generate the pseudorandom key stream. This algorithm makes use of a secret key and in the case of WEP an initialization vector (IV) that is 24 bits long. Because the key is constant for all transactions, the same pseudorandom key stream is generated if the IV is not changed. An attacker could capture two streams of encrypted frames, XOR them together, and eliminate the key stream. He would then have an XOR of two data frames. If by some chance he knows the contents of one data frame, he can get the other as well. Since the IV is only 24 bits long, it is possible for an attacker to break the encryption scheme. One well-publicized attack is the Fluhrer/Mantin/Shamir (FMS) attack on RC-4. In addition, there are several weak keys that could make the encryption scheme easier to break. It is also possible for an attacker to replay packets depending on the sequence numbers that are being used. To ensure that an attacker has not modified a message, the WEP protocol uses the in-built CRC to verify the integrity of the message. Checking the integrity of the message using the CRC has vulnerabilities that have been publicized in recent years.

Key Distribution in IEEE 802.11

The IEEE 802.11 standard does not specify how the shared keys must be distributed to devices (AP and MSs). It is usually a manual installation of keys where a user will type the key in the device driver software. This process is unfortunately not scalable and also has several human vulnerabilities. Users may write down the key on a piece of paper when they buy a new device and lose this paper. Some vendors have automated methods of key distribution. Cisco’s Light Extensible Authentication Protocol makes use of the challenge/response mechanism to generate a key at the AP and an identical matching key locally in the MS that could then be used in a successful encrypted communication.

Ongoing and Proposed Security Features

A Task Group I of the IEEE 802.11 working group has prepared an enhanced security framework for IEEE 802.11 called 802.11i that was approved as a standard in June 2004. Several vendors have already implemented elements of this standard. This framework includes what is called a *robust security network* (RSN) that is similar to WEP but has several new capabilities in devices (Edney,

2004). It is possible for both WEP and RSN devices to coexist in a *transitional security network* (TSN).

A consortium of major WLAN manufacturers has set up the Wi-Fi Alliance that is looking at options to improve security in legacy devices while 802.11i is being standardized. The proposal from this alliance is called Wi-Fi Protected Access (WPA) that introduces enhancements to WEP called *Temporal Key Integrity Protocol* (TKIP). In this protocol, RC-4 is still used as the encryption algorithm. However, this protocol adds some features to overcome weakness of WEP. A message integrity code is used instead of the CRC check. It changes the way in which IVs are generated. It changes the encryption key for every frame, increases the size of the IV and also adds a mechanism to manage keys.

In 802.11i, RC-4 is replaced by the Advanced Encryption Standard (AES). In particular, the key stream and message integrity check will be generated by a counter mode cipher block chaining MAC protocol (CCMP). AES is a block cipher—it operates on fixed blocks of data unlike a stream cipher that generates a key stream. However, any block cipher can operate in different *modes* and cipher block chaining (CBC) is one such mode of operation. The counter mode is another mode of operation. It is expected that the counter mode will be used to generate the key stream and the CBC will be used to generate the message integrity check. Both these modes have been used in other systems with good security.

Both TKIP and AES-CCMP provide confidentiality and message integrity. To perform entity authentication, the IEEE 802.11 system has to still rely on challenge response protocols. Over the years, there have been several protocols developed for dial-up entity authentication and for port security in wired LANs. These include 802.1X, the extensible authentication protocol (EAP), and Remote Authentication Dial-In User Service (RADIUS). Note that all these protocols are not equivalent; for instance, both 802.1X and RADIUS could use EAP for entity authentication and key distribution. EAP itself would use some challenge/response protocol such as Challenge Handshake Authentication Protocol (CHAP) or SSL to authenticate the devices. Both WPA and RSN mandate 802.1X and EAP as part of the access control mechanism for 802.11 networks. Note that access control is increasingly becoming an important problem with the emergence of hot spot networks in airports, cafes and so on.

RECENT ACTIVITIES

Table 6 summarizes the status of the completed 802.11 group activities and lists some of the recent ongoing activities. There are some other amendments to the 802.11 standard that have been approved recently. They do not directly change the protocol on the air in the United States but provide extensions to the way 802.11 systems may operate. One of the important issues in wireless networks is roaming between different points of access to the wired network. This is possible only if equipment from different vendors supports the same set of protocols and is interoperable. Previously, there existed a task group F that had proposed an interaccess point protocol (IAPP) to achieve multivendor interoperability. For example, when a MS moves from one AP to another and sends a reassociation

request, the new AP must be able to converse with the old AP over the distribution system to inform it of the handoff and to free the resources in the old AP. This is achieved using the IAPP now standardized as 802.11f in July 2003. The 802.11f standard specifies the information and format of the information to be exchanged between access points and includes the recommended practice for multivendor access point interoperability via the IAPP across distribution systems. The competing standard for wireless LANs in Europe is the HIPERLAN/2 standard that is specified for the U-NII bands. HIPERLAN/2 uses the same physical layer as IEEE 802.11a, although it accommodates a few different data rates. In this standard, there are mechanisms suggested for power measurement and control and radio resources management. Previously there existed a task group H that was enhancing the current 802.11 MAC and 802.11a PHY with network management and control extensions for spectrum and transmit power management in the U-NII bands with the possibility of dynamic channel selection capabilities. In this case, APs would be able to dynamically select channels based on information they can obtain about neighboring APs that may transmitting on the same channel. This way, a laborious network planning process could be simplified. The 802.11h standard completed in October 2003 considers such transmit power control (TPC) and dynamic frequency selection (DFS) to satisfy the regulatory aspects in Europe.

Outside of the standards that have been specified already, there are several ongoing activities in the IEEE 802.11 working group. There are several task groups that are engaged in enhancing aspects of the IEEE 802.11 standard. We discuss some of these ongoing activities in this chapter. In particular, we look at the following task groups.

Task Group E: The 802.11 DCF considers all traffic to be the same and provides only a best effort service. This task group is evaluating enhancements to the MAC layer so as to provide some mechanisms for supporting quality of service (QoS) in wireless LANs for real-time applications such as audio, video, and media stream distribution. One technique that is being actively considered is to have different IFS and CW values for different classes of traffic. For example, a traffic class with higher priority would have a smaller IFS and CW range so that it waits for a smaller time compared to a traffic class with lower priority. This way, time sensitive traffic could get access to the channel earlier. This technique is similar to service differentiation in wired networks.

Task Group J: This task group is considering enhancements to the current standard to provide operations in the frequency band between 4.9 and 5 GHz for use in Japan. The reason for this task group is to make changes in the 802.11 standard to accommodate the regulatory demands in this spectrum that exist in Japan. There will be expected changes to both the MAC and PHY layers to meet these regulations.

Task Group K: This task group is looking at enhanced radio resource management outside the purview of 802.11h. Once power measurements and reporting are possible in a standardized manner, they can be exploited to make better use of the spectrum, reduce interference and so on.

Task Group N: The current MAC and PHY layers of the IEEE 802.11 standard constrain the raw data rate to

Table 6 Summary of Task Groups and Status

Group	Group Activities	Status as of September 2004
A	5-GHz operation (High Data Rate Extension based on OFDM)	Completed
B	2.4-GHz operation (High Data Rate Extension up to 11 Mbps)	Completed
E	QoS enhancements to the MAC layer	Draft (not approved)
F	Interaccess Point Protocol	Completed (July 2003)
G	2.4-GHz operation (High Data Rate Extension up to 54 Mbps)	Completed
H	Spectrum and transmit power management in Europe	Completed (October 2003)
I	Security enhancements to 802.11	Completed (June 2004)
J	Operation in 4.9- to 5-GHz bands in Japan	In progress
K	Radio resource management	In progress
N	High throughputs greater than 100 Mbps	In progress
R	Fast roaming between access points	In progress
S	Mesh networking of access points	In progress (started in 2004)

54 Mbps and the throughput to a fraction of that depending on traffic load, channel conditions, and so on. A new task group is looking at an IEEE 802.11n standard that will look at both MAC and PHY enhancements to improve the throughput. Some of the ideas being floated to improve throughput are to use directional antennas, multiple-input/multiple-output (MIMO) with OFDM, throughput enhancements at the MAC layer, and so on.

Task Group R: In an authenticated system using 802.11i or even WEP, there is a substantial delay because of the reassociation and reauthentication procedures, when an 802.11 device hands off from one BSS to another within an ESS. Such delays can be as high as 15 s and are unacceptable for real-time traffic. As voice-over IP becomes more important and its use over wireless LANs increases, these delays must be reduced to acceptable levels without compromising security. Such enhancements to the current 802.11 standard to provide fast handoffs between different BSSs is the responsibility of Task Group R.

Task Group S: The idea of this task group is to develop enhancements to the current IEEE 802.11 standard to provide a method to configure the distribution system using the four MAC addresses thereby enabling some form of mesh networking between access points. This could be a wired or wireless mesh network that allows for automatic topology learning and dynamic path configuration over self-configuring multihop topologies. There are already proprietary protocols performing this task to extend coverage within homes, but the standard will allow for different scenarios with different requirements (e.g., quick set up and tear down and maximizing throughput). Table 6 provides a summary of the above activities.

Although not directly changing or adding to the standards, there are task groups that are involved in maintenance and other issues related to 802.11. Task group M is performing the maintenance of the 802.11 standard. Task group D is looking at regulatory domain updates. There are also some new proposed activities that are pending approval at various levels as of the time of the writing—an 802.11p effort on wireless access for the vehicular environment and an 802.11t that aims to recommend practices for wireless performance prediction. In addition, there are several study groups looking at harmonizing the 802.11 and the European ETSI standards

and some investigating the possibility of improvements to the 802.11 standard to provide higher throughput.

Other IEEE Wireless Standards: The IEEE also has other wireless standards that it manages. The IEEE 802.15 standard looks at *personal area networks* (PANs) that are networks related to an operating space around one person. Examples of PANs are Bluetooth (Haartsen, 2000) networks. In fact 802.15 is based on Bluetooth. Like 802.11, in 802.15 there are many subcategories of standards. One of these subcategories called 802.15.4 is also commercially popular as the Zigbee standard. Another IEEE wireless standard is the 802.16 standard (WiMax) that looks at fixed wireless access. In this case, the goal is to provide fixed broadband wireless links to organizations and residences. These broadband links would replace the last hop copper or coaxial cable and provide Internet access, video, and telephone services to the customer.

GLOSSARY

Advanced Encryption Standard The encryption algorithm used in the latest security standard for 802.11.

Advanced Mobile Phone System The very first cellular telephone service in the United States.

Clear-to-Send Command used by an 802.11 mobile station to indicate to all other mobile stations in its receiving range about a pending transmission toward reducing the hidden terminal problem and to acknowledge an RTS packet.

Complementary Code Keying A modulation and encoding scheme used in the 802.11b standard to increase the data rate from 2 to 11 Mbps while maintaining the original chip rate of 11 Mcps.

Counter Mode with Cipher Block Chaining Message Authentication Code Protocol The method for ensuring confidentiality and authentication in 802.11i that uses the advanced encryption standard.

Direct Sequence Spread Spectrum A modulation technique used in the original 802.11 standard that spreads the spectrum providing robustness against multipath.

Distributed Coordination Function The basic medium access method in all 802.11 networks that uses carrier sense multiple access with collision avoidance.

Interframe Space The waiting time of 802.11 mobile stations to assist in collision avoidance. Different values are used for acknowledgements, regular frames, and polling frames.

Orthogonal Frequency Division Multiplexing The modulation scheme used in 802.11a and 802.11g standards. It splits the channel into many narrow subcarriers, thereby avoiding problems related to the coherence bandwidth of the radio channel.

Point Coordination Function An optional polling medium access mechanism that is not widely deployed in 802.11 systems.

Request-to-Send Frames used by an 802.11 mobile station to indicate to all other mobile stations in its receiving range about a pending transmission and reduce the hidden terminal problem.

Wired Equivalent Privacy The weak security protocol used in legacy 802.11 systems that made use of the RC-4 stream cipher to provide confidentiality and authentication in ways that did not make the system secure.

INTRODUCTION

The Platform for Privacy Preferences (P3P 1.0) Specification defines a standard way for Web sites to encode their privacy policies in a computer-readable format and standard mechanisms for locating these policies and associating them with specific online content. Developed by the World Wide Web Consortium (W3C), P3P 1.0 was adopted as an official W3C Recommendation in April 2002 (Cranor, Langheinrich, Marchiori, Presler-Marshall, & Reagle, 2002a). P3P functionality has been built into popular Web browsers as well as browser add-ons and editing tools.

HOW P3P WORKS

Web sites that adopt P3P translate their privacy policies into a computer-readable format called XML (Bray, Paoli, Sperberg-McQueen, & Maler, 2000) and place the resulting P3P “policy” file on their Web sites. They also create an XML-encoded P3P “policy reference file” used to indicate the parts of a Web site to which a P3P policy applies.

Software tools that fetch and read P3P policies are referred to as “P3P user agents.” P3P user agents may be stand-alone software tools or modules built into Web browsers or other software. To fetch a P3P policy, user agents use the HTTP protocol (Fielding, Gettys, Mogul, Frystyk, Masinter, Leach, & Berners-Lee, 1999) that Web browsers use to fetch Web content. Using this protocol, user agents send a request called a “GET” request to a Web site. If the site has the requested file, it responds by sending that file, along with some header information. If the site does not have the requested file, it responds with an appropriate error code.

To obtain a P3P policy, user agents first make a GET request for a site’s P3P policy reference file. Most Web sites place their policy reference files at a standard “well-known location”: /w3c/p3p.xml. Thus, P3P user agents can make a GET request for this file to learn the location of the P3P files on a Web site. After parsing this file, P3P user agents can make additional GET requests to obtain P3P policy files. As P3P policies generally apply to many (or all) URLs on a site, it is not necessary for user agents to fetch these files every time a user requests a new page on a site. By default, P3P files have a lifetime of 24 hr, meaning that if a user returns to a site within one day, no new P3P files need to be fetched. Optionally, P3P policies may be embedded

in policy reference files to simplify site administration and reduce the number of round trips necessary to retrieve P3P files from a site.

P3P 1.0 also supports two additional mechanisms for locating policy reference files. Webmasters can place policy reference files at arbitrary locations on their sites and reference them through links embedded in HTML content or in special P3P HTTP headers. The HTML link method is provided primarily for the benefit of Web sites that are part of a larger site but are operated independently of the larger site. For example, many universities allow their students to create Web sites hosted on the university’s Web server. Students may create their own P3P policies but do not have the ability to edit the policy reference file at the well-known location on the university server. The HTTP header method is provided primarily for use by sites that use more than one P3P policy reference file. Sites may wish to use more than one policy reference file if they have a very large number of P3P policies (for example, a site that hosts content for hundreds of other companies) or if they are concerned that a single policy reference file may reveal information about the structure of their site that they do not want to make public.

P3P 1.0 specifies a format for a P3P “compact policy” that can be transmitted in a P3P HTTP header sent in the same response in which a cookie is set (Kristol, 2001). P3P compact policies are short summaries of full P3P policies that describe a Web site’s data practices for any cookies set during that HTTP response. Compact policies are optional for P3P-enabled Web sites; however, some P3P user agents rely on them heavily. Sites that use compact policies are also required to post full P3P policies and policy reference files.

P3P POLICIES

P3P policies are XML (Bray et al., 2000) documents that include standard information about a Web site’s privacy practices. Much of this information is encoded in a multiple choice format and thus might not be as detailed as the information provided by a Web site in its human-readable privacy policy. However, the standardized format often results in clearer and more complete disclosures than Web sites typically make in their human-readable privacy policies.

Here is an example of a P3P policy for a Web site that does not collect very much information:

```

<POLICIES xmlns="http://www.w3.org/2002/01/P3Pv1">
<POLICY discuri="http://p3pbook.com/privacy.html" name="policy">
  <ENTITY>
    <DATA-GROUP>
      <DATA
        ref="#business.contact-info.online.email">privacy@p3pbook.com
      </DATA>
      <DATA
        ref="#business.contact-info.online.uri">http://p3pbook.com/
      </DATA>
      <DATA ref="#business.name">Web Privacy With P3P</DATA>
    </DATA-GROUP>
  </ENTITY>
  <ACCESS><nonident/></ACCESS>
  <STATEMENT>
    <CONSEQUENCE>Our Web server collects access logs containing
      this information.</CONSEQUENCE>
    <PURPOSE><admin/><current/><develop/></PURPOSE>
    <RECIPIENT><ours/></RECIPIENT>
    <RETENTION><indefinitely/></RETENTION>
    <DATA-GROUP>
      <DATA ref="#dynamic.clickstream"/>
      <DATA ref="#dynamic.http"/>
    </DATA-GROUP>
  </STATEMENT>
</POLICY>
</POLICIES>

```

This policy is encoded using the computer-readable language XML. An XML document contains a single XML element, which may contain other XML elements. Each element is composed of one or more XML tags. An XML tag begins with a left angle bracket (<) and ends with a right angle bracket (>). Some XML elements contain no other elements. These elements are represented by a single XML tag that ends with a slash character, for example <nonident/>. Elements that contain other elements are represented using a pair of XML tags that surround one or more other XML tags. In the above example, <ACCESS><nonident/></ACCESS> represents a nonident element, which is contained inside an ACCESS element. Some XML elements have attributes. In the above example the POLICY element has two attributes, discuri and name. The discuri attribute has the value *http://p3pbook.com/privacy.html* and the name attribute has the value *policy*.

The rest of this section provides an overview of the information included in a P3P policy in the order required by the P3P 1.0 specification. Not all elements of a P3P policy are detailed here.

POLICY attributes

The “discuri” and “opturi” attributes of the P3P POLICY element indicate the location of a site’s human-readable privacy policy and human-readable description of opt-out mechanisms, respectively.

TEST

The TEST element indicates that a policy is for testing purposes only.

ENTITY

The ENTITY element identifies the legal entity making the representation of the privacy practices contained in the policy. It includes online or physical-world contact information for that entity.

ACCESS

The ACCESS element provides information about the ability of individuals to access information that a Web site has collected about them. Web sites choose one of six ACCESS choices that best describes their practices. Choices range from providing no access to providing access to all identified information.

DISPUTES

The DISPUTES element describes dispute resolution procedures that may be followed for disputes about a Web site’s privacy practices. Sites may describe multiple dispute resolution procedures, including contacting a customer service representative, contacting an independent organization, filing a legal complaint, or relying on a particular law. Sites must provide a URL that references each dispute resolution procedure. They may also provide human-readable descriptions and images for each.

REMEDIES

The REMEDIES element describes remedies in case a privacy policy breach occurs. Sites may describe one type of remedy for each dispute resolution procedure, including correcting wrongful actions, monetary payments, and relying on a particular law.

STATEMENT

The **STATEMENT** element is used to indicate a set of data for which the same privacy practices apply. The **STATEMENT** element contains a number of other elements that represent types of data and data practices. Web sites typically create one or more statements in their P3P policies, each representing a bundle of data. For example, a site might create one statement for information collected in Web logs and another statement for information entered by users in an order form.

NONIDENTIFIABLE

The presence of the **NONIDENTIFIABLE** element in a P3P policy indicates that either a Web site does not collect identifiable information or the information it collects is anonymized.

CONSEQUENCE

The consequence element allows sites to provide a short human-readable explanation of their data practices.

PURPOSE

The **PURPOSE** element describes the ways that collected information may be used. Web sites must disclose as many of the 12 purpose choices as apply. Optionally, sites may use the “required” attribute of the **PURPOSE** element to indicate that a particular use of information is performed on an opt-in or opt-out basis.

RECIPIENT

The **RECIPIENT** element describes the extent to which information may be shared with other entities. Web sites must choose one or more of six possible types of recipients, including companies that use information only to help fulfill user requests, delivery companies, companies with similar privacy policies, companies with different privacy policies that are accountable to the entity collecting the data, any companies regardless of their privacy practices, and people who access information from a public area such as a bulletin board or chat room. Optionally, sites may use the “required” attribute of the **PURPOSE**

element to indicate that sharing with a particular type of recipient is done on an opt-in or opt-out basis.

RETENTION

The **RETENTION** element describes how long a Web site may keep information. Rather than describe retention in terms of a number of days, weeks, or years, the retention element allows Web sites to select one of five possible types of retention policies, including retaining information only for the current online session, retaining information only long enough to perform the activity for which it was collected, retaining information only as long as needed for legal purposes, retaining information according to a policy described in the site’s human-readable privacy practices, and retaining information indefinitely.

DATA

The **DATA** element describes the type of data a Web site may collect. Sites may describe specific pieces of information such as “first name” or “last name” or they may describe general categories of information. There are 17 categories of information defined in the P3P 1.0 specification.

A P3P PREFERENCE EXCHANGE LANGUAGE

A separate W3C specification called A P3P Preference Exchange Language (APPEL) provides syntax for encoding user preferences about privacy policies (Cranor, Langheinrich, & Marchiori, 2002b). APPEL is a rule-based language encoded in XML. P3P user agents can compare APPEL-encoded preferences with a P3P policy to determine whether a site’s policy matches a user’s preferences; however, P3P user agents are not required to use APPEL. Unlike the P3P 1.0 Specification, APPEL is not an official W3C Recommendation and is considered somewhat experimental. Nonetheless, it is used in several P3P software implementations.

Here is an example of an APPEL ruleset with four rules, including a default “otherwise” rule. Rules are evaluated in the order in which they appear in the ruleset. When the pattern in the body of a rule matches a P3P policy, the rule fires and the action described by the “behavior” attribute is carried out.

```
<appel:RULESET xmlns:appel="http://www.w3.org/2002/03/APPELv1"
  xmlns:p3p="http://www.w3.org/2002/01/P3Pv1">
  <appel:RULE behavior="limited" description="Site does not allow you to
  remove yourself from marketing/mailling list">

</appel:RULESET>

```

P3P SOFTWARE

A variety of software tools and services have been developed that support P3P, including P3P user agents, P3P editors and validators, and services that help P3P-enabled Web sites.

Microsoft's Internet Explorer 6 (IE6) Web browser includes basic P3P functionality. IE6 checks the HTTP headers sent with cookies for P3P compact policies. Under IE6's default setting, cookies without compact policies may be blocked if they are set by a "third-party" Web site—that is, if they are associated with an advertisement or other content embedded in a Web page that is served from a different domain than the page in which it is embedded. Other cookies may be blocked or restricted depending on the substance of a compact policy and the user's cookie settings. A small icon featuring a picture of an eye with a Do Not Enter sign appears in the lower right corner of the browser window when a cookie is blocked or restricted. IE6 also offers a "privacy report" feature that users can select from the browser's View menu. Selecting this feature causes the browser to check for a site's full P3P policy. If the browser is able to fetch the policy, it parses the XML and displays a human-readable representation of the policy.

Netscape Navigator 7 has similar P3P features as IE6. It employs a slightly different cookie interface and default settings. Netscape can also generate a human-readable version of a site's P3P policy. The Netscape version of a P3P policy is shorter and uses sentence fragments and bulleted lists where IE6 uses complete sentences and paragraphs.

AT&T Privacy Bird is an IE5/6 add-on available as a free download (AT&T Privacy Bird, 2003). Once installed, a bird icon appears on the right side of the IE6 title bar. Privacy Bird checks for P3P policies at every site a user visits and compares them with the privacy preference settings the user has configured through a menu accessed by clicking on the bird. Privacy Bird checks for P3P policies for all

content embedded in a page. At sites that match a user's privacy preferences, the bird icon turns green; at sites that do not match the icon turns red; and at sites that are not P3P enabled the icon turns yellow. Symbols in the bird's song "bubble" also help distinguish these three icons. In addition, users can optionally configure Privacy Bird to play distinctive sounds corresponding to the appearance of each icon. Privacy Bird can also generate and display a human-readable version of a site's P3P policy. Similar to the Netscape version, this version also uses short phrases and bulleted lists.

Future P3P user agents may be built into electronic wallets, search engines, and other tools. For example, a P3P-enabled search engine would allow users to sort their search results so that sites that match both their search criteria and their privacy preferences are listed first. Tools like this will allow users to more easily compare privacy policies at similar Web sites and identify sites with policies they find acceptable.

A number of companies have developed software and services to assist Web masters in P3P enabling their sites. One of the most popular P3P tools for Web sites is the P3P Policy Editor offered as a free download from the IBM Alphaworks Web site (Presler-Marshall, Gilmore, & Bleizeffer, 2004). This tool includes a graphical user interface that allows P3P policies to be visually constructed. The tool generates XML encoded P3P policies, as well as human-readable versions of each policy. It also generates policy reference files and compact policies and provides guidance on how IE6 will respond to a particular compact policy.

Some companies are exploring the use of P3P to assist in the maintenance of back-end customer information databases and to automate compliance with privacy policies. Database records can be annotated with information about the P3P policy in effect when the data were collected. In addition, IBM has proposed a language called Enterprise Authorization Language (EPAL) that is

designed for writing detailed rules for data handling in an organization (Ashley, Hada, Karjoth, Powers, & Schunter, 2003). These very granular rules can then be mapped onto a less granular P3P policy for public dissemination.

W3C maintains an online P3P Validator (W3C P3P Validator, 2003). Users can type in the URL for a site and the Validator will check to see whether the site is properly P3P enabled. It checks to make sure P3P files are located in the proper locations on the site and use the correct syntax.

P3P ADOPTION

P3P will be most useful once it is widely adopted by Web sites. A number of surveys have been undertaken to assess P3P adoption. It is not feasible to check every Web site in existence for P3P compliance, nor is this a particularly useful metric. What is more interesting is to examine the fraction of P3P-enabled sites among the most popular sites on the Internet.

A July 2003 study found that 30% of the top 100 Web sites were P3P enabled and 23% of the top 500 sites were P3P enabled (Byers, Cranor, & Kormann, 2003). In general, the most popular sites are the ones most likely to be P3P enabled. Although these numbers demonstrate that there is a long way to go, these adoption levels are substantial for a specification that was published little over a year earlier.

Advertising networks and other Web sites that frequently set third-party cookies are among the early adopters of P3P, because of concerns that their cookies may be blocked by IE6. Many other companies adopted P3P early to demonstrate their commitment to privacy and to show corporate leadership on privacy issues.

CONCLUSION

The P3P 1.0 Specification represents the first standardized computer-readable encoding of privacy policies. Now that such an encoding exists, a variety of applications are possible that make use of it. P3P policies may be used to inform Web users about Web site privacy policies, compile statistics on Web site privacy policies, and assist companies in managing their data practices.

The P3P development process spanned over 5 years and involved dozens of individuals from around the world. Throughout this process, P3P has been somewhat controversial and has received much criticism. Many companies and industry groups voiced concerns about the extent to which P3P would require sites to make disclosures that they might not be required legally to make. They also expressed concerns that posting P3P policies might open companies up to additional liability. Conversely, some privacy advocates raised concerns that P3P would not serve to actually improve privacy protections for individuals (Hochheiser, 2002). Despite the international composition of the P3P working group, concerns were also raised that P3P was developing with too much of an American focus. Part of the reason the P3P development process took so long is that the working group attempted to address as many of these diverse concerns as possible (Cranor, 2002).

One of the major goals of P3P has been to provide an easy way for users to learn about Web site privacy policies without having to stop at every Web site and read a lengthy and difficult-to-understand privacy policy (Turow, 2003). As more sites adopt P3P and new P3P user agents emerge, this goal is beginning to be achieved. In addition, we are beginning to see some secondary effects of P3P. Because sites must choose between a number of "multiple choice" options when writing a P3P policy, they sometimes end up making clearer and more explicit statements in their P3P policies than they previously had in their human-readable privacy policies. Also, some sites have actually improved their privacy policies so that their P3P policies would not make them look bad or to avoid having their cookies blocked by IE6. Ideally, the increased transparency brought about by P3P will eventually result in more policy improvements and will facilitate more informed debate about the effectiveness of regulatory and self-regulatory privacy programs (Cranor & Wenning, 2002).

GLOSSARY

Identifiable Information Information that can be used to directly or indirectly identify a particular individual by reference to an identification number or to one or more factors specific to his or her physical, physiological, mental, economic, cultural, or social identity. In some cases information can be used by itself to identify a particular individual; in other cases it must be used in combination with other information to identify an individual.

Identified Information Information that can reasonably be used by a data collector to identify an individual. In some cases *identifiable* information may not be considered *identified* information because of the fact that the identifiable information identifies a particular individual only when combined with other information not readily available to the data collector.

Opt-In The ability of individuals to have a company or organization use or share their personal information on request. For example, an individual might ask to have her name put on a catalog mailing list. If individuals do not take explicit action to request that their information is used or shared for a particular purpose, they have not opted-in.

Opt-Out The ability of individuals to have a company or organization remove their names from marketing or mailing lists or refrain from sharing their personal information with other companies or organizations. Individuals must take explicit action to opt-out.

P3P Compact Policy A short summary of a Web site's P3P policy with respect to cookies. Compact policies are transmitted in P3P HTTP headers. Web sites that use compact policies must also post corresponding full P3P policies.

P3P Policy A computer-readable version of a Web site's privacy policy. P3P policies are encoded in XML and include information about the types of data a Web site collects and how it will be used.

P3P Policy Reference File An XML file that indicates the location of P3P policies on a Web site and the URLs to which each applies.

Privacy Policy A description of the privacy practices of a company or organization.

Third-Party Cookie A cookie associated with an image or other object embedded in a Web page that is served from a domain other than the domain from which that Web page is served.

URL Uniform resource locator; the address for a Web page. The P3P 1.0 specification also refers to uniform resource identifiers (URIs). URI is a more general term that includes URLs.

User Agent A software tool that can locate and fetch P3P policies and take actions on a user's behalf, such as displaying a human-readable version of a P3P policy or comparing the policy with a user's preferences.

Well-Known Location A standard location on a Web site where P3P policy reference files are posted. Although Web sites may post policy reference files at any location, posting them at the well-known location allows user agents to find them quickly. The well-known location for P3P policy reference files is `/w3c/p3p.xml`.

XML Extensible markup language; a computer-readable language used for representing information. P3P files are encoded using XML.

 security threats, 901–902
 state of, 917–918
- Internet service providers (ISPs), 3, 128,
 327, 576, 784. *See also* Broadband
 ISPs
 e-learning and, 286, 289
 regional, 534
 relays with, 846–847
 as a security threat, 132
 under TCP/IP, 953
- Internet services, electronic commerce
 and, 6–7
- Internet technologies, in intranets,
 205
- Internet telephony, 6, 7
- Internet transport protocols, 528
- Internet use, growth of, 18
- Internet-based EDI, 183, 187
- Internet-related security problems, 164
- Internets, under TCP/IP, 953–954
- Internetworking, 3, 953–956
 of heterogeneous networks, 739–747
 security standards for, 901
 technical issues with, 740
 wireless Internet, 739–743
- Inter-operable secure object stores
 (ISOS), 68
- Interorganizational communication,
 KDC versus PKI, 854
- Interorganizational information system
 (IOIS), 187
 electronic data interchange as, 179
- Interorganizational systems (IOSs), 9
- Interrealm authentication, Kerberos,
 927
- Interruption
 of the EDI process, 180–181
 in router and switch security, 355
- Inter-satellite link (ISL), 757
- Intersymbol interference (ISI), 392, 393,
 397, 417, 635
- Intersymbol interference channels, 421
- Inter-Web service modeling, 154–155
- Interworking, MAN and WAN, 455–456
- Interworking function (IWF), 698
- Intranet client/server implementations,
 497–498
- Intranet development, 212
- Intranet publishing strategy, 8–9
- Intranet security (IS) department,
 209–210
- Intranets, 7–8, 13, 205–214, 436, 224,
 945
 access and control for, 210
 advantages of, 8–9
 applications of, 8–9
 building and maintaining, 209–213
 content management for, 209
 cost/benefit calculations for, 211–213
 defined, 213
 ease of use of, 209
 evaluating, 212
 extranets mirroring, 219
 extranets versus, 9, 10
 failure of, 212–213
 features of, 205–207
 growth of, 208, 215
 implementation of, 210
 information provided by, 8
 maintenance and management of, 211
 network availability/security and, 210
 pilot studies of, 210–211
 privacy of, 213
 role and applications of LANs in, 436
 standards versus flexibility in, 209
 under TCP/IP, 953–954
 technology related to, 207–209
 time clocks and, 207
 training and support related to,
 209–210
 uses for, 474
- Intrasystem co-channel interference, in
 communications satellite systems,
 758
- Intrasystem mail, 839
- Intra-Web service modeling, 154
- Intrinsic security, satellite network,
 764–765
- Introduction to Digital Libraries*
 (Chowdhury & Chowdhury), 49
