To so many fine memories of my mother, Ashraf, my father,
Mohammad, and my brother, Mohsen, for their uncompromising
belief in the power of education.

About the Editor-in-Chief

Hossein Bidgoli, Ph.D., is professor of Management Information Systems at California State University. Dr. Bidgoli helped set up the first PC lab in the United States. He is the author of 43 textbooks, 27 manuals and over five dozen technical articles and papers on various aspects of computer applications, information systems and network security, e-commerce and decision support systems published and presented throughout the world. Dr. Bidgoli also serves as the editor-in-chief of *The*

Internet Encyclopedia and the *Encyclopedia of Information Systems*.

The *Encyclopedia of Information Systems* was the recipient of one of the *Library Journal's* Best Reference Sources for 2002 and *The Internet Encyclopedia* was recipient of one of the PSP Awards (Professional and Scholarly Publishing), 2004. Dr. Bidgoli was selected as the California State University, Bakersfield's 2001–2002 Professor of the Year.

<i>Richard A. Spinello</i>		<i>Xukai Zou and Amandeep Thukral</i>	
Copyright Law	357	Secure Electronic Voting Protocols	647
<i>Randy Canis</i>		<i>Helger Lipmaa</i>	
Patent Law	369	Digital Evidence	658
<i>Gerald Bluhm</i>		<i>Robin C. Stuart</i>	

Digital Watermarking and Steganography <i>M. A. Suhail, B. Sadoun, and M. S. Obaidat</i>	664	Hacking Techniques in Wireless Networks <i>Prabhaker Mateti</i>	83
Law Enforcement and Digital Evidence <i>J. Philip Craiger, Jeff Swauger, and Mark Pollitt</i>	679	Computer Viruses and Worms <i>Robert Slade</i>	94
Forensic Computing <i>Mohamed Hamdi, Nouredine Boudriga, and M. S. Obaidat</i>	702	Trojan Horse Programs <i>Adam L. Young</i>	107
Computer Forensics Procedures and Methods <i>J. Philip Craiger</i>	715	Hoax Viruses and Virus Alerts <i>Robert Slade</i>	119
Computer Forensics—Computer Media Reviews in Classified Government Agencies <i>Michael R. Anderson</i>	750	Hostile Java Applets <i>David Evans</i>	126
Forensic Analysis of UNIX Systems <i>Dario V. Forte</i>	763	Spyware <i>Tom S. Chan</i>	136
Forensic Analysis of Windows Systems <i>Steve J. Chapin and Chester J. Maciag</i>	781	Mobile Code and Security <i>Song Fu and Cheng-Zhong Xu</i>	146
Operating System Security <i>William Stallings</i>	796	Wireless Threats and Attacks <i>Robert J. Boncella</i>	165
UNIX Security <i>Mark Shacklette</i>	806	WEP Security <i>Nikita Borisov</i>	176
Linux Security <i>A. Justin Wilder</i>	822	Bluetooth Security <i>Susanne Wetzel</i>	184
OpenVMS Security <i>Robert Gezelier</i>	853	Cracking WEP <i>Pascal Meunier</i>	198
Windows 2000 Security <i>E. Eugene Schultz</i>	870	Denial of Service Attacks <i>E. Eugene Schultz</i>	207
Software Development and Quality Assurance <i>Pascal Meunier</i>	885	Network Attacks <i>Edward Amoroso</i>	220
The Common Criteria <i>J. McDermott</i>	897	Fault Attacks <i>Hamid Choukri and Michael Tunstall</i>	230
Volume III: Threats, Vulnerabilities, Prevention, Detection, and Management		Part 2: Prevention: Keeping the Hackers and Crackers at Bay	
Part 1: Threats and Vulnerabilities to Information and Computing Infrastructures		Physical Security Measures	263
Internal Security Threats <i>Marcus K. Rogers</i>	3	<i>Mark Michael</i>	
Physical Security Threats <i>Mark Michael</i>	18	RFID and Security <i>Stephen A. Weis</i>	289
Fixed-Line Telephone System Vulnerabilities <i>Mak Ming Tak, Xu Yan, and Zenith Y. W. Law</i>	30	Cryptographic Privacy Protection Techniques <i>Markus Jakobsson</i>	300
E-Mail Threats and Vulnerabilities <i>David Harley</i>	40	Cryptographic Hardware Security Modules <i>Nicko van Someren</i>	311
E-Commerce Vulnerabilities <i>Sviatoslav Braynov</i>	57	Smart Card Security <i>Michael Tunstall, Sebastien Petit, and Stephanie Porte</i>	326
Hacking Techniques in Wired Networks <i>Qijun Gu, Peng Liu, and Chao-Hsien Chu</i>	70	Client-Side Security <i>Charles Border</i>	342
		Server-Side Security <i>Slim Rekhis, Nouredine Boudriga, and M. S. Obaidat</i>	355
		Protecting Web Sites <i>Dawn Alexander and April Giles</i>	370

Database Security <i>Michael Gertz and Arnon Rosenthal</i>	380	Part 3: Detection, Recovery, Management, and Policy Considerations	
Medical Records Security <i>Normand M. Martel</i>	395	Intrusion Detection Systems Basics <i>Peng Ning and Sushil Jajodia</i>	685
Access Control: Principles and Solutions <i>S. De Capitani di Vimercati, S. Paraboschi, and Pierangela Samarati</i>	406	Host-Based Intrusion Detection System <i>Giovanni Vigna and Christopher Kruegel</i>	701
Password Authentication <i>Jeremy L. Rasmussen</i>	424	Network-Based Intrusion Detection Systems <i>Marco Cremonini</i>	713
Computer and Network Authentication <i>Patrick McDaniel</i>	439	The Use of Agent Technology for Intrusion Detection <i>Dipankar Dasgupta</i>	730
Antivirus Technology <i>Matthew Schmid</i>	450	Contingency Planning Management <i>Marco Cremonini and Pierangela Samarati</i>	744
Biometric Basics and Biometric Authentication <i>James L. Wayman</i>	459	Computer Security Incident Response Teams (CSIRTs) <i>Raymond R. Panko</i>	760
Issues and Concerns in Biometric IT Security <i>Philip Statham</i>	471	Implementing a Security Awareness Program <i>K. Rudolph</i>	766
Firewall Basics <i>James E. Goldman</i>	502	Risk Management for IT Security <i>Rick Kazman, Daniel N. Port, and David Klappholz</i>	786
Firewall Architectures <i>James E. Goldman</i>	515	Security Insurance and Best Practices <i>Selahattin Kuru, Onur Ihsan Arsun, and Mustafa Yildiz</i>	811
Packet Filtering and Stateful Firewalls <i>Avishai Wool</i>	526	Auditing Information Systems Security <i>S. Rao Vallabhaneni</i>	829
Proxy Firewalls <i>John D. McLaren</i>	537	Evidence Collection and Analysis Tools <i>Christopher L. T. Brown</i>	840
E-Commerce Safeguards <i>Mark S. Merkow</i>	552	Information Leakage: Detection and Countermeasures <i>Phil Venables</i>	853
Digital Signatures and Electronic Signatures <i>Raymond R. Panko</i>	562	Digital Rights Management <i>Renato Iannella</i>	865
E-Mail Security <i>Jon Callas</i>	571	Web Hosting <i>Doug Kaye</i>	879
Security for ATM Networks <i>Thomas D. Tarman</i>	584	Managing a Network Environment <i>Jian Ren</i>	893
VPN Basics <i>G. I. Papadimitriou, M. S. Obaidat, C. Papazoglou, and A. S. Pomportsis</i>	596	E-Mail and Internet Use Policies <i>Nancy J. King</i>	908
VPN Architecture <i>Stan Kurkovsky</i>	612	Forward Security Adaptive Cryptography: Time Evolution <i>Gene Itkis</i>	927
IP-Based VPN <i>David E. McDysan</i>	624	Security Policy Guidelines <i>Mohamed Hamdi, Noureddine Boudriga, and M. S. Obaidat</i>	945
Identity Management <i>John Linn</i>	636	Asset–Security Goals Continuum: A Process for Security <i>Margarita Maria Lenk</i>	960
The Use of Deception Techniques: Honeypots and Decoys <i>Fred Cohen</i>	646	Multilevel Security <i>Richard E. Smith</i>	972
Active Response to Computer Intrusions <i>David Dittrich and Kenneth Einar Himma</i>	664		

Multilevel Security Models <i>Mark Stamp and Ali Hushyar</i>	987	Security Policy Enforcement <i>Cynthia E. Irvine</i>	1026
Security Architectures <i>Nicole Graf and Dominic Kneeshaw</i>	998	Guidelines for a Comprehensive Security System <i>Hossein Bidgoli</i>	1041
Quality of Security Service: Adaptive Security <i>Timothy E. Levin, Cynthia E. Irvine, and Evdoxia Spyropoulou</i>	1016

Corporate Spying: The Legal Aspects

Preface

The Handbook of Information Security is the first comprehensive examination of the core topics in the security field. *The Handbook of Information Security*, a 3-volume reference work with 207 chapters and 3300+ pages, is a comprehensive coverage of information, computer, and network security.

The primary audience is the libraries of 2-year and 4-year colleges and universities with computer science, MIS, CIS, IT, IS, data processing, and business departments; public, private, and corporate libraries throughout the world; and reference material for educators and practitioners in the information and computer security fields.

The secondary audience is a variety of professionals and a diverse group of academic and professional course instructors.

Among the industries expected to become increasingly dependent upon information and computer security and active in understanding the many issues surrounding this important and fast-growing field are: government, military, education, library, health, medical, law enforcement, accounting, legal, justice, manufacturing, financial services, insurance, communications, transportation, aerospace, energy, biotechnology, retail, and utility.

Each volume incorporates state-of-the-art, core information, on computer security topics, practical applications and coverage of the emerging issues in the information security field.

This definitive 3-volume handbook offers coverage of both established and cutting-edge theories and developments in information, computer, and network security.

This handbook contains chapters by global academic and industry experts. This handbook offers the following features:

- 1) Each chapter follows a format including title and author, outline, introduction, body, conclusion, glossary, cross-references, and references. This format allows the reader to pick and choose various sections of a chapter. It also creates consistency throughout the entire series.
- 2) The handbook has been written by more than 240 experts and reviewed by more than 1,000 academics and practitioners from around the world. These experts have created a definitive compendium of both established and cutting-edge theories and applications.
- 3) Each chapter has been rigorously peer-reviewed. This review process assures accuracy and completeness.
- 4) Each chapter provides extensive online and off-line references for additional readings, which will enable the reader to learn more on topics of special interest.
- 5) The handbook contains more than 1,000 illustrations and tables that highlight complex topics for further understanding.
- 6) Each chapter provides extensive cross-references, leading the reader to other chapters related to a particular topic.
- 7) The handbook contains more than 2,700 glossary items. Many new terms and buzzwords are included to provide a better understanding of concepts and applications.
- 8) The handbook contains a complete and comprehensive table of contents and index.
- 9) The series emphasizes both technical as well as managerial, social, legal, and international issues in the field. This approach provides researchers, educators, students, and practitioners with a balanced perspective and background information that will be helpful when dealing with problems related to security issues and measures and the design of a sound security system.
- 10) The series has been developed based on the current core course materials in several leading universities around the world and current practices in leading computer, security, and networking corporations.

We chose to concentrate on fields and supporting technologies that have widespread applications in the academic and business worlds. To develop this handbook, we carefully reviewed current academic research in the security field from leading universities and research institutions around the world.

Computer and network security, information security and privacy, management information systems, network design and management, computer information systems (CIS), decision support systems (DSS), and electronic commerce curriculums, recommended by the Association of Information Technology Professionals (AITP) and the Association for Computing Machinery (ACM) were carefully investigated. We also researched the current practices in the security field carried out by leading security and IT corporations. Our research helped us define the boundaries and contents of this project.

TOPIC CATEGORIES

Based on our research, we identified nine major topic categories for the handbook.

- Key Concepts and Applications Related to Information Security
- Infrastructure for the Internet, Computer Networks, and Secure Information Transfer
- Standards and Protocols for Secure Information Transfer
- Information Warfare
- Social, Legal, and International Issues

- Foundations of Information, Computer, and Network Security
- Threats and Vulnerabilities to Information and Computing Infrastructures
- Prevention: Keeping the Hackers and Crackers at Bay
- Detection, Recovery, Management, and Policy Considerations

Although these topics are related, each addresses a specific concern within information security. The chapters in each category are also interrelated and complementary, enabling readers to compare, contrast, and draw conclusions that might not otherwise be possible.

Though the entries have been arranged logically, the light they shed knows no bounds. The handbook provides unmatched coverage of fundamental topics and issues for successful design and implementation of a sound security program. Its chapters can serve as material for a wide spectrum of courses such as:

- Information and Network Security
- Information Privacy
- Social Engineering
- Secure Financial Transactions
- Information Warfare
- Infrastructure for Secure Information Transfer
- Standards and Protocols for Secure Information Transfer
- Network Design and Management
- Client/Server Computing
- E-commerce

Successful design and implementation of a sound security program requires a thorough knowledge of several technologies, theories, and supporting disciplines. Security researchers and practitioners have had to consult many resources to find answers. Some of these resources concentrate on technologies and infrastructures, some on social and legal issues, and some on managerial concerns. This handbook provides all of this information in a comprehensive, three-volume set with a lively format.

Key Concepts and Applications Related to Information Security

Chapters in this group examine a broad range of topics. Theories, concepts, technologies, and applications that expose either a user, manager, or an organization to security and privacy issues and/or create such security and privacy concerns are discussed. Careful attention is given to those concepts and technologies that have widespread applications in business and academic environments. These areas include e-banking, e-communities, e-commerce, e-education, and e-government.

Infrastructure for the Internet, Computer Networks, and Secure Information Transfer

Chapters in this group concentrate on the infrastructure, popular network types, key technologies, and principles

for secure information transfer. Different types of communications media are discussed followed by a review of a variety of networks including LANs, MANs, WANs, mobile, and cellular networks. This group of chapters also discusses important architectures for secure information transfers including TCP/IP, the Internet, peer-to-peer, and client/server computing.

Standards and Protocols for Secure Information Transfer

Chapters in this group discuss major protocols and standards in the security field. This topic includes important protocols for online transactions, e-mail protocols, Internet protocols, IPsec, and standards and protocols for wireless networks emphasizing 802.11.

Information Warfare

This group of chapters examines the growing field of information warfare. Important laws within the United States criminal justice system, as they relate to cybercrime and cyberterrorism, are discussed. Other chapters in this group discuss cybercrime, cyberfraud, cyber stalking, wireless information warfare, electronic attacks and protection, and the fundamentals of information assurance.

Social, Legal, and International Issues

Chapters in this group explore social, legal, and international issues relating to information privacy and computer security. Digital identity, identity theft, censorship, and different types of computer criminals are also explored. The chapters in this group also explain patent, trademark, and copyright issues and offer guidelines for protecting intellectual properties.

Foundations of Information, Computer, and Network Security

These chapters cover four different but complementary areas including encryption, forensic computing, operating systems and the common criteria and the principles for improving the security assurance.

Threats and Vulnerabilities to Information and Computing Infrastructures

The chapters in this group investigate major threats to, and vulnerabilities of, information and computing infrastructures in wired and wireless environments. The chapters specifically discuss intentional, unintentional, controllable, partially controllable, uncontrollable, physical, software and hardware threats and vulnerabilities.

Prevention: Keeping the Hackers and Crackers at Bay

The chapters in this group present several concepts, tools, techniques, and technologies that help to protect information, keep networks secure, and keep the hackers and computer criminals at bay. Some of the topics discussed include physical security measures; measures

for protecting client-side, server-side, database, and medical records; different types of authentication techniques; and preventing security threats to e-commerce and e-mail transactions.

Detection, Recovery, Management, and Policy Considerations

Chapters in this group discuss concepts, tools, and techniques for detection of security breaches, offer techniques and guidelines for recovery, and explain principles for managing a network environment. Some of the topics highlighted in this group include intrusion detection, contingency planning, risk management, auditing, and guidelines for effective security management and policy implementation.

Acknowledgments

Many specialists have helped to make the handbook a resource for experienced and not-so-experienced readers. It is to these contributors that I am especially grateful. This remarkable collection of scholars and practitioners has distilled their knowledge into a fascinating and enlightening one-stop knowledge base in information, computer, and network security that “talks” to readers. This has been a massive effort, as well as a most rewarding experience. So many people have played a role, it is difficult to know where to begin.

I would like to thank the members of the editorial board for participating in the project and for their expert advice on selection of topics, recommendations of authors, and review of the materials. Many thanks to the more than

1,000 reviewers who provided their advice on improving the coverage, accuracy, and comprehensiveness of these materials.

I thank my senior editor, Matt Holt, who initiated the idea of the handbook. Through a dozen drafts and many reviews, the project got off the ground and then was managed flawlessly by Matt and his professional team. Many thanks to Matt and his team for keeping the project focused and maintaining its lively coverage.

Tamara Hummel, editorial coordinator, assisted the contributing authors and me during the initial phases of development. I am grateful for all her support. When it came time for the production phase, the superb Wiley production team took over. Particularly, I want to thank Deborah Schindlar, senior production editor. I am grateful for all her hard work. I thank Michelle Patterson, our marketing manager, for her impressive marketing campaign launched on behalf of the handbook.

Last, but not least, I want to thank my wonderful wife, Nooshin, and my two children, Mohsen and Morvareed, for being so patient during this venture. They provided a pleasant environment that expedited the completion of this project. Mohsen and Morvareed assisted me in sending out thousands of e-mail messages to authors and reviewers. Nooshin was a great help in designing and maintaining the authors’ and reviewers’ databases. Their efforts are greatly appreciated. Also, my two sisters, Azam and Akram, provided moral support throughout my life. To this family, any expression of thanks is insufficient.

Hossein Bidgoli
California State University, Bakersfield

Guide to The Handbook of Information Security

The Handbook of Information Security is a comprehensive coverage of the relatively new and very important field of information, computer, and network security. This reference work consists of three separate volumes and 207 different chapters on various aspects of this field. Each chapter in the handbook provides a comprehensive overview of the selected topic, intended to inform a broad spectrum of readers, ranging from computer and security professionals and academicians to students to the general business community.

This guide is provided to help the reader easily locate information throughout *The Handbook of Information Security*. It explains how the information within it can be located.

Organization

This is organized for maximum ease of use, with the chapters arranged logically in three volumes. While one can read individual volumes (or articles) one will get the most out of the handbook by becoming conversant with all three volumes.

Table of Contents

A complete table of contents of the entire handbook appears in the front of each volume. This list of chapter titles represents topics that have been carefully selected by the editor-in-chief, Dr. Hossein Bidgoli, and his colleagues on the editorial board.

Index

A subject index for each individual volume is located at the end of each volume.

Chapters

The author's name and affiliation are displayed at the beginning of the chapter.

All chapters in the handbook are organized in the same format:

Title and author

Outline

Introduction

Body

Conclusion

Glossary

Cross-References

References

Outline

Each chapter begins with an outline that provides a brief overview of the chapter, as well as highlighting important subtopics. For example, the chapter "Internet Basics" includes sections for Information Superhighway and the World Wide Web, Domain Name Systems, Navigational Tools, Search Engines, and Directories. In addition, second-level and third-level headings will be found within the chapter.

Introduction

Each chapter begins with an introduction that defines the topic under discussion and summarizes the chapter, in order to give the reader a general idea of what is to come.

Body

The body of the chapter fills out and expands upon items covered in the outline.

Conclusion

The conclusion provides a summary of the chapter, highlighting issues and concepts that are important for the reader to remember.

Glossary

The glossary contains terms that are important to an understanding of the chapter and that may be unfamiliar to the reader. Each term is defined in the context of the particular chapter in which it is used. Thus the same term may be defined in two or more chapters with the detail of the definition varying slightly from one chapter to another. The handbook includes approximately 2,700 glossary terms. For example, the chapter "Internet Basics" includes the following glossary entries:

Extranet A secure network that uses the Internet and Web technology to connect two or more intranets of trusted business partners, enabling business-to-business, business-to-consumer, consumer-to-consumer, and consumer-to-business communications.

Intranet A network within the organization that uses Web technologies (TCP/IP, HTTP, FTP, SMTP, HTML, XML, and its variations) for collecting, storing, and disseminating useful information throughout the organization.

Cross-References

All chapters have cross-references to other chapters that contain further information on the same topic. They

appear at the end of the chapter, preceding the references. The cross-references indicate related chapters that can be consulted for further information on the same topic. The handbook contains more than 1,400 cross-references in all. For example, the chapter “Computer Viruses and Worms” has the following cross references:

Hackers, Crackers and Computer Criminals, Hoax Viruses and Virus Alerts, Hostile Java Applets, Spyware, Trojan Horse Programs.

References

The references in this handbook are for the benefit of the reader, to provide references for further research on the given topic. Review articles and research papers that are important to an understanding of the topic are also listed. The references typically consist of a dozen to two dozen entries, and do not include all material consulted by the author in preparing the chapter.

INTRODUCTION

This chapter provides a basic introduction to the Internet and Web technologies. It provides a brief history of the Internet and then explains domain name systems, navigational tools, and search engines. The chapter defines intranets and extranets and compares and contrasts them with the Internet. The chapter concludes with a brief survey of popular applications of the Internet in various industries and fields, including tourism and travel, publishing, higher education, real estate, employment, banking and brokerages, software distribution, healthcare, and politics. Other chapters throughout the *Handbook* discuss in more detail most of the topics presented here.

INFORMATION SUPERHIGHWAY AND THE WORLD WIDE WEB

The backbone of the information superhighway and electronic commerce (e-commerce) is the Internet. The Internet is a collection of millions of computers and networks of all sizes. Simply put, the Internet is the “network of networks.” The information superhighway is also known as the Internet. No one actually owns or runs the Internet. Each network is locally administered and funded, in some cases by volunteers. It is estimated that, in 2005, more than 200 countries are directly or indirectly connected to the Internet. This number is increasing on a daily basis and makes global e-commerce a reality.

The initial phases of the Internet started in 1969 as a Defense Department project called ARPANET (Advanced Research Projects Agency Network). It served from 1969 through 1990 as the basis for early networking research and as a central backbone network during the development of the Internet. Since the Internet began, it has grown rapidly in size.

ARPANET evolved into the NSFNET (National Science Foundation Network) in 1987. NSFNET is considered the initial Internet backbone. The term “Internet” was derived

from the term “internetworking,” which signified the connecting of networks. NSFNET initially connected four supercomputers located in San Diego, California; Cornell University in Ithaca, New York; Pittsburgh, Pennsylvania; and Illinois to form the backbone. Other universities and government laboratories were subsequently added to the network. These backbones linked all existing networks in a three-level structure:

backbones;
regional networks; and
local area networks (LANs).

Backbones provide connectivity to other international backbones. The NAPs (network access points) are a key component of the Internet backbones. An NAP is a public network exchange facility where Internet service providers (ISPs) can connect with one another. The connections within NAPs determine how traffic is routed over the Internet and also are the focus of Internet congestion. LANs provide the standard user interface for computers to access the Internet. Phone lines (twisted pair), coaxial cables, microwaves, satellites, and other communications media are used to connect LANs to regional networks. TCP/IP (transmission control protocol/Internet protocol) is the common language of the Internet that allows the network systems to understand each other. TCP/IP divides network traffic into individually addressed packets that are routed along different paths. Protocols are conventions and rules that govern a data communications system. They cover error detection, message length, and transmission speed. Protocols provide compatibility among different manufacturers’ devices.

The National Science Foundation (NSF) and state governments have subsidized regional networks. NSFNET’s acceptable use policy initially restricted the Internet to research and educational institutions; commercial use was not allowed. Because of increasing demand,

additional backbones were eventually allowed to connect to NSFNET and commercial applications began.

The World Wide Web (WWW or the Web) changed the Internet by introducing a true graphical environment. It has been around since 1989, when it was proposed by Tim Berners-Lee at CERN. The WWW is an Internet service that organizes information using hypermedia. Each document can include embedded references to audio, text, images, full-motion video, or other documents. The WWW constitutes a large portion of the Internet that contains hypermedia documents. Hypermedia is an extension of hypertext. Hypertext allows a user to follow a desired path by clicking on highlighted text to follow a particular “thread” or topic. This involves accessing files, applications, and computers in a nonsequential fashion. It allows for combinations of text, images, sounds, and full-motion video in the same document. It allows information retrieval with the click of a button. Hypertext is an approach to data management in which data are stored in a network of nodes connected by links. The nodes are designed to be accessed through an interactive browsing system. A hypertext document includes document links and supporting indexes for a particular topic. A hypertext document may include data, audio, and images. This type of document is called hypermedia. In hypertext documents, the physical and logical layouts are usually different. This is not the case in a paper document. In a paper document, the author of the paper establishes the order and readers follow this predetermined path.

A hypertext system provides users with nonsequential paths to access information. This means that information does not have to be accessed sequentially, as in a book. A hypertext system allows the user to make any request that the author or designer of the hypertext provides through links. These link choices are similar to lists of indexes and allow the reader to choose a “custom path.”

Any computer that stores hypermedia documents and makes them available to other computers on the Internet is called a server or a Web server. The computers that request these documents are called clients. A client can be a personal computer at home or a node in a LAN at a university or an organization. The most exciting feature of the Internet and the WWW is that these hypermedia documents can be stored anywhere in the world. A user can easily jump from a site in the United States to a site in Paris, France, all in a few milliseconds.

DOMAIN NAME SYSTEMS

Before a user can begin to navigate the Internet and use it for personal use or e-commerce applications, an understanding of domain name systems (DNS) (also called domain name servers) is essential. Domain names are unique identifiers of computer or network addresses on the Internet. The following are examples of domain names:

Netscape.com
 Microsoft.com
 UN.org
 Whitehouse.gov

Table 1 Organizational Domains (Generic Top-Level Domains, gTLD)

.com	Commercial organizations (e.g., Microsoft)
.edu	Education and academic organizations (e.g., California State University)
.int	International organizations (e.g., United Nations)
.mil	U.S. military organizations (e.g., U.S. Army)
.gov	U.S. government organizations (e.g., Internal Revenue Service)
.net	Backbone, regional, and commercial networks (e.g., the National Science Foundation's Internet Network Information Center)
.org	Other organizations such as research and nonprofit organizations (e.g., the Internet Town Hall)

They come in two forms: English-like names and numeric or IP (Internet protocol) addresses.

The Internet Corporation for Assigned Names and Numbers (ICANN) is the nonprofit corporation that assigns and keeps track of these addresses. This was previously performed under U.S. government contract by IANA (Internet Assigned Numbers Authority) and other entities.

IP addresses are less convenient because numbers are more difficult to remember. The English-like names are electronically converted to IP addresses for routing (transferring information from one network to another network). Domain names are used in URLs (uniform resource locator or universal resource locator) to identify a particular Web page. A URL is basically the address of a file or a site on the Internet. For example, in the URL <http://www.csub.edu/~hbidgoli>, the domain name is [csb.edu](http://www.csub.edu). Every domain name has a suffix that indicates to which top-level domain (TLD) it belongs. In this example the suffix is [edu](http://www.csub.edu), which stands for educational institutions. Combinations of the letters of the alphabet as well as the numerals 0 through 9 can be used in domain names. The hyphen is the only other character utilized; spaces are not allowed.

The TLD is the data that comes after “www.” It denotes the type of organization or country the address specifies. TLDs are divided into organizational (generic) and geographic (country code) domains. (See Tables 1 through 3.)

This system makes it easy to identify the type or location of the organization by looking at the last section of the domain name. Organization, which is the second field from the right, refers to the name of the organization. A name for a small company is as easy as a company name. The two leftmost fields of the domain name refer to the computer. This is relevant for large organizations with several levels of subdomains. An example of a relatively complete Internet address is the address of a document in the Virtual Tourist Web site: <http://www.vtourist.com/vt/usa.htm>. A brief explanation from left to right follows:

http—Means of access, hypertext transfer protocol. This is how the majority of Web documents are transferred.

Table 2 Examples of Proposed New Domain Names

.aero	For the aviation industry
.arts	For entities emphasizing cultural and entertainment activities
.biz	For businesses
.coop	For cooperative or cooperative service organizations
.firm	For businesses or firms
.inc	Corporations
.info	For entities providing information services
.law	For those in the legal profession
.museum	For a museum or professionally affiliated personnel
.name	For a noncommercial site associated with a private individual
.nom	For individuals or family names
.pro	For a site associated with a certified professional or professional organization
.news	For news-related sites
.rec	For entities emphasizing recreation and entertainment activities
.shop	For businesses offering goods and commodities
.store	For electronic storefronts
.web	For entities emphasizing activities related to the WWW
.xxx	For adult content

www.vtourist.com—This is the address of the Web site. It is uniquely defined and differentiated from all other Web sites. WWW is an Internet service that organizes information using hypermedia.

vt—This is a path or directory. A server may be divided into a series of directories for better organization.

usa.htm—This is the document itself. The htm extension indicates that this is an HTML (hypertext markup lan-

guage) document. It is the authoring language used to create documents on the Web. HTML defines the structure and layout of a Web document by using a variety of tags and attributes. Most hypermedia documents are written in HTML format. Servers that do not support long extensions display “htm,” whereas other servers display “html.”

NAVIGATIONAL TOOLS, SEARCH ENGINES, AND DIRECTORIES

Navigational tools allow the user to surf the Internet and search engines provide access to various resources available on the Internet, such as those that provide library searches for writing a term paper or reservations for an airline ticket. Directories use indexes of information based on key words in the document. As will be discussed elsewhere in this chapter, Yahoo! is a popular directory on the Internet.

The original command language of the Internet was based on computer commands and was difficult to learn for most users. Character-based languages were used for tasks such as downloading files or sending e-mails. These languages are UNIX based, which meant the user was required to know the specific syntax of many commands. Everything was communicated in plain text, and graphics, sound, and animation data were not available. The introduction of graphical browsers such as Netscape Navigator changed all of this. Microsoft Internet Explorer and Netscape Navigator are the best-known graphical browsers available for navigating the Internet. Each of these browsers combine powerful graphics, audio, and video capabilities. Each Web server has a “homepage” or a Web site that publishes information about the location. Using character-based browsers such as Lynx, a user will find this information in text form, whereas graphical browsers such as Microsoft Internet Explorer support images and sound clips as well.

Navigational Tools

Microsoft Internet Explorer is the most popular graphical browser in the Internet world. With strong marketing support from Microsoft and improvement in its features, Internet Explorer (IE) has gained the lead in the browser market. Netscape Navigator is another graphical browser available for all major operating system platforms. Netscape, similar to IE, provides a true graphical environment that allows the user to surf the Internet using a mouse and the point-and-click technique. Similar to other Windows applications, both IE and Netscape Navigator feature a standard menu bar and toolbar buttons for frequently used commands.

Directories and Search Engines

There are several search engines and directories in use. Yahoo! is the most popular directory and Google, Excite, and Infoseek are three of the most popular search engines. These programs allow a user to scan the Internet and find information through the use of key words or phrases. A search could be for research for a term paper, finding an

exotic antique for a personal collection, or anything in between. The following paragraphs briefly describe Yahoo!, Google, and Excite (Bidgoli, 2002).

Jerry Yang and Dave Filo founded Yahoo! in April 1994. Yahoo! is one of the best-known directories on the Internet. A directory is a search service that classifies Web sites into a hierarchical, subject-based structure. For example, Yahoo! includes categories such as art, business, and entertainment. These categories are organized by topic. The user can go to a category and then navigate for specific information. Yahoo! also includes an internal search engine that can expedite the search process. Yahoo! soon expanded to offer other services and became a portal on the Internet. A portal or gateway for the WWW is an application that serves as an information search organizer. Portals provide a single-point integration and navigation through the system. Portals create an information community that can be customized for an individual or a corporation. Portals serve as the major starting sites for many individuals who are connecting to the Internet. Some of the services offered by Yahoo! include Yahoo! Travel, Yahoo! Classifieds, Yahoo! Pager, and Yahoo! Autos.

Excite, Inc. was founded in June 1994. Its basic mission is to provide a gateway to the Internet and to organize, aggregate, and deliver information to meet users' needs. The Excite Network, including the Excite and Web-Crawler brands, contain a suite of specialized information services that combine proprietary search technology, editorial Web reviews, aggregated content from third parties, and bulletin boards. The Excite Network serves as a central place for consumers to gather and interact during each Web experience. Excite PAL is an instant paging service. By entering the names and e-mail addresses of friends, family, and colleagues into Excite PAL, a user can find them online.

Larry Page and Sergey Brin, two Stanford Ph.D. candidates, founded Google in 1998. Google helps its users find the information they are looking for with high levels of ease, accuracy, and relevancy. The company delivers its services to individuals and corporations through its own public site, <http://www.google.com>, and through cobranding its Web search services. To reach the Google Web site, the user simply types www.google.com (its URL) into the location box of the Web browser and presses the Enter key. At the initial Google screen, the user enters the desired search item(s), for example "computer viruses," and then again presses the Enter key or clicks on the "Google Search" button. In a few seconds, the items that closely match the search items will be displayed. Although the Web site's default language is English, the user can choose a different language by clicking the down arrow to the right.

INTERNET SERVICES THAT SUPPORT ELECTRONIC COMMERCE

Electronic mail (e-mail), news and discussion groups, Internet Relay Chat (IRC), instant messaging, and the Internet phone are among the services offered by the Internet that could enhance a successful e-commerce program. Other chapters in the *Handbook* will provide a more in-

depth discussion of these services. In this chapter a brief overview of these services is presented (Bidgoli, 2002).

E-mail is one of the most popular services available on the Internet. Using e-mail, a user can create a message electronically and send it via the communications media. New products and services can be announced to customers using e-mail. Confirmations can be sent using e-mail and also many business communications can be effectively performed using e-mail. When a user sends an e-mail, the message usually stays in the recipient's e-mail server until the recipient reads it. In most e-mail systems, the receiver is able to store the e-mail message in an electronic folder for future reference. E-mail is fast and will get to the recipient's computer in a matter of seconds or minutes. All that is needed to send an e-mail message is the e-mail address of a recipient. A user can also send a single e-mail message to a group of people at the same time. A user can apply all the word processing tasks such as spell-checking and grammar correction before sending the e-mail message. Document files and/or multimedia files can be attached to an e-mail message and a user could ask for delivery notification. With e-mail, a user can usually establish various folders with different contents and send a particular e-mail to a specific group. Using e-mail enables a user to establish an effective message-distribution system for advertising products and services. (For detailed information on this topic, consult the chapter on E-Mail and Instant Messaging.)

The Internet brings together people with diverse backgrounds and interests. Discussion groups to share opinions and ideas facilitate this. Each person in a discussion group can post messages or articles that can be accessed and read by others in the group. Newsgroups can be established for any topic or hobby and allow people to get together for fun and entertainment or for business purposes. For example, a user may join a newsgroup interested in ancient civilization, or a user may join a newsgroup that can help in writing and debugging a computer program in a specific programming language. Newsgroups can serve as an effective advertising medium in an e-commerce environment.) For detailed information on this topic, consult the chapter on Online Communities.)

Internet Relay Chat (IRC) enables a user to interactively communicate in written form with other users from all around the world. It is similar to a coffee shop where people sit around a table and start chatting. The three major differences between this electronic coffee shop and a real coffee shop are that there is no coffee, the user does not see the people that he/she is chatting with, and IRC leaves a "chat trail," which can be used later. However, a user is able to participate in many different discussions with people anywhere in the world who have the same interest. (For detailed information on this topic, consult the chapter on Internet Relay Chat.)

Instant messenger (IM) is a communication service that enables a user to create a private chat room with another user. Different instant messengers offer different capabilities. They typically alert a user whenever someone on the user's private list is online so that a user may initiate a chat session with that particular individual. (For detailed information on this topic consult the chapter on E-Mail and Instant Messaging.)

Internet telephony is the use of the Internet rather than the traditional telephone-company infrastructure to exchange spoken or other audible information. Because access to the Internet is available at local phone connection rates, an international or other long-distance call will be much less expensive than through the traditional calling arrangement. This could be a major cost savings for an e-commerce site that offers hotline, help desk, and other services. (For detailed information on this topic, consult the chapter on Voice over Internet Protocol [VoIP].)

Three new services are now or will soon be available on the Internet:

1. The ability to make a normal voice phone call (despite whether the person called is immediately available; that is, the phone will ring at the location of the person called). In most of the technologies currently available, a “phone meeting” must be arranged in advance, and then both parties log onto the Internet at the same time to conduct the conversation.
2. The ability to send fax transmissions at very low cost (at local call prices) through a gateway point on the Internet in major cities.
3. The ability to leave voice mail at a called number.

WHAT IS AN INTRANET?

The excitement created by the Internet has been transferred to another growing application called intranets. In simple terms, whatever a user can do with the Internet, a user should also be able to do with an organization’s private network, or intranet.

An intranet provides users with easy-to-use access that can operate on any computer regardless of the operating system in use. Intranet technology helps companies disseminate information faster and more easily to both vendors and customers and can be of benefit to the internal operations of the organization. Although intranets are fairly new, they have attracted a lot of attention in a very short time (Bidgoli, 1999, 2002).

The intranet uses Internet and Web technologies to solve organizational problems traditionally solved by proprietary databases, groupware, and scheduling and workflow applications. An intranet is different from a LAN or wide area network (WAN), although it uses the same physical connections. An intranet is an application or service (or set of applications or services) that uses the computer networks (the LANs and WANs) of an organization, and that is how it is different from LANs and WANs. The intranet is only logically internal to the organization. Intranets can physically span the globe, as long as access is specifically defined and limited to the specific organization’s community of users behind a firewall or a series of firewalls.

In a typical intranet configuration, all users in the organization can access all the Web servers. The system administrator must define the degree of access for each user. They can constantly communicate with one another and post information on their departmental Web servers. However, usually a firewall (or several firewalls) separates these internal networks from the Internet (the worldwide network).

Within these departmental Web servers, individual employees can have their own Web pages, divided by department. For example, the following departments each may include several Web pages as parts of the organization’s intranet program:

finance,
human resources,
information services,
manufacturing,
marketing, and
sales.

So what is an intranet? In simple terms, an intranet is a network within the organization that uses Web technologies (TCP/IP, HTTP, FTP [file transfer protocol], SMTP [simple mail transfer protocol], HTML, and XML [extensible markup language]) for collecting, storing, and disseminating useful information throughout the organization. This information supports e-commerce activities such as sales, customer service, and marketing.

Employees can find internal information and they can bookmark important sites within the intranet. Furthermore, individual departments can create their own Web sites to educate or inform other employees about their departments by implementing intranet technology. For example, marketing can present the latest product information, and manufacturing can post shipping schedules and new product designs. The human resources department can post new jobs, benefit information, new promotions, and 401K plan information. The finance and accounting departments can post cost information and other financial reports on their sites. The president’s office might post information about the next company picnic on its site. This information collectively supports a successful e-commerce program. (For detailed information on this topic, consult the chapter on Intranets: Principals, Privacy and Security Considerations.)

INTERNET VERSUS INTRANETS

The Internet is a public network. Any user can access the Internet, assuming the user has an account with an ISP. The Internet is a worldwide network, whereas intranets are private and are not necessarily connected to the Web. Intranets are connected to a specific company’s network, and usually the users are the company’s employees. An intranet is separated from the Internet through the installation and use of a firewall (or several firewalls). Intranets usually have higher throughput and performance than the Internet and are usually more secure than the Internet.

Apart from these differences, the two have a lot in common. They both use the same network technology, TCP/IP, and they both use browsers for accessing information. They both use documents in HTML and XML formats, and both are capable of carrying documents with multimedia formats. Also, they both may use the Java programming (or its derivatives) language for developing applications.

Table 4 Internet versus Intranet

Key Feature	Internet	Intranet
User	Anybody	Employees only
Geographical scope	Unlimited	Limited to unlimited
Speed	Lower than that of an intranet	Usually higher than that of the Internet
Security	Lower than that of an intranet	Usually higher than that of the Internet
Technology used	TCP/IP	TCP/IP
Document format	HTML	HTML
Multimedia capability	Could be lower than that of an intranet	Could be higher than that of the Internet

Intranets may or may not use any of the technologies beyond HTML, that is, Java programming, JavaScript or VBScript, Active X, Dynamic HTML, or XML. One of the advantages of an intranet is that because the organization can control the browser used, it can specify a browser that will support the technologies in use. Beyond Web documents, the organization can also specify the use of the Internet phone, e-mail, video conferencing, and other Web technologies supported by the chosen browser. Table 4 summarizes the similarities and differences of these two technologies.

SELECTED APPLICATIONS OF AN INTRANET

A properly designed intranet can make the type of information listed in Table 5 available to the entire organization in a timely manner. This information directly or indirectly can improve the efficiency and effectiveness of an organization (Bidgoli, 1999, 2002).

Many internal applications in use today can be easily converted to an intranet or can be supported using an intranet. Human resources applications, such as job information, name and phone number lists, and medical benefits, can be displayed on a human resources Web site. The finance Web site might present information on time cards, expense reports, or credit authorization. Employees can easily access the latest information on a server. With e-mail, e-mail distribution lists, and chat lines, employees can retrieve meeting minutes and much more.

The intranet also allows organizations to evolve from a "calendar-" or "schedule"-based publishing strategy to an "event-driven" or "needs-based" publishing strategy. In the past, companies published an employee handbook once a year. Traditionally, the handbooks would not be updated until the following year even though they may have been outdated as soon as they arrived on the users' desks. Some of these organizations sent a few loose pages as an update every so often. The employee is supposed to add these additional pages to the binder. After a while, these materials become difficult to go through to retrieve specific information.

With an intranet publishing strategy, information can be updated instantly. If the organization adds a new

Table 5 Possible Information Provided by an Intranet

--

mutual fund to the 401K programs, content on the benefits page can be updated immediately to reflect that change, and the company internal homepage can include a brief announcement about the change. Then, the employees have the new information at their desktops as soon as they look up the 401K programs.

Intranets dramatically reduce the costs and time of content development, duplication, distribution, and utilization. The traditional publication model includes a multistep process including:

- creation of content,
- production of the draft,
- revision of the draft,
- final draft preparation,
- migration of the content to the desktop publishing environment,
- duplication, and
- distribution.

However, intranet technology reduces the number of steps to only two (it eliminates the duplication and distribution steps):

- creation of content and
- migration of content to the intranet environment.

However, content still needs review and approval regardless of the medium used for delivery.

WHAT IS AN EXTRANET?

Interorganizational systems (IOSs) facilitate information exchange among business partners. Some of these systems, such as electronic funds transfer (EFT) and e-mail, have been used in traditional businesses as well as in the e-commerce environment. Among the most popular IOSs are electronic data interchange (EDI) and extranets. Both EDI and extranets provide a secure connection among business partners. Their roles in business-to-business e-commerce are on the rise. These systems create a seamless environment that expedites the transfer of information in a timely matter.

Some organizations allow customers and business partners to access their intranets for specific business purposes. For example, a supplier may want to check the inventory status or a customer may want to check account balances. These networks are referred to as extranets. It should be noted that an organization usually makes only a portion of its intranet accessible to these external parties. Also, comprehensive security measures must ensure

that access is given only to authorized users and trusted business partners. (For detailed information on this topic, consult the chapter on Extranets: Applications, Development, Security and Privacy.)

An extranet is defined as a secure network that uses Internet and Web technology to connect two or more intranets of business partners, enabling business-to-business, business-to-consumer, consumer-to-consumer, and consumer-to-business communications. Extranets are a network service that allows trusted business partners to secure access to useful information on another organization's intranet. Table 6 provides a comparison of the Internet, intranets, and extranets (Bidgoli, 2002; Fletcher, 1997).

There are numerous applications of extranets in the e-commerce world. Toshiba America Inc. is an example of a company that uses an extranet. Toshiba has designed an extranet for timely order-entry processing. Using this extranet, more than 300 dealers can place orders for parts until 5 p.m. for next-day delivery. Dealers can also check accounts receivable balances and pricing arrangements, read press releases, and much more. This secure system has resulted in significant cost savings and has improved customer service (Jones, 1998).

Another example of an extranet is the Federal Express Tracking System (<http://www.fedex.com>). Federal Express uses its extranet to collect information and make it available to its customers over the Internet. The FedEx Web site is one of the earliest and best-known examples of an extranet—an intranet that is opened to external users. The customer can access FedEx's public site, enter a package's tracking number, and locate any package still in the system. Using this system, a customer can enter all the information needed to prepare a shipping form, obtain a tracking number, print the form, and schedule a pickup.

Extranets provide very secure, temporary connections over public and private networks between an organization and a diverse group of business partners outside of the organization. These groups may include:

- customers,
- vendors,
- suppliers,
- Consultants,
- distributors,
- resellers, and
- outsourcers, such as claim processors, or those with whom the company is doing research and development (R&D) or other collaborative work, such as product design.

Table 6 Comparison of the Internet, Intranets, and Extranets

	Internet	Intranet	Extranet
Access	Public	Private	Private
Information	Fragmented	Proprietary	Proprietary
Users	Everybody	Members of an organization	Groups of closely related companies, users, or organizations

Extranets not only allow companies to reduce internet-working costs, they also provide companies with a competitive advantage, which may lead to increased profit. A successful extranet program requires a comprehensive security system and management control. The security system should provide comprehensive access control, user-based authentication, encryption capability, and comprehensive auditing and reporting capabilities.

An extranet offers an organization the same benefits that an intranet offers while also delivering the benefits that derive from being linked to the outside world. Some of the specific advantages of an extranet include (Bidgoli, 2002):

Coordination—An extranet allows for improved coordination among participating partners. This usually includes suppliers, distributors, and customers. Critical information from one partner can be made available so that another partner can make a decision without delay. For example, it is possible for a manufacturer to coordinate its production by checking the inventory status of a customer.

Feedback—An extranet enables an organization to receive instant feedback from its customers and other business partners. It gives consumers an opportunity to express their views about products or services before those products or services are even introduced to the market.

Customer satisfaction—An extranet links the customer to an organization. This provides the customer with more information about products, services, and the organization in general. This also makes ordering products or services as easy as a click of the mouse. Expediting business-to-business e-commerce is definitely one of the greatest benefits of an extranet.

Cost reduction—An extranet can reduce the inventory costs by providing timely information to the participants of a supply network program. Mobil Corporation, based in Fairfax, Virginia, designed an extranet application that allows distributors throughout the world to submit purchase orders. By doing this, the company significantly increases the efficiency of the operation. It also expedites the delivery of goods and services (Maloff, 1997).

Expedite communication—Extranets increase the efficiency and effectiveness of communication among business partners by linking intranets for immediate access to critical information. A traveling salesperson can receive the latest product information remotely before going to a sales meeting. A car dealer can provide the latest information to a customer on a new model without making several phone calls and going through different brochures and sales manuals.

SELECTED INTERNET APPLICATIONS

Several segments of service industries have significantly benefited from the Internet and its supporting technologies. The Internet has enabled these businesses to offer their services and products to a broad range of customers with more competitive prices and convenience.

Table 7 Popular Internet Applications

Marketing and advertising
Distance learning
Electronic conferencing
Electronic mail (e-mail)
Electronic posting
Healthcare management
Home shopping
Interactive games
Inventory management
News groups and discussions
News on demand
Online banking
Online employment
Online software distribution
Online training
Online politics (voting, participating in political forums, chat groups, and using the Internet for political fund raising)
Remote login
Sale of products and services
Telecommuting
Transferring files with FTP
Video on demand
Videophones
Online demonstrations of products and services throughout the world
Virtual reality games
Online request for proposal (RFP), request for quotes (RFQ), and request for information (RFI)

The Internet offers numerous tools and advantages to these businesses to sell their products and services all over the world. Table 7 lists popular Internet applications.

In the following pages, some of the major beneficiaries of the Internet and e-commerce will be reviewed.

Tourism and Travel

Tourism and travel industries have significantly benefited from various Internet and e-commerce applications. As an example, the Tropical Island Vacation (<http://www.tropicalislandvacation.com>) homepage directs prospective vacationers to an appropriate online brochure after vacationers respond to a few brief questions about the type of vacation they would like to take. Customers simply point and click on appealing photographs or phrases to explore further. Another example is Zeus Tours (<http://zeustours.com>), which has been very effective at offering unique and exciting tours, cruises, and other travel packages online. Many Web sites allow customers to reserve tickets for planes, trains, buses, cruises, hotels, and resorts. Sites such as biztravel.com (<http://biztravel.com>) allow its business customers to plan a trip, book a vacation, gather information on many cities, gather weather information, and much more. Expedia.com, Travel.com, Travelocity.com, Priceline.com, hotels.com and Yahoo! Travel are other examples of sites that offer all types of travel and tourism services.

Publishing

Many major textbook publishers in the United States and Europe have homepages. An interested individual can read the major features of forthcoming books or books in print before ordering them. The Web sites of some publishers include a sample chapter from specific books, or entire books that can be read online for free for 90 days, whereas others allow online customers to purchase portions of a book rather than the entire book. The Web site of John Wiley & Sons (<http://wiley.com>), publisher of *The Handbook of Information Security*, allows a prospective buyer to search the online catalog based on the author's name, the title of the book, and so forth. When the desired book is found, it can be ordered online.

Higher Education

Major universities also have homepages. An interested individual can go on a tour of a university and read about different departments, programs, faculty, and academic resources. Many universities throughout the world are creating virtual divisions that offer entire degree programs on the Internet. Many professional certificate programs are also offered through the Internet. These programs and courses provide a real opportunity and convenience for individuals in remote areas and individuals who cannot attend regular classes to enroll in these courses. They also provide a source of revenue for many colleges and universities that are facing enrollment decline in their service areas. They also allow renowned experts to teach courses to broad geographic audiences. (For detailed information on this topic, consult the chapters on E-Education and Information Privacy and Security and Security in E-Learning.)

Real Estate

Numerous real estate Web sites provide millions of up-to-date listings of existing and new homes for sale throughout the world. These sites are devoted entirely to buying and selling real estate. The buyer or seller can review neighborhoods, schools, and local real estate prices. These sites allow the customer to find a realtor, find brokerage firms, and learn many home-buying tips. Some of these sites offer or will soon offer "virtual tours." These virtual tours enable a buyer to view a prospective property from distance. This is achieved by using virtual reality technologies. Some of the services offered by a typical real estate site are listed below:

- appraisal services,
- buying,
- checking neighborhood profiles,
- checking schools profiles,
- financing,
- home improvement advice,
- obtaining credit reports,
- posting a free listing,
- renting services,
- selling advice, and much more.

Table 8 lists examples of major real estate sites.

Table 8 Examples of Online Real Estate Sites

<p>Prudential California (http://www.prudential.com) provides wireless listing services and property data for agents.</p> <p>ERA (http://www.era.com) is an Internet-based application with listing information for agents.</p> <p>Century 21 (http://www.century21.com) is an electronic system for tracking agent referrals worldwide and also offers home buying, home selling, financing, and property listings.</p> <p>Re/Max (http://www.remax.com) is a contact management tool for agents that interfaces with personal digital assistant (PDA) devices.</p> <p>Homestore.com (http://www.homestore.com) provides a listing of more than 1 million properties throughout the United States.</p> <p>Mortgage Expo.com (http://www.mortgageexpo.com) provides a listing of more than 800 home lenders throughout the United States.</p>

Employment

Employment service providers have established Web presences. Table 9 provides a listing of some of the popular sites to use for finding or recruiting for a job, especially if it involves information technology.

Banking and Brokerage Firms

Online banking is here. Many U.S. and Canadian banks and credit unions offer online banking services. Although online banking has not been fully accepted by customers, many banking-related resources are being utilized. For example, many banks use e-mail to communicate with their corporate customers. E-mail is a less expensive and more convenient alternative to a telephone call, especially for long distance communications. Financial reports for banks can be easily distributed via e-mail to mutual fund investors or customers.

The banking industry's ultimate goal is to carry out many of their transactions through the Internet. Consumer acceptance is the major factor that has kept this business from exploding. It is generally believed that a secure nationwide electronic banking system is almost in place. Soon people will be able to use their personal computers (PCs) and the Internet to do all types of banking activities.

As is discussed in another chapter in the *Handbook*, digital signatures are a key technology for the banking

Table 9 Some of the Popular Sites to Use for Finding or Recruiting for a Job

Table 10 Some of the Services Available via the Internet for Banking Activities

24/7 customer service by e-mail
Accessing current and old transactions
Categorizing transactions and producing reports
Exporting banking data to popular money management software
Obtaining online funding for checking accounts
Obtaining online mortgage and certificate of deposit applications
Obtaining written guarantee against frauds and late payments
Obtaining instant approval for personal loans
Obtaining interactive guides to aid selection of a proper banking product or service
Obtaining interactive tools for designing a savings plan, choosing a mortgage, and/or obtaining online insurance quotes all tied to applications
Obtaining online application for both checking and savings accounts
Obtaining online forms for ordering checks and issuing a stop payment
Obtaining free checks and free foreign ATM use
Obtaining IRA and brokerage account information
Obtaining loan status and credit card account information online
Paying bills
Paying credit card accounts
Transferring funds
Viewing digital copies of checks

and brokerage industry because they provide an electronic means of guaranteeing the authenticity of the sending party and assurance that encrypted documents have not been changed during transmission. The current mergers and acquisitions taking place and the frequent downsizing within the financial industry are two reasons to support Internet banking. Table 10 lists some of the services available via the Internet for banking activities. (For detailed information on this topic, consult the chapter on Online Retail Banking: Security Concerns, Breaches, and Controls.)

Many brokerage firms offer stock and other security transactions online. They provide quotations for stocks, bonds, and other securities. To encourage more customers to use these services, they may offer discounts.

Software Distribution

Several major software vendors offer software on the Internet. Customers can view listings of available software, order, and designate an installation time. Nearly all hardware manufacturers offer drivers and patches as updates on the Web. Microsoft and several other software companies already offer free software via the Internet. Routine downloading of the Netscape Navigator and Microsoft Internet Explorer browser applications are

two good examples. Both are relatively small programs. In contrast is the Microsoft Office Suite, which would take significantly longer to download through an online application service provider. Given today's communications throughput and bandwidth limitations, program size definitely poses a challenge to online software distribution.

A successful application in this area is the distribution of antivirus programs over the Internet. Several of the vendors of this software application are already using the Internet to sell their software to prospective buyers. A major advantage of this method is the frequency of automatic updates that vendors provide for their customers. The Internet makes this process a cost-effective venture for both the vendors and the customers.

The development of online copyright-protection schemes continues to be a challenging problem. If users need an encryption code to "unlock" software, backups may not be possible. However, the odds are in favor of online software distribution because it provides an inexpensive, convenient, and speedy method of purchase and implementation (Cross, 1994; Hayes, 1995).

Healthcare

Electronic patient records on the Internet could provide complete medical information and allow physicians to order laboratory tests, admit patients to hospitals, refer patients to other physicians or specialists, and order prescriptions. Test and consultation results would be directed automatically to electronic patient records. The advantages of this approach include the fact that all patient information would be accessible from one central location. Another positive side of this application is that it would allow easy access to critical health information. Imagine a person who is far away from home and has a serious health problem because of injury or other causes. Any physician in any location will be able to download the complete medical history of this patient and prescribe a suitable treatment in a short period. However, these systems may offer disadvantages, such as potential problems with information privacy, accuracy, and currency.

Telemedicine (<http://telemetoday.com>) may provide the medical profession with the ability to conduct remote consultation, diagnosis, and conferencing. This could result in major annual savings in travel costs and overhead for medical care professionals. As part of the information superhighway, a personal health information system (PHIS) could conceivably provide interactive medical tools to the public. Public kiosks located in shopping malls would be equipped with user-friendly computer equipment for Internet access. Patients would be prompted through the diagnosis procedure by a series of questions. Premature onset of disease could be minimized with this aggressive and proactive approach (Anonymous, 1994).

Virtual medicine on the Internet may allow specialists at major hospitals to operate on patients remotely. Telepresence surgery, as this is called, would allow surgeons to operate all over the world without physically traveling anywhere. A robot would perform the surgery based on the digitized information sent by the specialist via the Internet. Robots would have stereoscopic cameras

to create three-dimensional images for the surgeon's virtual reality goggles. Physicians would operate in a virtual operating room. Tactile sensors on the robot would provide position information to the surgeon so that he/she can feel what the robot feels. Already, prescription drugs are sold online and there are several Web sites that offer medical services (Bazzolo, 2000). (For detailed information on this topic, consult the chapter on Security of Medical Records.)

Politics

In the United States in recent years, the Internet has become a major promotional tool for all major political contenders in races for the White House, the House of Representatives and Senate, and other races. Political candidates use the Internet to announce the platforms that they are running on, their major differences with their opponents, their leadership styles, forthcoming debates, political events, and so forth. They even use the Internet for fund-raising.

The Internet may facilitate empowering voters and revitalizing democracy. Twenty-first century citizens may vote using a computer connected to the Internet, resulting in increased participation. Part-time legislators may have remote access to Washington and they may be able to remain geographically close to their constituents. Of course, an identification system would have to be in place, which could very likely use voice identification, face scan, finger image, or some other biometric verification technology. If such a system becomes available, then the security of the voting application, security of voting results, and counting accuracy must be carefully analyzed. Currently, the U.S. House of Representatives is attempting to put all pending legislation online. Presidential documents can be found on the Internet. Full-text versions of speeches, proclamations, executive orders, press briefings, daily schedules, the proposed federal budget, health-care reform documents, and the Economic Report of the President are available. There are a number of repositories of this information that can be found using search engines. (For detailed information on this topic, consult the chapters on Legal, Social, and Ethical Issues of the Internet and Secure Electronic Voting Protocols.)

GLOSSARY

ARPANET (Advanced Research Projects Agency Network) Started in 1969 and continued through 1990 as the basis for early networking research and as a central backbone network during development of the Internet.

Directories An index of information based on key words in a document. Yahoo! is a popular directory on the Internet.

Domain Name Systems (or Domain Name Servers, DNS) Unique identifiers of computer or network addresses on the Internet. Whitehouse.gov and csu.edu are two examples. The first one uniquely identifies the White House and the second identifies California State University in Bakersfield.

Extranet A secure network that uses the Internet and Web technology to connect two or more intranets of trusted business partners, enabling business-to-business, business-to-consumer, consumer-to-consumer, and consumer-to-business communications.

Hypermedia This allows links for combinations of text, images, sounds, and full-motion video in the same document. It allows information retrieval with a click of a button.

Hypertext This provides users with nonsequential paths to access information whereby information does not have to be accessed sequentially, as in a book.

Internet A collection of millions of computers and networks of all sizes. Simply put, the Internet is the "network of networks."

Intranet A network within the organization that uses Web technologies (TCP/IP, HTTP, FTP, SMTP, HTML, XML, and its variations) for collecting, storing, and disseminating useful information throughout the organization.

Navigational Tools These allow the user to surf the Internet; Microsoft Internet Explorer and Netscape Navigator are two prime examples.

Search Engines These provide access to various resources available on the Internet, such as library searches for writing a term paper or resources for making a reservation for an airline ticket. Google.com is an example.

URL (Uniform/Universal Resource Locator) The address of a file or a site on the Internet used to identify a particular Web page.

INTRODUCTION

“IT and the Internet amplify brain power in the same way that the technologies of the industrial revolution amplified muscle power.”

—Bradford DeLong, Professor of Economics, University of California, Berkeley, quoted in Woodall (2000)

The purpose of this chapter is to explain what the “digital economy” is and how it fits into broader economic trends that are shaping the economies of the United States and other countries. Essentially, the term “digital economy” can refer to the use of digital information technology in various forms of economic activity and its effects on economic activity. As such, the term includes more specific activities, such as e-commerce and e-business, and is closely related to terms such as knowledge economy and information economy.

All groups in the economy are affected by the pervasive use of information technology: this includes consumers, business firms, and governments. Activities that are not directly commercial, such as personal communications, are also affected. The fundamental driving force is the falling costs of processing, storing, and transmitting data or information that has been put in digital electronic form as a result of innovations in these areas. These declines in costs have made further innovations possible that permit easy and widespread communications via extensive networks, the existence of large and rich databases of information and knowledge that are freely or easily accessible, and the ability to conduct most or all stages of economic transactions over long distances, without relying on alternative methods of information exchange. These new

applications have, at the same time, spurred innovation in the core technologies of storage, processing, and transmission, creating a “positive feedback loop.”

The additional results of these expanded capabilities for accessing, using, and sharing information in digital form include new and more efficient ways of organizing markets; new and more efficient methods for businesses to communicate and transact with each other and with consumers, employees, and job seekers; dramatically lower costs for individuals in locating or gathering information of all kinds, including market and product-related information; changes in the organization of business firms and in their strategic behavior; and changes in the overall societal organization of work, leisure, and general communities of shared interest.

The chapter is organized as follows. In the section titled Information Technology, the Digital Economy, and E-Commerce, we discuss the definitions of the basic terms, including those we have used in this introduction. Size and Growth of the Digital Economy provides some data on the size and growth of the digital economy and e-commerce and discusses the measured effects of information technology on the economy as a whole, as well as some of the problems of measurement. Implications for Markets and Organizations describes changes in the nature, structure, and performance of firms and markets as digital technologies help make information more ubiquitous and as information increases in importance as an economic good. Security examines several aspects of security and how they interact with or affect the other developments in the digital economy. Government Policies examines several aspects of government policy with respect to the digital economy, including intellectual property law, privacy, antitrust and other regulation,

and international trade. Work, Play, and Communities briefly discusses broader implications of the information revolution, examining how it changes the ways in which individuals work, play, and interact within organizations and communities.

INFORMATION TECHNOLOGY, THE DIGITAL ECONOMY, AND E-COMMERCE

Although there is no absolute agreement on what the digital economy is, this section provides a working definition, discusses how the term is related to e-commerce and e-business, and discusses the measurement of the digital economy and the effects on overall economic activity.

Defining the Digital Economy

A computer is essentially a machine for storing and processing data. Although one might count the abacus or mechanical, gear-based calculating machines as computers, the term typically refers to electronic machines that use on/off electrical signals to convey and process data. The two states, “on” and “off,” based on whether an electric current is flowing or not, represent the digits 1 and 0. These are “binary digits” or “bits.” Ultimately, all data that are input to a computer, and are processed by it, are translated into bits. “Information” refers to data organized in meaningful ways, although “information” is often used to subsume “data” and we follow this practice here. Information technology (IT) therefore refers to anything connected to the storage, processing, and transmission of information converted to digital form. The use of IT for purposes related to economic transactions gives us the term “digital economy.” Here is one possible definition:

The digital economy involves conducting or facilitating economic activities electronically, based on the electronic processing, storage, and communication of information, including activities that provide the enabling physical infrastructure and software.

Dramatic and rapid reductions in the costs of processing information, storing it, and transmitting it to others (see Table 1) have made the uses and benefits of IT

Table 1 Falling Costs of Computing (US \$)

Costs of Computing	1970	1999	2004
1 MHz of processing power	7,600	0.17	<0.02
1 megabyte of storage	5,260	0.17	<0.01
1 trillion bits transmitted	150,000	0.12	<0.01

Note: For processing and storage, these are hardware and basic software costs and do not include ongoing costs of use and management of the hardware and software. For transmission, these are average costs based on full capacity use. Source: 1970 and 1999, Woodall (2000), p. 6, Chart 1 (see also <http://www.dallasfed.org/fed/annual/1999p/ar99.pdf>, Exhibit 3); 2004, author’s estimates from various sources and calculations, viz. processing power from Moore’s Law and trends in prices of Intel chips, storage based on cost of desktop hard drives, and transmission from current costs of basic data transfer.

potentially span the whole economy, spurring further innovation in core technologies and leading to an “information revolution.” On the basis of these falling costs, innovations such as personal computers, color graphics, point-and-click interfaces, and other developments have made IT much easier to use. The Internet and the World Wide Web are the latest elements of the progress of IT over the past half-century, adding easy two-way communication of rich information (text, graphics, audio, video, etc.). The changes that the increased importance of IT brings about in people’s daily lives are captured in the term “new economy.” The term suggests that IT and the Internet shift the focus of economic activity to information and away from traditional activities such as manufacturing, although it must be recognized that the manufacturing industry has used IT to improve efficiency in various aspects of operations, such as scheduling, quality control, and assembly. Similar terms are possibly more descriptive: knowledge economy, information economy, and digital economy. The last of these, as noted, emphasizes the fundamental technology that drives everything: the conversion of information to digital form.

The terms “information economy” and “knowledge economy” focus on what is being digitized. Information and knowledge are related, but distinct concepts, even though the distinction is sometimes fuzzy (we postpone a discussion of information and knowledge as economic goods to the section Implications for Markets and Organizations). Information in this context is more general and basic, as it denotes anything that can be put into concrete form before digitization. For example, a popular song is information, from an IT perspective. The sounds can be reduced to a digital file that can be stored, transmitted, and processed by various kinds of computers. If a person internalizes information about the song (its title, tune, lyrics, etc.), then that constitutes knowledge, just as the ability to write computer programs that allow users all over the world to share songs (as digital files) is knowledge. To push these examples further, a particular song-sharing software program is also information. In this case, knowledge helps to produce and transmit information. People can also gather information, process it in some way, and gain knowledge, as when they study how to program in a particular computer language. Some of the same distinction comes up in the differences between copyright and patent law, which protect different kinds of intellectual property rights (see Government Policies): copyright law protects particular expressions of ideas, or information, whereas patent law protects inventions, or the ideas themselves, if they are useful knowledge. In all these cases, digitization (through the use of IT generally, and the Internet in particular) amplifies the benefits of knowledge and makes the spread of information easier.

E-Commerce

E-commerce (or electronic commerce) is a popular term that emphasizes the use of the Internet and associated aspects of IT for business purposes. While businesses previously adopted IT for many internal and back-end activities (see the next section), the Internet and World Wide Web have allowed business-to-consumer (B2C) commercial interactions to be more closely and comprehensively

mediated by IT. Examples of e-commerce include buying retail items using a Web interface and paying for them by providing credit card information online; downloading a media player or other software (for a trial, free use, or through a purchase) via the Internet; checking the news, weather, and movie reviews on a portal, possibly “paying” for these services by giving attention to online advertisements; going to an auction Web site and bidding on collectibles or other items; and paying a monthly subscription for Internet access to chat online with friends or others one meets in cyberspace.

More formal definitions of e-commerce encompass all these examples and include commercial transactions among all kinds of organizations, not just B2C interactions. Here are two general definitions:

Electronic commerce refers generally to all forms of transactions relating to commercial activities, including both organizations and individuals, that are based upon the processing and transmission of digitized data, including text, sound and visual images. (OECD, 1997)

In ever greater numbers, people are shopping, looking for jobs, and researching medical problems online. Businesses are moving their supply networks online, participating in and developing online marketplaces, and expanding their use of networked systems to improve a host of business processes. And new products and services are being created and integrated into the networked world. (U.S. Department of Commerce, 2000, p. 7)

The scope of what constitutes commercial transactions is quite broad in these definitions. Information gathering or exchange that does not directly involve a direct monetary payment may still have an economic motivation. Even leisure-related activities typically require some measured economic activity. In the example of using the Internet for chatting, one pays for access to the infrastructure that enables the leisure activity. Activities that involve the government (e.g., filing one’s individual tax return electronically over the Internet) are not commercial in the narrow sense but are clearly related to economic activity that is measured in the national accounts statistics.

Of course, not all IT-based activities qualify as e-commerce in the sense of involving the Internet. For example, many home activities involving personal computers (PCs) do not involve Internet use at all: record keeping, children’s homework, creating (paper) greeting cards, typing holiday newsletters, and so on. Similarly, small retail stores may have computerized inventory systems that have no links to any other computer. However, this gap between computer use and Internet use is shrinking, and for many individuals and businesses, using computers or IT automatically means using the Internet.

E-Business

The encompassing definition of e-commerce presented earlier includes a broad range of online transactions and interactions that are connected to some economic motive. Therefore, this is broader than the term “e-business,”

defined here as the use of IT, including networked computing, by business firms. For example, if individuals transact directly online, so that no business firm is directly involved, then that would qualify as e-commerce but not e-business. Similarly, we include government/individual transactions in e-commerce but not in e-business.

E-business (and therefore e-commerce) includes not just transactions across firms but also activities that take place within the boundaries of a business but that do not cross them. Internal accounting, inventory control, and other forms of business record keeping and tracking have been electronically based in industrial countries for more than a decade, especially in larger businesses. These purely internal records and transactions, when handled electronically, are often to what e-business is taken to refer. The use of IT provides cost advantages over traditional means (i.e., paper) in terms of storage, manipulation, and retrieval of large amounts of information, provided that the scale of use is large enough to spread the substantial fixed costs initially associated with IT investments. In fact, until computers became affordable as household items as a result of falling costs and associated innovations, large organizations were the only purchasers of IT products and services.

In fact, the digital economy, in the form of business-to-business (B2B) transactions based on older electronic communication methods (electronic data interchange or EDI, using proprietary software and dedicated communication links), substantially predates the Internet and the World Wide Web. Electronic links between financial firms and between large retailers and their suppliers were two prominent examples of this form of e-business, or B2B e-commerce. The Internet and World Wide Web have extended the economic feasibility of such links to a much wider range of businesses through their use of shared networks and nonproprietary communication software and the resulting reduction in the costs of information exchange. Advances in ease of use and speed of transmission have also contributed to this trend by further increasing accessibility and flexibility. Another potential effect of these developments, which supports the use of broader definitions of terms such as e-commerce and e-business, is the blurring of the boundaries of the firm, as information flows more freely across firms as well as within them.

SIZE AND GROWTH OF THE DIGITAL ECONOMY

The size and growth of the digital economy can be gauged in several ways. Basic measures of numbers of Internet users, Web sites, and so forth are popular. Clearly, these do not directly measure the economic activity that takes place online, though the provision of Internet access is itself an economic activity. More direct and better measures are data on transactions that take place online, as well as the share of IT-related activities in the overall economy. This section examines in turn these different approaches to measuring the digital economy and its effects. None of the measures is perfect, which reflects the newness of the digital economy as a challenge for economic statisticians.

Internet Use

Three kinds of statistics that are often used to gauge the growth of the digital economy are the number of people with Internet access, the number of unique Web pages, and the number of Web sites, with the latter two being conceptually very close. The U.S. Department of Commerce, using data from the U.S. Census Bureau, reported that 143 million Americans, or 54 percent of the population were using the Internet in September 2001, up from 117 million thirteen months earlier (U.S. Department of Commerce, 2002). Nielsen NetRatings, 2001, estimated a higher number of Americans, 168 million, online in January, 2001). Furthermore, a broader cross section of Americans is using the Internet, reducing earlier fears of a “digital divide” between those with access to these new communication tools and those without (especially the poor). In fact, the growth in Internet use during the period 2000–2001 was fastest among Americans with household income less than \$15,000 a year (U.S. Department of Commerce, 2002). By February 2004, according to another survey, 204 million Americans had Internet access from home, representing close to 75% of the population (Nielsen Net Ratings, 2004). Another important trend that has emerged recently in the United States is the acceleration in the proportion of Internet-connected households with broadband access, crossing 45% in February 2004 (Websiteoptimization, 2004, March).

The Internet is also increasingly global, with the worldwide number of users estimated at 729 million (Global Reach, 2004), of whom more than half used a language other than English. With the exception of the United States and a few European and Asian countries, the numbers of Internet users are still low relative to population sizes, which reflects generally lower levels of income in much of the world, but as costs continue to fall, even poor villagers in Asia, Africa, and Latin America are beginning to use the World Wide Web to get weather and crop price information or to check on village land-ownership records from government Web sites. This represents another aspect of overcoming the initial digital divide introduced by the Internet. Table 2 gives a sampling of Internet use by language, from Global Reach. In most cases, there is a close correspondence between countries and languages, with English, Arabic, Spanish, and Chinese being more dispersed.

Table 2 Global Internet Use, 2004

Language	Internet Users (millions)	Total Population (millions)
English	287.5	508
European languages (excluding English)	276.0	1,218
Arabic	10.5	300
Chinese	102.6	874
Japanese	69.7	125
Korean	29.9	78

Source: Global Reach (n.d.).

Rough measures of the Internet resources available to the growing number of users are given by counts of the number of Web pages and Web sites. The number of unique World Wide Web pages was reported to be more than 1 billion by January 2000, up from just 100 million in October 1997 (Inktomi, 2000; NUA, 1997). The number of Web sites in August 2004 was more than 53 million, well up from the 43 million estimated a year earlier and a different order of magnitude altogether from the 19,000 sites estimated in August 1995 (Netcraft, 2004a and 2004b). Of course, neither measure indicates how much time people actually spend online or how that time affects economic activity. In particular, they do not tell us how much money people spend directly or indirectly as a result of their Internet use. For that, one would use the approach of national income and product accounting, which estimates value added in market transactions. There are problems with this way of measuring economic activity, such as the failure to account for the value of time used in nonmarket transactions or in activities that affect market transactions,¹ but official methods of calculating economic activity are the best we have. In particular, they are designed to capture market-based economic activity relatively well and to avoid problems such as double counting, which occurs if the gross values of transactions at various stages of the value chain are added up.

Types and Measures of Online Transactions

The problem of double counting is avoided when one looks at final sales to consumers. B2C e-commerce seemed to hold out great potential in 1999 and the early part of 2000, resulting in a rather frenzied burst of entrepreneurial activity backed by eager venture capitalists. This fever has cooled, but the growth remains. The U.S. Bureau of the Census estimated electronic retail (e-tail) sales in 2001 to be \$34.3 billion, \$44.3 billion in 2002, and \$56.0 billion in 2003. However, even after this impressive growth, online sales remained just under 2 percent of all U.S. retail sales.² In Europe, figures for online retail sales are less standardized, but one estimate for 2002 put them at about \$30 billion, or comparable to the U.S. figures in magnitude.³ A more recent survey by VISA estimated

¹ For example, time spent in gathering information that affects purchase decisions is not valued in national accounts. Shifts in this activity from traditional, physical methods (such as browsing print media, telephoning, and driving around to stores) to online search will not show up in the data, except as changes in business spending (from magazine ads to Web ads), or even *reductions* in economic activity (less spending on magazines by consumers).

² These statistics are reported at <http://www.census.gov/mrts/www/data/html/04Q4.html> (U.S. Census Bureau, 2004), which also gives historical data, calculation methods, and charts. Other surveys give somewhat higher figures. For example, AOL reported that its members alone spent \$33 billion online in 2001 (CNET, 2002). However, this may include travel spending, which, if excluded reduces estimates considerably. The figures reported in the text exclude travel spending, which would add another 50% to those figures if included. See comScore, 2002.

³ The estimate is from Forrester Research, as reported in the International Herald Tribune (2002). Gartner, another IT research firm, estimated somewhat higher numbers (GartnerG2, 2002), but they seem too high compared with U.S. figures, given somewhat lower Internet penetration in Europe. Higher numbers for Europe may include travel and financial services transactions. See OECD (2002a) for a discussion and detailed comparisons.

that e-tailing took off in the beginning of 2004 in several European countries, doubling in the first quarter as compared to a year earlier (European Online Sales up Across the Continent, 2004). Statistics for online retail sales in Asia are still less reliable, but one can estimate them to be about one quarter to one third of European figures, based on various Internet sources.

B2B transactions may involve products that are indistinguishable from consumer products (computers and office supplies, for example). The only difference is that they are sold to businesses rather than to households or consumers. However, a large segment of B2B transactions involve raw materials and intermediate products, as well as services that are specific to businesses (for example, accounting, human resource management, and, increasingly, IT services). Although estimates of B2B e-commerce vary widely, it is widely agreed that the numbers are much more substantial than for B2C e-commerce. The reasons have to do chiefly with the historical scale of IT, compounded by the cost-saving incentives of businesses in competitive markets. As noted in the previous discussion of e-business, Internet-based e-commerce represents the effect of cost reductions in expanding the size of the communications network, and hence the market, from just large firms to including small firms as well as households.

There is a conceptual problem with most estimates of B2B e-commerce, which simply add up revenues from a variety of firms. Because B2B transactions involve intermediate products and services, aggregating revenues across businesses will involve double counting, because revenues for intermediate products sold to other businesses are a cost for those businesses. Still, one can use the numbers, and changes in them, to get some idea of the importance of B2B e-commerce. Although the U.S. Census Bureau does not yet estimate B2B e-commerce, private forecasters do. Estimates for 2001 varied widely,⁴ ranging in a sample of forecasters (based on a combination of surveys and guesswork) from US\$ 474 billion to US\$ 1,138 billion for worldwide B2B e-commerce, with 70–80% of this being in the United States (estimates are from surveys; eMarketer, 2002). The numbers vary greatly across sources, but they are all of similar orders of magnitude, and all project substantial growth. One can safely conclude that B2B e-commerce substantially exceeds B2C in size, and it may be growing somewhat faster on average. Finally, the cost advantages of using the Internet,⁵ plus the benefits of being part of a larger network, are expected to cause a relative shift to the Internet from EDI. Small businesses, in particular, can use Internet-based e-commerce where EDI would not be economical for

them. Furthermore, electronic marketplaces are potentially economically viable using the Internet, but not with traditional EDI, because the Internet permits more flexible and less costly access.

One final category of e-commerce is consumer-to-consumer (C2C). Although firms such as eBay—which is the dominant C2C marketplace, with more than 60% of market share (Rudl, 2003)—have entered the popular imagination through their electronic auctions for collectible or unique items, the value of C2C transactions is relatively small. However, eBay now handles B2C and B2B transactions as well. In 2003, eBay's net sales, from transaction fees on \$15 billion in gross revenues, reached \$1.2 billion (Hof, 2003). Again, one should caution that the total value of a transaction does not represent the economic value added of an activity. If a used item is bought and sold through a dealer, the dealer's profit is a better measure of the value created in the overall transaction, and this is what is measured in the national accounts. Thus eBay's own revenues, adjusted appropriately for its market share, may be a better indicator of the importance of C2C e-commerce than the value of goods transacted through eBay. A complication for this approach is the increasing use of eBay for B2C sales. Of course, a used item sold privately (say, in a flea market) will not show up at all in that official accounting.

Information Technology and GDP

E-commerce, measured as actual transactions conducted online, represents only a small fraction of the U.S. gross domestic product (GDP), which was 10.9 trillion dollars in 2003. However, overall spending on IT may be a better measure of the significance of the digital economy, because the use of IT has become pervasive in businesses of all kinds and sizes. A useful discussion and justification for this view is OECD (2002a). This includes the use of computers for managing transactions, inventory, and logistics, even without use of the Internet. At the same time, the boundaries between general IT use and e-commerce are increasingly blurred. Networks exist within corporate walls and simultaneously are part of the larger network of the Internet. Telecommunications infrastructure that carries telephone conversations is also used for World Wide Web data. Total IT spending in the United States (without any double counting) now makes up about 7% of GDP, or more than 700 billion dollars.⁶ This includes hardware, software, services, and telecommunications spending. This means that there is still a substantial part of economic activity that is not directly related to information technology. However, it is a reasonable forecast that the 7% figure will increase over the next few decades. A slightly different measure, the percentage of ICT value added in business sector value added, yielded an average of close to 10% for 25 OECD countries in 2000, with the United States being somewhat above this average, and extremes ranged from more than 15% for Ireland and Finland to about 5% for Greece and Mexico.

⁴ One area where differences in estimates can arise is with respect to EDI, which uses private networks and proprietary software, and has been restricted to larger firms. For example, the Boston Consulting Group estimated U.S. EDI for 1998 at \$571 billion, dwarfing its estimate of Internet-based B2B e-commerce of \$92 billion. At the same time, they projected EDI to grow only slowly, to \$780 billion in 2003, while projecting US Internet-based B2B e-commerce to be \$2 trillion in 2003.

⁵ For example, retailer Sears Roebuck, one of the pioneers of EDI, has an EDI system that costs it about \$150 per hour. Internet-based exchange with its suppliers could reduce this figure to as little as \$1 an hour. See Guy (2000).

⁶ See Jorgenson (2001) for detailed estimates. Figures from IT market research groups such as International Data Corporation (IDC) are a little higher.

(The “C” refers to “communication,” which has become increasingly digitized, and is counted with IT in many statistical and conceptual exercises. The data are from OECD, 2002b.)

One factor working *against* an increase in IT as a proportion of GDP is the fall in the costs of IT. The empirical regularity observed by Intel cofounder Gordon Moore, and enshrined as “Moore’s Law,” says that the number of transistors per microprocessor doubles every 18 months. This ability to pack more and more circuitry on tiny wafers of silicon keeps reducing the cost of processing power. Similar factors are at work in storage and communication of information, resulting in enormous reductions in the overall cost of computing (recall Table 1). To the extent that only expenditures are measured when economic activity is calculated, some of the impact of the digital economy is being missed. For a simple example, a \$2,000 home computer is many times faster than a \$2,000 home computer available five years ago; it has much more storage capacity and it can communicate much faster with other computers than was possible half a decade earlier. Even neglecting adjustments for inflation (which would mean that the \$2,000 computer now is cheaper in real terms), the same amount of money spent now allows one to work more quickly and effectively or to enjoy one’s leisure more. Thus, the same spending on information technology today gives much more “bang for the buck” than five years ago.

The changes in computing go beyond having more capacity or saving time and encompass activities that were impossible in the past: online games, music listening and sharing, interactive distance learning, and so on. Again, these increased capabilities are not fully accounted for in the standard accounting of economic activity. Of course, these measurement problems have always existed. Innovation that introduces new products or improves the quality of old products has always been difficult to account for. One might argue, however, that IT has accelerated innovation and magnified the problem of underestimating the benefits of certain economic activities (Brynjolfsson & Hitt, 2000).

The problem of accounting for improvements in quality and variety goes beyond the IT sector. If IT can be used to more effectively design new products or improve the design of existing products, then its value will be greater than is simply reflected in spending on IT itself. In other words, better, cheaper, more versatile computers make it possible to have better, cheaper, more varied cars, houses, toys, and so on. This is partly what Brad DeLong (see Introduction) means when he says that IT amplifies brainpower. For example, in crash testing new cars, actually crashing a car could cost approximately \$60,000 each time. This is how it used to be done, with the results analyzed partly by computer. Simulating the entire crash on a computer can now instead be done for close to \$100 (Woodall, 2000, p. 5).

Despite these seemingly obvious benefits of IT, one paradox that proponents of the new economy have faced has been the lack of hard evidence for these benefits in the overall GDP data, which measure economic activity. Initially, increased investment in IT did not appear to be improving productivity in any measurable way. The

conclusion of skeptics was that much of this IT spending had no real effect. We turn to this issue next.

Information Technology, Growth, and Productivity

Much of the attention to productivity growth has been with respect to the United States, which has spent the most on IT and which had a prolonged slowdown in productivity growth in the 1970s and 1980s. Early investments in IT seemed to have no countervailing effect to reverse or mitigate this slowdown. Analysis of the introduction of electric power a hundred years ago (David, 2000) suggests that the benefits of innovation can take decades to appear in quantifiable form. This seems to fit with what happened in the last five years of the twentieth century, when U.S. productivity growth did increase substantially, just as the penetration of PCs into homes approached 50% and as the Internet took off.

Some work on the recent U.S. experience (Gordon, 2000) suggests that the increase in productivity growth is confined to a small segment of the economy (computers and durable goods). Furthermore, the productivity boost may have been entirely the result of the prolonged economic expansion in the United States (productivity rises during economic booms). This skeptical view is supported by studies that find productivity gains have been low in sectors where IT investments have been high. For example, measured productivity in banking and education actually fell from 1987 to 1997, even though these were the sectors with the highest spending on IT as a proportion of output. Possible explanations for the failure of IT investments to show up as improved productivity include, on the benefit side, the inability to account for time savings, increased outputs of public knowledge, availability of greater variety, and general improvements in the quality of products and services. Thus, some of the most important benefits of the digital economy could also be the ones that slip through the cracks in measuring economic activity. Alternatively, the benefits may simply not be there, rather than being unmeasured. Explanations include lags in learning how to get the most from new technologies, the need for complementary investments required to boost output, and the presence of network effects, which limit gains unless there are many adopters. Baily (2004) and Gordon (2004) provide detailed reviews of these and other cautionary arguments with respect to the impact of IT on productivity growth.

Despite the caveats, two recent, comprehensive analyses, by Jorgenson (2001) and Stiroh (2002), suggest that IT has been an important contributor to productivity growth in the 1990s. (See also Oliner & Sichel, 2002.) Jorgenson directly traces this effect to the rapid fall in the prices of semiconductors and of IT products in general, especially after 1994. For 1995–1999, Jorgenson estimates that two thirds of the United States’ productivity gains were the result of IT use. Stiroh goes even further, with a detailed, industry-level analysis of the United States. He finds that the U.S. productivity revival was indeed broad-based, that much of it took place in IT-producing industries, and that industries that are IT-use-intensive also had higher productivity gains. Thus Stiroh’s work appears to tilt the

scales in favor of a positive assessment of the effects of the digital economy, at least for the United States. Work by Triplett and Bosworth (2003) provides additional positive evidence, estimating that IT investments have been significant in contributing to productivity growth in the service sector.

Studies for other countries are also beginning to find significant impacts of IT on productivity growth. Daveri (2000) reaches positive conclusions with respect to the impact of IT on overall economic growth. His exercise includes 18 OECD countries, and his results for the United States are broadly similar to those of Jorgenson and Stiroh. For Canada, Japan, Australia, New Zealand, and 13 European countries, he obtains varied results, with Canada, Australia, New Zealand, the Netherlands, and the United Kingdom having relatively high contributions of ICTs to growth, with Italy and Spain at the other extreme. Daveri also argues why his results are more positive than those of another cross-country study (Colecchia & Schreyer, 2002), which uses a narrower definition of IT. These studies use data for 1991–1997, and therefore miss the end of the 1990s, when significant growth in IT, as well as overall growth, took place. Jorgenson (2004) examines data for the G7 countries (Canada, France, Germany, Italy, Japan, the United Kingdom, and the United States) for 1980–2001. He documents the importance of IT capital spending for the overall contribution of capital investment to growth, as well as the effect of IT production on overall productivity growth. The results across the G7 are not too dissimilar, indicating that the United States has not been an outlier in this respect.

IMPLICATIONS FOR MARKETS AND ORGANIZATIONS

This section discusses how the use of IT and the Internet affect the structure and outcomes of markets and the organization and strategies of firms, all from a microeconomic perspective. The consequences of the special nature of information as an economic product are also highlighted.

Information and Markets

The most basic way that the information revolution changes the economics of the marketplace is in making information about all kinds of products and services more widely available. Although basic models of the market system often take it for granted that information about products and about buyers and sellers is abundant, in practice, this is not the case. In fact, one of the virtues of the competitive market system is its ability to economize on the use of information. Textbook-style competitive markets cannot overcome some kinds of lack of information: for example, the quality of a product may be observable to sellers who provide it, but not to buyers. In practice, many kinds of institutions arise to overcome informational problems: brand names, warranties, consumer protection laws, and so on. Business firms and other organizations may themselves be viewed partly as a response to information problems that prevent the use of markets for all transactions (Coase, 1937), with such transactions being internalized within firms. With firms as major actors,

the market economy can be viewed as a scene of constantly shifting attempts to create advantages over competitors by finding opportunities for greater efficiency or satisfying wants more effectively.

In this situation, the availability of greater information about products and services may upset existing institutions by changing the relative costs and benefits of current ways of doing things. How firms organize their own internal operations and transactions can change, and how they interact with consumers can also change. New kinds of firms may arise simply to manage the new possibilities for market interaction. For example, firms may specialize in providing price or quality comparisons to consumers, in ways that were not cost-effective before. Firms may find it easier to outsource manufacturing, because they can maintain closer links with suppliers through regular electronic information exchange. Other firms may provide combinations of services that were impossible or unlikely in the past, combining traditional media content (news, entertainment, and product information) with individual services such as auctions and communications.

From the perspective of consumers, or buyers more generally, the Internet lowers search costs by providing large amounts of product-related information anytime and anywhere. In addition to information from sellers, buyers can also more easily access information from intermediaries that rank products or make price comparisons or from other buyers. In consumer markets, this ability to gather information from dispersed buyers represents a major extension of word-of-mouth methods of information sharing.

Preliminary work on the functioning of markets online suggests that there are measurable effects of the greater availability of information. A survey by Smith, Bailey, & Brynjolfsson (2000) examines the evidence on four dimensions of price competition in B2C online markets, as compared to traditional transactions mediated through physical stores:

1. Price Levels: Are posted prices lower online?
2. Price Dispersion: Are prices of online sellers less spread out?
3. Price Adjustment: Do sellers adjust posted prices more finely or frequently online?
4. Price Sensitivity: Are buyers more responsive to price changes online?

Overall, the results of various empirical studies indicate that prices are lower online, there is less price dispersion, and prices are adjusted more often and in smaller increments. All of these conclusions are consistent with the general hypothesis that online markets are more competitive. The results on price sensitivity are mixed and may be related to factors that cannot be controlled for, such as differences in the characteristics of online consumers. The lack of evidence for perfect competition (persistence in price dispersion, for example) can be explained by the continued importance of factors such as trust and reputation, switching costs associated with search that is still costly (though less so), investments by consumers in seller-specific information, loyalty programs, and price

discrimination—possibly supported by customization of offerings (e.g., with “dynamic packaging” of vacation packages at online travel sites) where resale or consumer-to-consumer information exchange is not effective.

These studies examined only posted price markets, in the context of a small number of products such as books and compact discs (CDs). Possible efficiency gains exist through the better matching of buyers and sellers in markets that otherwise relied on more costly methods of intermediation. In addition to online auctions of collectibles and other used items, job markets, personal-relationship matching markets, and many fragmented B2B markets appear to have taken off precisely because the Internet and Web allow buyers and sellers to match more efficiently, which creates higher-value matches as well as lower costs associated with agreeing on a price and completing a transaction. Three important consumer markets where the Internet also appears to have had an impact are those for automobiles, housing, and financial services. All these markets have been characterized by high search costs and the presence of intermediaries with significant market power (car dealers, real estate agents, stock brokers, insurance agents, and so forth). The use of the Internet for basic information search and price comparisons appears to be providing some degree of increased competition in all these cases. In some cases, particularly digital products such as financial assets, the entire transaction can be completed online. In others, the Internet provides a vehicle for a significant proportion of the information exchange that accompanies a transaction.

The Internet also expands markets across national boundaries and affects international trade through its ability to increase the quantity and richness of the information that is available. As in complex transactions within national boundaries, the kind of information that the Internet can provide does not remove the potential need for traditional face-to-face interactions, particularly when a relationship is being formed. However, it reduces the cost of much of the search process, in terms of where a potential buyer might want to invest more time and money in gathering the information necessary to decide whether to transact. Furthermore, once a relationship is established, the ongoing costs of routine information exchange and even transactions are reduced. In such cases, the products that are traded may well be traditional physical products: e-commerce does not involve transforming the products, but rather changing the nature of the search and transaction processes. Even in this case, the savings in terms of transaction costs may be substantial enough to significantly boost international trade. For small consumer items such as handicrafts, the Internet and Web provide a cost-effective way for even rural artisans in developing countries to advertise globally.

Information as an Economic Product

A basic effect of the information revolution is on information itself as an economic good. The best-known example of the magnitude of this impact is what happened to the *Encyclopedia Britannica*. The *Britannica* was the premier encyclopedia, with thousands of pages of articles by

renowned experts. It sold for thousands of dollars, priced to recover the cost of a well-paid direct sales force as well as the high printing cost for its two dozen volumes. This business was destroyed by the ability to put a reasonably large amount of information on a single CD-ROM, sold for under a hundred dollars, or even bundled in “free” with a home computer system. CD-ROM encyclopedias were inferior in academic quality but were “good enough” for most people, and the price was right.

The ability to store, process (including copying), and transmit large quantities of digital information at lower and lower costs is now the central characteristic of information as an economic product. A world where the marginal costs of providing information approach zero is a world where businesses that deal in information have to find new ways to provide value to consumers, ways for which they can actually charge enough to recover the costs of producing the information in the first place. To do this, information may have to be bundled, personalized, or managed within a service that creates a long-term relationship with the buyer. To the extent that other products and services have also been bundled with information in the marketplace, and that this bundling changes, firms have to create new bundles of value. For example, online retailers try to provide their customers with suggestions and ideas, based on tracking the buying and browsing patterns of individual customers and those with similar interests. This is not dissimilar to the old personalized service in the local store but can be done at a scale that was earlier impossible. Bundling may also take place without personalization, the combination of hardware and software being the most obvious example.

The ability to process large quantities of information in increasingly sophisticated ways is at the heart of the information revolution, extending not only to the ability to make suggestions about existing products, but also to design products in collaboration with individual customers, and to do it at a large scale. Flexible mass customization, referring to the ability to quickly satisfy the diverse wants of large numbers of individual consumers, is one of the possible pillars of business strategy in the digital economy (see the next section). In all these cases, businesses also have to be able to capture the value that they create, which may require strategies including a combination of technology (e.g., software to control copying), law (e.g., enforcement of copyrights—see the next section), and economics (e.g., pricing).

In addition to the low marginal cost of providing information, there are several additional aspects of information or knowledge as an economic product that affect the working of markets and organizations. In particular, information is a shareable or nonrival good in consumption, where the terms refer to the ability of more than one person to consume the same thing. Low-cost copying, storage, and transmission enable this shareability to be implemented in new ways, such as peer-to-peer music-file swapping, which bypasses traditional commercial distribution channels. In many cases, the use value of the information is unaffected by its being shared, or it may even be increased. For example, news and entertainment can be conveyed to large numbers of people simultaneously or sequentially, and no single person’s enjoyment of

a TV program is diminished as a result and may even be higher if the program can subsequently be discussed with friends (a positive externality). In other cases, the value of information may be reduced if others have access to it (a negative externality). Information that affects the value of financial assets is a good example, where insider knowledge bestows an advantage in the marketplace. A seller's knowledge of a buyer's circumstances (or vice versa) is another example, in which one party may be better off without the other side knowing their valuation. In the examples of the previous subsection, where the effect of better information about the products and market opportunities was discussed, the market-related information could involve either type of externality. In cases where information is the final consumption good itself, such as entertainment, status considerations might create negative externalities, but the positive externality case seems more common.

The shareable nature of information and knowledge also raises concerns for the legal definition and enforcement of property rights, which are crucial for all market economies. In the digital economy, knowledge is increasingly important as a driver of economic activity and growth. To play this role, it must be part of the system of economic incentives. Knowledge or information is legally characterized as intellectual property (IP), but this is fundamentally different from physical property and requires its own system of legal definitions and rights. Thus, IT and the Internet amplify not only brainpower but also the importance of the legal system that governs the economic rewards to brainpower. Furthermore, technological advances that make copying and sharing of information of all kinds incredibly quick and inexpensive are having a major impact on legal issues relating to intellectual property, as in the case of music-file swapping. We give a flavor of the issues here.

Briefly, there are four areas of IP law: (a) trade secret law, which protects valuable information not generally known that has been kept secret by its owner; (b) trademark law, which protects words, names, and symbols used by manufacturers and businesses to identify their goods and services; (c) patent law, which protects new, useful, and "nonobvious" inventions and processes; and (d) copyright law, which protects original "works of authorship." All these concepts of intellectual property predate e-commerce by centuries, of course, developing along with capitalism and the industrial revolution. The information revolution provides some new challenges in this arena, especially in the area of copyright law, although patent law also has been stretched by the information revolution and the rise of e-commerce, and issues of trademarking have arisen with respect to basic online activities such as the use of hyperlinks on the World Wide Web.

Although patents are not granted for scientific truths or their mathematical expression (including computer programs as mathematical algorithms), an invention including software is patentable if the software controls real-world processes or numbers that represented real-world concepts. The commercial use of IT fits this description in ways that were unimaginable when the courts ruled in this way, and software patenting has exploded in the last few years. E-commerce software patents include broad

(many argue, too broad) ideas such as one-click buying and reverse auctions. In addition, the increased use of IT to govern internal business processes such as inventory control and work flow has also generated numerous software patents. Although a strong system of granting and enforcing patents is consistent with the idea of providing incentives for innovation, it may reduce the social benefits that accrue from widespread adoption of innovations. Policy and legal debates are likely to continue, because there is no universal right answer to the issue of the nature and degree of optimal patent protection.

Copyright law differs from patent law in preventing the unauthorized copying of the expression of ideas but not ideas themselves. Therefore, copyright law does not protect against someone stealing an invention or someone else independently creating a similar expression. However, copyright does provide some protection against "nonliteral infringement," such as the near duplication of screen displays. The primacy of information products, or "content," in e-commerce, and the ease with which digital information can be copied and distributed, have made copyright law for the Internet a major area of concern. Again, there are arguments on both sides, with associations of copyright owners of content such as music and movies pushing for strict controls on digital copying and others supporting broader notions of fair use and free expression as limits on copyright law.

In addition to legal and technological strategies to enforce copyrights (see the section Intellectual Property), IP holders have also turned to innovations in business strategy to capture the potential value of their IP. Several initial attempts to create Web-based music download services foundered because of lack of breadth of offerings, mispricing, or poor marketing. More recently, Apple's iTunes service has been a substantial success, offering a wide range of songs for download at 99 cents each in the United States. In addition to pricing, marketing, and breadth of product offering, a key success factor in this case has been the availability of attractive portable hardware for playing the downloaded music. In fact, Apple's sole source of profits so far has been sales of its iPods, rather than song downloads. Attempts by competitors to offer compatibility across hardware and software platforms suggest that this market may not have reached long-run equilibrium. Nevertheless, there does seem to be evidence that viable business models of paid digital delivery of copyrighted material can be constructed. In fact, this observation extends to other forms of digital content, such as news and research material, although these markets are not as prominent as that for music and other entertainment.

Market Structure and Strategy

The nature of information, where marginal costs of delivery are small and fixed costs of production may still be large, is often alleged to favor winner-take-all outcomes, because a single firm serving the whole market has the lowest average costs. These supply-side economies are reinforced by economies of scale on the demand side, that is, the benefits of creating and controlling large networks. Consumers will presumably join the network that is already large to get the highest benefits of being able to

select a transaction partner from a bigger pool or other advantages of interaction. Thus buyers will look on eBay, because it is the largest online auction site, whereas sellers will list there for the same reason. The size advantage associated with these positive network externalities (that joining a network increases the benefits to others as well as oneself) keeps reinforcing itself, because the marginal value of the network is an increasing function of the network's size. On the other hand, if individuals can simultaneously participate in more than one network, and if a smaller, competing network can offer a price break to attract them, then the advantage of the winner will be limited and taking all may not be feasible. Intellectual property rights may also create winner-take-all outcomes, if a single firm is able to establish a default technical standard for an entire market (e.g., desktop operating systems). All these factors may push firms to seek first-mover status, with competition being for the market itself rather than market share.

Even in cases where traditional competition for market share remains paramount, focusing on information leads to a different emphasis in terms of the economics of business strategy. Pure price competition has to be less important than competition along an array of different dimensions, because price competition over homogeneous goods in a world of high fixed costs and low marginal costs will lead to firms losing money. (For example, the Bertrand model of price competition suggests that firms with homogeneous products will be pushed toward pricing at marginal cost, making it impossible to recover their sunk fixed costs.) Pricing itself becomes more complex because the use of IT increases the possibilities for price discrimination, differentiating across consumers and over time. Pricing strategy must be combined with strategies for marketing, product differentiation, and raising the costs that customers incur in switching to competitors. All these dimensions of strategy exist independently of the Internet and e-commerce, but they become more salient in a world where information technology operates throughout the stages of production (what business strategists call the "value chain"), as well as in the interaction of buyers and sellers in the marketplace. The ability to gather information about buyers and sellers, to organize this information, and to analyze it creates the potential to integrate the different dimensions of strategy in ways that were not possible earlier. For example, travel packages offered online can be created, priced, and offered in real time as a potential customer searches and can take account of aspects of the individual's search pattern and even past purchase information.

One can distinguish between two separate aspects of firms' strategies and how they can change as a result of IT and the Internet. First, firms can create more value by meeting consumer wants more effectively. Thus, being able to elicit consumer preferences more directly and at lower cost potentially allows firms to design products and services that create greater consumer surplus. The design, manufacture, and delivery (the last particularly in the case of digital products such as content or software, although IT also improves the logistics of physical delivery) of these products can also be made more efficient through the use of IT within the firm and in its communications

with its direct and indirect suppliers (its "supply chain"). (As discussed in the next subsection, these efficiencies may come about through changes in the organization of firms, with less need for vertical integration of the stages of production under common ownership.) Furthermore, consumer tastes not only can be better matched on average but also can be served through greater customization, in which products and services can be designed and manufactured to precisely meet individual tastes as specified by the customer online. This customization is particularly valuable for information products, such as content, and also for very personal items such as cosmetics and beauty products. The use of IT internally, and through the supply chain, allows for the more flexible approach to production required by mass customization. Where the products and services are digital, product differentiation can also include bundling in new ways. For example, online portals provide bundles of content and services that are not matched by traditional media companies or content aggregators such as newspapers and magazines.

The second aspect of business strategy is value capture. In this case, the greater ability to gather information about buyer preferences through tracking online behavior—including observational and information-gathering behavior as well as buying patterns—allows for pricing to be more finely tuned so that prices are closer to buyers' maximum willingness to pay. Thus, the ability to potentially use online interactions to gather and analyze buyer information allows for greater value capture through various kinds of price discrimination. In such cases, product differentiation may be an important supporting strategy for value capture, in addition to its role in value creation. Product differentiation can reduce the ability of competitors to undercut a price discrimination strategy. The ability to vary prices more easily and often in online markets may also be used as part of a price discrimination strategy, just as seasonal sales are used in traditional retailing. Bundling of products is another example of how firms may tailor products to capture greater value from buyers, although it is not always used for this purpose.

A slightly different way of analyzing business strategies in e-commerce is to think of online shopping as offering a bundle of three different categories of goods and services: the products themselves, the service of time in physically assembling the order and delivering it, and an information service that is made possible by the infrastructure of the Internet and the World Wide Web. The digital information processing and communication capability of this infrastructure is what makes the bundling of the other two services economical. In the case of many physical products, such as groceries, the service of assembling the order and delivering it would not be cost-effective without the information infrastructure and service. The nature of the information service is what particularly distinguishes catalog shopping for physical products from online shopping, because catalog shopping offers more limited information exchange. In the case of shopping in a store for physical products, the bundle offered to the buyer is further differentiated, because in store shopping the buyer bears the costs of "last-mile" fulfillment (bringing the product home). Interestingly, hybrid models of

online search and transaction, with physical pickup by the buyer from a store, are also emerging. In the case of digital products and services, the differences are greatest compared with traditional methods, because the product itself can be delivered via the same infrastructure that is used for ordering. As one might expect, online transactions for digital products and services provide greater potential for changing ways of doing business.

Changes in Firm Organization

The use of digital technologies has several different possible implications for the organization of firms. A simple hypothesis is based on the transaction cost theory of the firm (Coase, 1937), which argues that firms exist to overcome transaction costs associated with market exchange. If using IT and the Internet reduces market transaction costs by increasing the speed and richness of information flows, then firms will be replaced by markets. Although this argument has merit, the use of IT within firms also improves, so the opposite case can be made—that firms are able to become larger as a result of IT. Certainly, the globalization of firms in areas such as sourcing inputs, or serving different geographic markets, appears to be aided by the use of IT, and the Internet in particular.

One reason that firms will not disappear is that the need to control complementary assets, especially different kinds of skilled labor or human capital, is a reason for the existence of firms that is not invalidated by improved information flows. In general, one can argue that efficient incentive provision—for current effort as well as investment-related activities—often requires the use of hierarchical organizational forms, rather than pure reliance on market transactions.

Nevertheless, two trends are evident, and both appear to be accelerated by the developments in IT and communications. First, the growth of markets, which has been driven by lower transportation costs and trade barriers, and by higher incomes, as well as dramatically improved communications, permits greater outsourcing and therefore some decrease in vertical integration of firms (Brynjolfsson & Hitt, 2000, p. 36). This is an example of Adam Smith's classic maxim that the division of labor is limited by the extent of the market. The economic logic is that serving a larger market allows specialized firms to emerge along portions of the value chain, because they are able to spread the fixed costs of a separate organization more effectively. Contract manufacturing is an important example of the phenomenon of outsourcing, where the supply chain becomes more geographically dispersed as well as being more divided among different firms. Business process outsourcing has, more recently, followed manufacturing along this path. These trends illustrate a broader concept, that of "virtualization," which emphasizes the use of IT to create changing networks of firms along a value chain. As we have argued, the need to control complementary assets in a coordinated manner places limits on virtualization to the extent that it involves separation of ownership.

Second, even when they do not outsource, firms themselves are becoming more decentralized as they incorporate IT in their internal business processes. For example,

one study of large firms found that greater internal levels of IT use were associated with "increased delegation of authority to individuals and teams, greater levels of skill and education in the workforce, and greater emphasis on pre-employment screening for education and training" (Brynjolfsson & Hitt, 2000, p. 35). Other studies indicate that the IT investments of decentralized firms are more productive and that such firms have higher market values, which suggests that market pressures will favor greater decentralization in the long run. The use of IT within an organization can also be seen as a form of virtualization, because control and collaboration can be retained in essential ways without physical proximity.

From the perspective of economies of scale and scope (Chandler, 1990), the factors affecting firm organization pull in different directions. On one hand, firms can become more specialized because their ability to serve geographically dispersed markets is enhanced by the Internet. For example, niche retailers can potentially sell globally because their marginal costs of reaching new customers are substantially reduced. Trading scope for scale means that the overall impact on firm size is indeterminate. In general, however, the lower cost of entry in online business—a Web site is cheaper to set up and operate than a physical store—suggests that smaller firms will thrive. At the other extreme, large firms can expand their scale and scope more easily using online presence and interactions, and especially in the case of digital products and services, offer very large ranges of offerings. Therefore, one plausible prediction is that the size distribution of firms will become more spread out, with firms in the middle losing out to those at either end (e.g., *The Economist*, 2002).

Returning to globalization, an important consequence of digitization is the ability to deliver digital products and services across national boundaries using the Internet. A related issue is the effect of greater information availability, which expands market reach. In both cases, the ability to complete transactions online is an additional feature, although not an essential one. Skills provision and services provision are examples of electronic delivery across national boundaries, with examples of these broad categories including software development, business process outsourcing, retail transactions, and customer care. Small IT projects may be handled entirely online. In other cases, there is typically some face-to-face meeting (the "high bandwidth" information exchange) and agreement, followed by more routine exchanges or deliveries of services that take place online. The outsourcing of software development from the developed world to countries such as India and Israel represents an important example of such activities. In another example, retail financial services may be conducted entirely online across national boundaries. An investor in Europe trading in U.S. stocks can fill out the application forms, transfer money into a U.S. account, and trade without using paper or moving from her screen. Commissions earned by the online brokerage then represent a payment for services that are international.

A final aspect of changes in firm organization in the digital economy is related to the new kinds of products, services, and delivery methods that are possible. In many cases, new types of digital economy firms are essentially

new intermediaries, which provide expertise or reputation, or economize on transaction costs. The following classification of firms is in terms of how they combine information, time services, and goods and services in new ways in their offerings to customers. It does not include traditional firms that merely include the Internet as another communication channel, nor does it classify firms by traditional sectors (e.g., finance) or functions (e.g., manufacturing).

1. Information request services provide general information on demand through search engine technology, a very basic aspect of the World Wide Web.
2. Content providers package particular sets of content, rather than just enable general searches for any kind of information, and can be considered a new kind of media firm.
3. E-tailers are a carryover from the world of physical retailing, including catalog sales, but offer a different bundle of products, time, and information services than traditional retailers.
4. Exchanges and brokers operate electronically without physically bringing together buyers and sellers or the objects being sold and act as “market-makers” or “market-expanders.”
5. Community creators provide online mechanisms for communication, networking, and collaboration.
6. Infomediaries focus only on providing information pertaining to potential market opportunities and are potentially neutral with respect to buyers and sellers.
7. Portals are aggregators, or diversified firms, that combine the previous six types of firms.
8. Infrastructure providers make and sell the hardware, software, and services that allow other firms to process, store, and send the information that makes their businesses possible. These include communications equipment, Web-hosting equipment, connectivity services, hosting services, application services, and many kinds of software developers.

As the seventh category itself suggests, there are many overlaps and combinations possible in these functions within different digital economy firms.

SECURITY

The need for security in exchanging information is as old as history. The earliest measures to ensure messages from falling into the wrong hands involved hiding the message itself. A famous example of this is the story told by the Greek chronicler, Herodotus, writing more than 2,000 years ago. The sender shaved the messenger’s head, wrote the message on his scalp, and waited for the hair to grow back before sending the messenger on his way. In more mundane instances, one simply seals communications in envelopes before mailing them and relies on legal penalties to deter would-be snoops. A different sort of concealment is obtained through writing a message in a code that only the recipient knows how to decipher. Julius Caesar, for example, commonly used ciphers for military missives. Concealment and encryption are independent and can be combined in many ways. Other security issues

revolve around correctly identifying the sender and recipient of information, protecting information from tampering, and authenticating information.

Security Issues

One of the peculiarities of the Internet and the Web is their inherent openness. This openness is what has allowed them to grow so quickly and so fruitfully. As long as the information being exchanged can itself be made public without any loss, this is fine. The job seeker who posts her resume or the hobbyist who lists information about his favorite computer games may not mind if the whole world has access to that information. However, for electronic commerce to be successful, more and more commercially sensitive and private information, from business purchasing orders to individual credit card numbers, must be stored in electronic databases connected to the Internet and transmitted over it. Hence, security for electronic storage and communications is essential, otherwise those possessing unauthorized information (ranging from individual credit card numbers to complete identities, as in identity theft) can cause substantial financial harm.

There are several dimensions of security. First, we may want to prevent unauthorized people from accessing certain information. To accomplish this, the information may be encrypted, so that even if it falls into the wrong hands, it cannot be read. Also, barriers can be erected to prevent unauthorized access to information. In the case of postal mail, we simply use sealed paper envelopes, accompanied by heavy legal penalties for tampering with mail. Electronic barriers are more complex. An example of an electronic barrier is a firewall, which prevents unauthorized access. At the same time, security also must allow authorized recipients to have access to the information. When we receive an important legal document by courier, we typically have to sign for it. We provide private information that identifies us when we use an automated teller machine (ATM) or obtain bank balance information via the telephone. Similar kinds of authentication mechanisms are required for electronic transmission of information. One of the biggest problems emerging now on the Internet is the forging of corporate identities in e-mail to elicit personal financial information from unwary recipients (a practice known as “phishing”). Again, the problem can be seen as one of identity authentication.

Another kind of authentication involves authorization of transactions. A user of a credit card may not only have to establish identity, but also his or her credit status. The latter is done through a verification procedure, now purely electronic, but one that originally involved a telephone call to the card issuer. A related idea is nonrepudiation of transactions, which ensures that a purchaser does not subsequently claim that he was not responsible for a valid transaction.

A third aspect of security is preventing tampering with information. This problem may well be correlated with the issue of access. A hacker may just as well want to damage information to which he obtains unauthorized access as to use that access for personal benefit without tampering. On the other hand, tampering may occur without unauthorized access. Authorized users of information could alter it, or they could be unsuspecting carriers of

Table 3 Traditional Security Mechanisms

Security Service	Nonelectronic Mechanisms	Electronic Mechanisms
Authentication	Photo ID card Knowledge of mother's maiden name Check with trusted person or institution	Encryption Passwords/PINs Biometric scanning Digital signatures
Access control	Locks and keys Checkpoint guard Passwords	Passwords/PINs Firewalls
Confidentiality	Sealed letter Invisible ink	Encryption
Integrity	Indelible ink Hologram on credit card	Check-values
Nonrepudiation	Notarized signature Certified mail	Digital signatures
Fraud detection	Inspection of ledgers and other records	Electronic inspection Data mining

Source: Adapted from Ford & Baum (1997), Table 4.1. Note: most electronic security mechanisms incorporate some form of encryption.

viruses or worms that damage digitally stored information. Thus firewalls have to deal with such problems as well by weeding out harmful programs as well as preventing unauthorized access. Detection of tampering, or accidental alteration of information, is a related security tool.

Yet another aspect of security pertains to monitoring and auditing electronic databases. Much of this involves a carry-over of traditional financial auditing roles to electronic accounts. Issues here can involve internal as well as external fraud or theft. In the former case, access may be fully authorized, but the individual acts in an illegal manner. Effective detection of such actions is the security objective in this case, and this is accomplished through the use of data mining or other statistical analysis, for example, to identify unusual transactions. A related issue is the auditing for regulatory compliance with respect to record keeping in general, in areas such as financial and health care services.

Table 3 provides a summary classification of security issues and gives familiar nonelectronic examples of achieving security goals, as well as electronic substitutes or equivalents for digital information. We next briefly consider the various security techniques that are employed on electronic databases and communication networks.

Security Techniques

We summarize techniques of encryption, authentication, and screening, as well as how combinations of these techniques are implemented through firewalls or similar measures. Details on these techniques can be found elsewhere in this *Handbook*.

Encryption. The process of encryption involves using a rule to transform information, such as a text message, into something that is unintelligible without reversing the process. The rule used can be very simple (replace A with Z, B with Y, etc.) or can involve complicated mathematical

transformations. Digitized text, which is represented as a sequence of bits, can be encrypted in this way, using computers to perform the transformation. The real conceptual difficulty is in developing an encryption system that can be applied practically. The most straightforward system of encryption involves both the sender and the receiver knowing a "key," which is a string of bits used in both the encryption transformation and its reverse. Only the sender and the receiver know the key, which is private. Because the same key is used at both ends, the system is symmetric. IBM developed the first widely used commercial symmetric encryption system in the 1970s, the Data Encryption Standard (DES), which was adopted as a standard by the U.S. government in 1977 and the financial industry in 1981. The practical difficulty with private key systems is how to securely and efficiently distribute the keys. This problem was conceptually solved in 1976, with the demonstration that public-key encryption systems were feasible. Later, the RSA encryption algorithm (named for creators Ron Rivest, Adi Shamir, and Len Adleman) solved the further problem of constructing a usable asymmetric cipher. Such systems use a pair of different but related keys, one for encryption and one for decryption. To protect message content, as when a customer is sending a credit card number over the Internet, the message can be encrypted using the public key. Only the merchant, who already knows the private key, is able to use it to decrypt the message. All customers of the merchant can use the same public key, unlike the case of private key encryption, where each communicating pair requires a different key. The different keys make the encryption system asymmetric, because the person who has only the public key can encrypt a message but cannot decrypt it.

Message Integrity. Suppose that confidentiality of a message is not an issue, but that the recipient needs to be sure that the message was not tampered with, or accidentally

altered, along the way. For example, in traditional postal communications, the recipient might see that the envelope has been opened and resealed or the contents damaged. With digital communications over the Internet, the risk of tampering or accidental alteration could be relatively high, and detection methods are not obvious. The approach that is taken is to use a mathematical transformation that calculates a particular value based on all the bits in the message: a “check value.” The method of generation of this check value must itself be encrypted. This can be done with a symmetric, private-key system. A public-key system can also be used for encrypting the transformation that computes the check value. In either case, the check value is transmitted along with the message. The financial industry uses a standard called MAC (Message Authentication Code), which was agreed upon in 1986.

Authentication. Another problem that can be tackled with encryption technologies is that of making sure that the sender of the message is genuine. In face-to-face communications and transactions, or via the telephone, we use special numbers, other private knowledge, or photographs to establish who we are. An asymmetric encryption system can be used to achieve authentication in electronic communications. The sender uses her private key to encrypt her message. Recipients use the corresponding public key to decrypt it. Note that this does not achieve confidentiality, because anyone can get and use the public key to view the message. The roles of the private and public key are reversed from the case where message confidentiality is desired. However, anyone who decrypts the message knows who the sender is, because the public key only works with the sender’s corresponding private key. One proposed approach to controlling spoof e-mails (those using false originating addresses) is authentication through encrypted digital signatures. Another uses a version of “caller ID,” where the authenticity of incoming e-mail is verified by checking it against the domain name system (DNS) database. There are several other methods of authentication on the Internet. Passwords and personal identification numbers (PINs)—familiar from using ATMs and telephone bank enquiries—are the most common ones in use on the World Wide Web. Third-party authentication is also possible: for example, a trusted firm may perform the initial authentication and then vouch for the identity of an individual thereafter. The identity of computers on a network may also be authenticated, using encryption or other checking methods, as in the case of dealing with spam e-mails. These tools also play a role in electronic authentication of transactions. In non-Internet situations, information technology is often used to enable biometric authentication methods, where computer software analyzes facial features or physical characteristics to verify identity. This approach is now being extended to long-distance authentication, using specially equipped computer mice to read fingerprints.

Digital Signatures. A digital signature typically combines authentication with message-integrity checking. Again, it uses basic encryption technologies to achieve this. For

example, the sender “signs” the electronic document using a private key and the receiver verifies the signature using a public key. Digital signatures must also be able to support nonrepudiation. This means that the sender cannot later deny that the signature is hers. Obviously, the recipient or anyone else should not be able to forge the digital signature. One way to implement digital signatures is to use RSA-type technology in the authentication mode by encrypting the message with the private key and sending it along with the unencrypted message. Decrypting the encrypted version and comparing it with the plaintext message provides a check on the contents and the sender. This can be costly in terms of computing resources and bandwidth, so an additional step is introduced in practice. A one-way mathematical transformation (i.e., one that cannot be reversed) is applied to the message. The transformation is called a hash function, and its output is a message digest. Tampering with the message will alter the digest. The digest is encrypted with a private key, and this acts as the digital signature. Different mathematical transformations provide alternatives to RSA-based digital signatures.

Access Control. Passwords provide a standard form of individual access control. A different sort of control prevents access from certain machines. Finally, certain forms of content and applications may be prohibited or screened. A firewall typically acts as a screen for controlling access and the entry of content and applications. Firewalls typically exist between internal corporate networks and the public part of the Internet. They can control incoming traffic and only allow authenticated users access from outside, and limit how internal users connect to the external network. Firewalls can also screen for malicious programs, such as viruses, which can cause damage to the internal network. Antivirus programs themselves exist independently of firewalls and are now a standard part of every computer’s armory. Firewalls include special hardware and software, such as screening routers to filter incoming data, proxy servers to screen requests for Internet services such as access to Web sites, and perimeter networks that act as buffers between internal networks and everything outside. Firewalls may also perform encryption tasks in linking two physically separate networks securely over the Internet to create what is called a virtual private network (VPN).

Web Security. Tampering with information on Web sites and electronic eavesdropping to steal valuable information such as credit card numbers are two of the greatest potential security problems on the Web. The most common general-security software is the secure sockets layer (SSL) protocol developed by Netscape. SSL works on top of the transmission control protocol (TCP) used for Internet communications and can be used to achieve security for hypertext transfer protocol (HTTP) and file transfer protocol (FTP) communications. It performs several functions, including authenticating the Web server (through a private key mechanism) so that a fake site is not gathering sensitive information from unsuspecting customers, checking integrity check values for message content, and encrypting for confidentiality. SSL is not

specifically for preventing hacking into Web sites: to stop that, firewalls must be employed. Other security methods are also available for the Web. In particular, Visa and MasterCard combined to develop the secure electronic transaction (SET) protocol for bankcard payments made during online shopping transactions. SET is based on a public key infrastructure that provides encryption, authentication of different participants in the transactions (cardholders, merchants, transaction processors), and integrity checking.

Legal and Market Approaches

Traditional commercial transactions are governed by well-defined laws and legal precedents. In particular, there is a clear concept of what constitutes a legally binding contract. Paper documents with signatures are the norm for contracts. Sometimes, notarization to authenticate the signatures is required. There are also disclosure requirements and escape clauses, particularly for consumers transacting with businesses. The legal issues in e-commerce contracting revolve around how identities can be verified, signatures can be authenticated, and content can be protected, when information is stored, processed, and transmitted electronically. Such techniques were discussed in the previous subsection.

Another category of problems arises in communications. We accept the U.S. mail and private courier services as reliable, secure methods of delivering physical documents. Tampering in such cases is difficult and costly to accomplish on a large scale, possible to detect, and subject to severe penalties. On the other hand, large-scale electronic eavesdropping or tampering with communications is not as difficult or costly. Scanning large volumes of electronic communications is quite different from opening hundreds or thousands of envelopes to check what is inside. As a result, ordinary e-mail via the Internet is much less secure than first-class mail via the U.S. Postal Service. Furthermore, tampering with the U.S. mail is a well-defined and serious legal offense. The same kind of legal protections and standards are still evolving for Internet communications.

Certification Authorities. In traditional transactions, where assuring identity is extremely important (large financial transactions in particular), signatures are often required to be authenticated by being done in the presence of a notary public, who acts as a trusted third party. Certification authorities in e-commerce are intermediaries that address verification problems relating to identity but without the physical proximity that traditional methods require (you have to be physically present to sign in front of the notary). A certification authority (CA), therefore, is a public or private entity that issues digital certificates to authenticate identities and messages or to attest that an action has occurred. CAs can provide verification or assurance of identity, verification of message content, and verification of events or actions. Private CAs in e-commerce have stepped in to fulfill roles traditionally played by trusted government agencies such as the U.S. Postal Service. How do private CAs themselves establish trust? They may need to be certified themselves or they can

build a reputation in the marketplace. In the long run, as e-commerce grows in scope and complexity, transactional certificates and time stamping may be more significant functions of CAs than simple identification, which will become more standardized over the Internet.

Contracts. The growth of e-commerce itself will depend on the ability of two parties to complete a contract, sign it in a legally binding manner, and transmit it, all purely electronically. The technology is not the stumbling block to this goal. The issue is one of clear, generally agreed on legal standards. For example, in the United States in June 2000, the president signed (electronically as well as with the traditional pen) a bill that sets these standards and will make it possible for businesses to close deals with electronic contracts and digital signatures. Similar legislation has been passed in other industrial countries. Electronic contracts are especially attractive for B2B transactions. However, the possibility of electronic contracting will probably require some updating of rules that protect consumers. Because a large percentage of households are not online, presumably consumers should still have the right to have all contract details and subsequent pertinent notices on paper without financial penalty. This makes the cost saving that electronic dealings offer to businesses harder to achieve, but presumably these will come with time, as electronic communications become cheaper and more ubiquitous. The technology of digital certification will also have to become more widespread and widely understood for it to serve the everyday needs of B2C transactions.

Communications. The problem of electronic communications is more widespread and basic than that of electronic contracts, because many communications are not directly relevant to transactions. One area where electronic distribution of information is very attractive, because of its speed, flexibility, and capacity, is in financial services. The Securities and Exchange Commission, which regulates financial services related to securities markets and transactions, noted in 1995 the "promise of electronic distribution of information in enhancing investors' ability to access, research, and analyze information, and in facilitating the provision of information by issuers and others" (SEC, 1995). The SEC went on to state that "given the numerous benefits of electronic distribution of information and the fact that in many respects it may be more useful to investors than paper, its use should not be disfavored." The SEC's approach used the analogy of traditional paper-based communications to define the parameters of what would be acceptable for electronic communications from financial services firms to investors. In 1997, the New York Stock Exchange handed down guidelines to its member firms, essentially following the SEC's lead. Prospectuses, stock trade confirmations, and statements are examples of documents that are required to be sent to investors and that may be delivered electronically once there is a sufficient level of trust and acceptance of the technology and the providers of the service. Content integrity, authentication, time stamping, and overall security and reliability are important for such financial communications. Private startups, as well

as the U.S. Postal Service, are developing products and services that meet these needs in ways that ordinary e-mail does not.

GOVERNMENT POLICIES

Any market economy relies on government regulation to maintain a framework of laws and property rights that allow production and exchange activities to occur in a stable environment. The rise of the digital economy has several effects on government management of the economy. We briefly examine several of these effects in this section.

Intellectual Property

Phenomena such as the widespread copying of digital music, using file-sharing software available from many different commercial and noncommercial providers, have heightened concerns about enforcement of copyrights on the Internet. Some have called for more stringent copyright laws, and, in the United States, the Digital Millennium Copyright Act (DMCA) of 1998 did introduce some additional protections in the guise of updating previous law to cover new technologies. The DMCA, combined with previously existing laws, provides quite strong protection, as indicated by court rulings against Napster and other providers of file-sharing software as well as successful recording industry lawsuits against individual file sharers. At the same time, the courts, in recent rulings, have placed some limits on the extent to which Internet infrastructure providers can be held responsible for illegal file sharing.

The DMCA included penalties for cracking protections designed to protect unauthorized copying. However, the legal application of the DMCA has had an effect on free speech, as demonstrated by examples such as a professor of computer science who forwent the presentation of a research paper that outlined methods of overcoming copy protection, when the professor was threatened with a lawsuit. Lobbying by industry groups that have ownership interests in copyright has also motivated potential U.S. legislation that requires copy protection be hardwired into consumer electronics items. In such cases, the doctrine of "fair use" in copyright law also appears to come under attack. In the United States, the DMCA was complemented by another law, which resulted in extending copyright protections by 20 years. Although European copyright laws have not tilted so much against users, the United States is a global leader in the production of copyrighted material such as music and films.

In the arena of patents, it has been court interpretations, as noted in *Information as an Economic Product*, rather than new legislation that has increased the scope of patent law, with hundreds of relatively broad software patents being granted in recent years. It has been suggested that a new category of patents, with a shorter lifetime, be granted for software, but this is likely to create further problems for assessing patent applications. It also misses the real problem, which is that of inadequate resources in the U.S. Patent and Trademark Office. Again, the United States is the largest market for intellectual property, and U.S. patent rules are disproportionately

significant in the global context. In general, the apparent broadening of both copyright and patent protection can be seen as a response to a situation where intellectual property is increasingly important for creating economic value but also easier to copy or imitate. Thus, these legal trends are a symptom of the digital information/knowledge economy.

Privacy

The digital economy, with its greater flows and tracking of information, raises serious concerns about privacy. Information about consumers allows firms to increase profits through various kinds of price discrimination. At the same time, some consumer information can help firms to tailor their products more effectively to consumer preferences. Privacy concerns often center on how the information is collected: do consumers realize that their behavior online is being tracked or that cookie files are being deposited on their computers?

Further issues arise with respect to who else may properly see the information collected. A customer may not mind a seller tracking the consumer's buying habits to serve her better, but she may not want the firm to sell that information to other firms. A related issue is the use of such information for mass marketing e-mails, commonly known as "spam." Employees, too, may find that their electronic communications and Internet browsing from work can be monitored by employers with great precision and intrusiveness. Finally, there are all kinds of information that various public agencies collect. Often such agencies are required to make that information available in response to requests from members of the public. However, making that information available online makes access much easier and broader than other forms of availability, with possible negative consequences.

The U.S. legislative branch was actively considering Internet privacy legislation after a report from the Federal Trade Commission in mid-2000 indicated that self-regulation was not working uniformly and some Web sites were proving resistant to privacy concerns. One stumbling block for legislative agreement was the simple issue of whether businesses should be required to explicitly get consumers to "opt in" to allow their personal data to be used beyond the specific transaction or relationship, or whether the burden should be on consumers to explicitly "opt out." Businesses naturally favored the latter approach, which gives them much more leeway. Business-supported groups have tried to argue that privacy legislation would be inordinately costly and also that consumers do not care enough for it to be worthwhile. On the other side are groups such as the American Civil Liberties Union and Consumers Union, which want stronger safeguards against data-collection practices that do not involve explicit consent. The aftermath of 9/11 has tilted the scales against strengthening privacy, because security has become a much greater concern. Therefore, it seems unlikely that any meaningful Internet privacy legislation will be passed any time soon in the United States, which leaves its online privacy laws some way behind those of the European Union, which protect consumer privacy more stringently.

Antitrust Policy and Regulation

Antitrust laws are designed to prevent monopolization of industries and anticompetitive practices such as price fixing. Does the digital economy require modifications in the government's enforcement of antitrust policy or even a change in the antitrust laws themselves? There are three key areas in which the proponents of a modified approach to antitrust policy make their points. First, there is the argument that antitrust enforcement must account for the effects on future innovation. The second argument is that network externalities and the economies of scale associated with information goods make monopolies more likely or more natural (winner takes all) and hence they must be tolerated—otherwise there will be no market or unnecessarily high costs. The third argument is that complementarities in information goods require firms to cooperate in ways that might seem collusive by more traditional measures.

The first of these, the increased importance of technological innovation and of patenting, certainly makes these variables more important in a firm's business strategy, but it does not, by itself, imply that antitrust law has to change. Firms can innovate profitably, using patent law, without having to run afoul of antitrust law. Second, network effects are demand-side economies of scale, which can interact with the usual cost-side economies of scale to promote market dominance. If information goods are subject to both kinds of economies of scale, one might have to be resigned to more cases of "natural" monopoly, driven purely by the structural characteristics of the market rather than by any illegal behavior. However, the importance of such natural monopolies is probably overstated, and their persistence is unlikely if the protection for patents is not too stringent.⁷ Finally, technology goods have to work in systems and are characterized by strong complementarities. This often requires firms to collaborate in research and development, as well as in production and installation. However, as long as single firms, or firms acting together, do not engage in behavior that reduces competition or harms competitors, there is no violation of antitrust laws. What is needed is not a reform of the laws, but simply enforcement by government officials who understand technology well enough to sort out different kinds of cooperative behavior among technology-oriented firms. Clearly, this is more difficult when markets are interrelated and technology evolves very rapidly.

Laws to manage privacy issues and antitrust laws can both be considered major examples of regulation by the government of private economic activity. They are not the only ones. There are specialized regulations for different sectors of the economy, such as financial services and telecommunications. There are also regulations meant to protect certain groups or to control certain types of activity. For example, pornography and hate materials are

controlled, and gambling is a heavily regulated activity. All these forms of regulation are affected by the Internet. Much of the problem is simply in the freedom with which information can be disseminated and shared on the Internet. The location of activities is also a problem: for example, online gambling can escape controls that are designed to operate within geographic jurisdictions. Controls on forms of payment, for instance, by using the major credit card companies, can be a way to solve the jurisdictional problem. The credit card companies cannot afford to be partners in crime. Here the law needs to change to deal with ability of digital activities to escape the requirement of meeting in a particular place.

In the case of financial services, the issues have to do with the quantity and the veracity of information that is made available. The Internet makes scams easier to implement in some ways, but the basic laws do not need to adjust. In the case of telecommunication companies, regulatory issues are centered on the technological changes that digitization has introduced, which make more effective competition possible. The U.S. Telecom Act of 1996 began the process of moving regulation into the modern era. Some regulation is still needed because parts of the network are still potential monopolies. Local telephone companies—the so-called Baby Bells—in particular have maintained their strongholds. Regulations to allow interconnection to parts of the Baby Bell networks by competing carriers have not really enabled the latter to gain significant market shares. While protecting their traditional markets in voice communications, the Baby Bells have been lobbying for the ability to compete more freely in markets for data communications, that is, the underpinnings of the Internet. The convergence of communications technologies that have been governed by different regulatory frameworks also creates regulatory challenges. For example, in 2003, a U.S. court ruled that the Federal Communications Commission (FCC) incorrectly classified cable networks as "information services" rather than "telecommunications services," where only the latter are required to share their broadband access lines.

International Trade

Countries often have customs duties or tariffs on imports, and these clearly affect international trade. They may also use quantitative restrictions on the entry of certain goods and services. An extreme case of this would be a total ban. Various reasons for restricting international trade do exist: to raise government revenue, to control undesirable materials, to protect some domestic groups, and so forth. Individual country choices made without coordination may lead to outcomes that are worse for all countries. Therefore, to try to achieve some measure of cooperation that can improve outcomes, trading nations use the World Trade Organization (WTO) to frame and enforce rules for international trade. Having such an organization does not remove conflicts, but it provides a mechanism for more orderly handling of disputes, as well as a clear set of "rules of the game."

The current provisional WTO agreement is that trade restrictions should not apply to electronic transmissions via the Internet. This leads to a symmetric treatment of

⁷ Arguments relating to network externalities as well as to innovation have been made in the Microsoft antitrust investigations, both of which concluded with out-of-court settlements. One can argue that any monopoly that Microsoft might have is related more to traditional anticompetitive practices such as the nature of its contracts with distributors, rather than any special features of the digital economy. In the European Union, there is an ongoing antitrust investigation of Microsoft.

online and offline transactions, as in the example of a European purchasing U.S. stocks or a U.S. hotel room while on vacation. In other cases, however, there is a difference. Thus, purchasing a large number of music CDs from another country might be subject to a customs duty (small purchases from abroad are exempt in the U.S., though not in many countries), but obtaining the same quantity of music as electronic files would escape the import tariff. This is superficially similar to the issue of sales taxation within the United States, but here we are looking across national borders, whereas in the U.S. sales tax case, the tax must be paid if the transaction is in-state rather than across states. Hence, the two cases are somewhat different although broadly related in spirit.

The WTO also includes provisions for trade-related intellectual property rights (TRIPS). The TRIPS agreement came about in the 1990s and sets minimum standards for copyright and patent law for member countries. In addition, these laws cannot discriminate between local citizens and citizens of other TRIPS signatories. The TRIPS agreement was substantially predated by the World Intellectual Property Organization (WIPO), which is a United Nations agency and has a substantially different governance structure. Global intellectual property rights (IPR) issues end up being debated in the WTO as well as in the WIPO, with the former providing more stringent protections and enforcement mechanisms in theory. However, there are substantial difficulties in enforcing IPRs across national borders, and worldwide low-cost digital copying of copyrighted material such as music, movies, and software is a substantial concern for copyright holders in countries such as the United States.

A further issue with respect to information products in particular is the blurred line between goods and services. For example, software development is a service that is now offered across national boundaries. Also, software is typically licensed rather than sold, and leasing software is common. Because traditional services, such as those in the financial sector, have been treated under a separate set of rules (the General Agreement on Trade in Services, or GATS), which is newer and more restrictive than the rules for goods or products, there is disagreement as to which set of rules should govern software. Countries such as the United States that are producers and net exporters of information and related services argue for the application of the rules for conventional trade, rather than the GATS.

WORK, PLAY, AND COMMUNITIES

Work is a large fraction of our lives. It is useful to recognize how drastically work was altered by the industrial revolution, the introduction of factories, and the rise of large corporations. Cottage or home production became relatively insignificant, as mechanization and economies of scale caused work to be concentrated in factories and offices. Now IT has loosened the bonds of location, making work once again more flexible for many.

Location of Work

Several trends have driven the changes in work. First, the increase in the importance of services relative to

manufacturing and of the information economy in general reduced the proportion of factory jobs. Next, the falling cost of computing power allowed many tasks to potentially be performed at home rather than in the office. Most important, the Internet has removed the isolation of the home worker. Communication and collaboration can take place among workers in different locations. Physical proximity for many jobs becomes only a part-time requirement. Clearly, this is most pronounced for jobs that involve “knowledge work,” where collaboration involves exchanges of information: software development is a prime example of this kind of job. In other cases, remoteness is no longer a barrier to carrying out some functions. A technical support person may guide a computer user through steps to repair a problem. Many software fixes can be done from a remote location. Even some surgery can now be performed by a doctor at a remote site who manipulates instruments through long-distance communications and control. Although these changes are just in freedom of location, there are also changes in the nature of the firm itself, sometimes reducing the bonds that define a firm, as was discussed in *Implications for Markets and Organizations*. Employees in such cases can become independent contractors, with their own capital (human and physical), almost harking back to the preindustrial era of home production.

Freedom of location has begun to affect the global distribution of work. The customer in the United States may have a telephone query answered by someone in Ireland, India, or the Philippines. Computer programming or program testing assignments may be sent via the Internet to wherever people with those skills are available, to be completed and sent back the same way. The supply of some kinds of skills becomes global rather than local or national. There is also a time dimension to this geographical dispersion of work. Time differences across the globe allow 24-hour customer service to be more cost-effective. In areas such as software development, they also allow global shift work. For example, two project teams in the United States and India can collaborate to achieve an almost continuous workflow by utilizing the night-and-day time difference between the two countries. However, the ubiquity of digital communication devices means that the notion of times and places where work does not intrude is severely eroded. A knowledge worker may find she is expected to access her e-mail via a wireless handheld computer at home, on vacation, and in general outside the normal place and time of work.

Finally, there are concerns that the efficiency gains of the digital economy come at the expense of jobs and workers. This is an old concern, which reflects the continued substitution of capital for labor that has occurred since the Industrial Revolution. In the United States in the early 21st century, this concern is arising because of the slow pace of job creation as the economy recovers from a recession. Although there has been some shifting of service jobs, such as call centers and business processes, to developing countries, this currently represents only a small fraction of the jobs that would normally be created. The alternative explanation is that the use of IT reduces the need for workers. Although such concerns may be valid in the short run, it is clear that in the long run new kinds

of jobs are created as productivity gains allow firms to develop new products and services or to expand existing markets. Perhaps a more significant issue is that of potential effects on income distribution: will a knowledge economy reward people more unequally? Clearly, access to education and training will be an important determinant of how this issue plays out in the future.

Leisure Activities

Leisure activities in the industrial age have been shaped by scale and specialization, just as happened in the case of work. Sports and the performing arts have become large-scale spectator or audience events. Radio and television introduced broadcasting, which created mass markets for entertainment while removing locational barriers. Recording technologies expanded the scope for listening to music or watching movies while introducing greater choice into consumer decisions. All these developments in people's leisure activities are enhanced and broadened by the Internet. Inexpensive digital recording and transmission of music and video provide a range of options unimaginable in the past.

Perhaps the greatest effect of the substitution of bandwidth for being in the same place has been in game playing. One can play traditional games, such as bridge and chess, via the Internet, with opponents and partners who may be anywhere in the world. More widespread is the enormous expansion of online game playing. Computer games become virtual worlds where individuals act out their fantasies and try out strategies. Game characters take on lives of their own, becoming valuable commodities themselves for game players who want to win any way they can. At one level, the interaction is no different from that of board games that have been played for hundreds or thousands of years, that of stylized competition. However, the complexity of such games has increased exponentially, and the Internet has demolished distance in creating the communities of game players.

Just as IT has allowed work to intrude into leisure spaces, it has also allowed the reverse phenomenon to take place. Workers who sit at a computer may play solitary games. If they have Internet access, they may engage in all kinds of leisure activities, including browsing news and entertainment content, shopping, and chatting as well as game playing. Hence, employers may respond with new kinds of monitoring and restrictions, as was discussed earlier in the context of privacy. However, the breaking down of barriers between work and play may be inevitable, to the extent that it represents a more natural existence for human beings. In this respect, the digital economy may provide the kind of interconnection that existed before the factory system came to dominate production methods.

Online Communities

From online game players to members of a project team designing a software program, people at work and play form communities based on shared goals or interests. IT allows these communities to be freed from the need to share a physical space. Interactions take place on computer screens instead of face-to-face, but the interactions that are possible in cyberspace are getting richer and

richer, which allows more and more communities to form. In particular, work collaborations of increasing complexity are becoming possible on the Internet, with simultaneous or asynchronous participation in activities involving product research, design, and development.

Work and play are not the only glue that binds communities. Any kind of shared interest can provide the impetus. Those suffering from a particular disease, fans of a rock star, or collectors of sports memorabilia can join together to exchange information, ideas, and experiences over the Internet. These communities may provide commercial opportunities, because they provide access to that ever-scarcer commodity, "attention," but they may also lead to more profound social changes. Political organization, in particular, takes on a new dimension, perhaps expanding the scope of democracy, while definitely changing its nature. Possibilities exist for Internet-based comment, feedback, and even voting by citizens in communication with their governments. Many of these possibilities are now lumped together under the concept of "social networking," where the Internet is used as a tool to create and maintain general or special purpose communities, based on shared interest, mutual help, or other common features.

Perhaps the most remarkable change of all is how, in just a few short years, the majority of people in the industrialized world have come to take for granted so many possibilities that alter their lives and may reshape the social fabric. The Internet, at its core, is a very human-centered development. This may seem somewhat paradoxical. The underlying IT is complex and abstract. But the Internet and its associated technologies allow people to be creative, to express their individuality, and to communicate and connect with other individuals in new ways and with new freedom. This extension of basic human capabilities, amplifying humanity and not just brainpower, is why the Internet excites so many and inspires sometimes-overstated rhetoric.

CONCLUSION

The digital economy is much more than simply online shopping. It involves a fundamental transition that has been taking place for more than two decades and which is based on the rapidly falling costs of processing, storing, and transmitting information in digital electronic form. Some of this transition was obscured by the dot-com mania, which often focused on using the Internet as a marketing and retailing channel. In fact, the digital economy includes this as just a small part. The internal organization of firms is changing, their nature is changing, the kinds of interactions that are possible between different economic agents are changing, and the location of different activities is changing. Social relations, governance, and leisure activities are all affected by the pervasiveness of digital technology. Measures of the digital economy can understate or overstate the current effects, but they do emerge in recent academic work, and they appear to be increasing.

GLOSSARY

Bandwidth Technically, the difference between the lowest and highest frequencies in a transmission channel,

but more often informally used to refer to the speed with which digital data can be transferred via a specific connection (telephone wire, cable, optical fiber, or wireless), for example, 10 Mbps, or 10 megabits per second.

Cyberspace All electronic interactions and data, especially those that are mediated by the Internet. The term was coined by William Gibson in his science-fiction novel *Neuromancer*.

Digital Divide A situation where particular socioeconomic groups have access to the Internet and information technology at levels that are substantially higher than other groups.

Digital Economy A term that emphasizes the importance for the overall economy of information that is stored, processed, and exchanged in digital electronic or optical formats.

E-Business A subset of e-commerce, including all electronically aided transactions and activities of businesses, including internal accounting, inventory control, and communications.

E-Commerce Short form of electronic commerce that refers to doing business electronically, based on the electronic processing, storage, and communication of information, including activities that provide the enabling physical infrastructure and software.

E-Commerce Interaction Types: B2B, B2C, C2G, C2C, B2E Acronyms for different interactions, implicitly but not necessarily electronic, among businesses, consumers, governments, and employees (e.g., B2B means business-to-business).

EDI (Electronic Data Interchange) A term that refers to the use of proprietary software and leased telecommunications lines for communications among firms, typically at different points of the value chain

E-Tailing Short for electronic retailing, which is the use of the Internet and World Wide Web for offering consumer products and services for sale and for completing transactions.

Flexible Mass Customization The ability to quickly satisfy the diverse wants of large numbers of individual consumers.

Information Economy A term that emphasizes the importance for the overall economy of all kinds of information, including entertainment, news, market and business information, research, and personal communications.

Information Revolution A term that emphasizes the dramatic effects of the steep fall in the costs of processing, storing, and communicating information as a result of advances in information technology.

Information Technology Any aspect of technology, including hardware, software, and services, that involves data in digital electronic or optical formats, including technologies for processing, storing, and transmitting such data.

Intellectual Property Useful inventions, original expressions of ideas, and names or symbols used in business the ownership of which is protected by various categories of law (trade secret, patent, copyright, and trademark).

Knowledge Economy A term that emphasizes the importance for the overall economy of all kinds of knowledge, including various types of expertise, skills, and understanding of particular markets, with an implicit emphasis on science, mathematics, and technology.

Moore's Law An empirical regularity, described by Intel cofounder Gordon Moore, that the processing power of microprocessors (measure by the number of transistors per square inch on integrated circuits) doubles every 18 months; therefore, an indicator of the rapid pace of innovation in the digital economy.

Network Externalities A situation where the value of being part of a network depends on the number of other members of a network. Typically, this value is positive. For example, if the value of a network with n members to an individual depends on the number of possible connections in the network, then this value is proportional to $n(n-1)/2$ (roughly, the square of the number of users, which is known as "Metcalfe's Law"), and the marginal value of an additional member is proportional to n , the network size.

New Economy A term that encompasses the ideas behind the terms "digital," "information," and "knowledge" economy, but also sometimes connotes that the workings of the economy are changed, either because information is a good with high fixed and low marginal costs, so competition is less stable, or because faster information flows reduce adjustment times and hence reduce swings in the economy.

Online Being actively connected to or being a user of the Internet (and possibly other electronic networks).

Supply Chain From the perspective of a firm, this is the portion of its value chain that involves its direct and indirect suppliers. From the perspective of the industry, it coincides with the value chain, with the emphasis being more on the physical processes and logistics as opposed to value added.

Value Chain A schematic representation of a firm's (or industry's) stages of production, possibly including activities that take place upstream or downstream of the firm's own activities. Examples of value chain stages include inbound logistics, production operations, outbound logistics, marketing and sales, and after-sales support. The emphasis is on the value added at each stage.

Winner-Take-All A market situation where the leader dominates because the high fixed costs and low marginal costs of producing information favor one or a few large firms, or because users of a network get much higher benefits when the network is larger.

INTRODUCTION

When the Internet backbone was privatized in the mid-1990s, it transformed the way many individuals conduct their day-to-day activities. It established a new and more efficient way for individuals to purchase plane tickets, order the latest best-sellers, or research a particular product of interest.

Bank-related activities are also among the growing activities that individuals perform online on a daily basis. According to a 2003 report from Jupiter Research, approximately 29.6 million households in the United States banked online in 2003, and this number is expected to reach 56 million households by 2008 (Greenspan, 2003). This will represent an average annual growth rate of about 14% in the 5-year period.

One of the driving factors for the increasing number of online banking activities is the customers' ease and convenience of accessing these services. Bank customers are no longer limited by the business hours of a bank to carry out their bank-related activities. They can now access a number of banking services via the Internet at anytime and from any location. Because the Internet has become a viable channel for them to serve their customers, banks are increasing their online offerings. Banks also realized that customers who conduct their banking activities online are more satisfied compared with customers who conduct their banking activities offline. They found that more-satisfied customers tend to have greater loyalty to their banks, which means that they are more likely to go to their banks to take out mortgages, loans, and equity lines. Not only are these products traditionally more profitable for the banks, they deepen the relationship with the customers and, hence, their share of wallet (Miles, 2002).

Despite the number of benefits associated with online banking, it has created a number of challenges for banks, specifically in the area of risk management. Although risk

management has historically been a concern for banks, the advent of online banking is creating a more complex environment for risk management because it has changed the way banks control their risk.

Prior to online banking, banks had full control over the risks they encountered. However, once customers order online banking services, some of these controls are relinquished. With online banking services, banks are offering their customers the convenience of accessing their accounts on demand via the Internet. Allowing the customers to access their accounts on demand means that a bank's customers will interact directly with a bank's internal system, thus permitting access to customers' accounts via the Internet. This means that a bank's internal system is now connected and accessible via the Internet, which is a public network. In addition, many of the increasingly sophisticated online banking services offered by banks involve new and evolving technologies, which are often beyond the capabilities of many banks and therefore require reliance upon third-party vendors to provide the online banking applications and platforms.

TYPES OF ONLINE RETAIL BANKING SERVICES

Online banking was first introduced in the mid-1980s, when a select number of bank customers were offered the opportunity to conduct a limited number of activities using their personal computers. Unfortunately, this delivery channel did not grow in popularity because of the need for proprietary software and the fact that networks, at the time, were not very user friendly (Sorkin, 2002). It was not until the mid-1990s that online banking found a new lease on life. The privatization of the Internet provided banks an opportunity to offer banking services over a public network that customers could access simply with a browser.

Wells Fargo bank, in 1994, was the first bank to establish a Web site to offer their customers information (Hall, 2003) and Security First Network bank, in 1995, was the first bank to offer online banking services (Hoffman & Kim, 1995).

Online offerings from many banks initially were limited to providing information related to their offline products and services. Many banks were skeptical of the Internet's potential as a channel to offer banking services and products to their customers. However, as online competition from entities other than banks, such as brokerage firms and financial Web sites, intensified, many banks began to step up their online banking offerings to individual customers (i.e., online retail banking services, Wan, 2004).

Today, banks offer a variety of banking-related (and non-banking-related) services to their individual customers via bank Web sites. These online retail banking services can be grouped into three categories: sources of information, customer services, and account-related activities (Wan, 2004).

Sources of Information

Banks are taking advantage of the Internet's qualities to deliver a variety of information to various target audiences and to provide interactive and unique experiences to those accessing these information sources. Customers accessing the banks' Web sites can retrieve a wealth of information regarding the variety of banking products and services offered. With their Web sites, banks are able to provide information that is more detailed than what is available in print and can update the information in a much more timely manner.

Many banks also understand that an educated customer is a good customer. It is no longer sufficient for banks to simply provide information about their products and services. They need to help their customers understand why they need these products and services. An increasing number of banks are offering an extensive collection of educational materials on a wide range of financial topics, such as planning for college and retirements, to help their customers better understand how various banking products can assist them in achieving their financial goals.

Customer Services

The Internet enables many banks the opportunity to reduce many of the costs associated with customer service by allowing them to offer, via their Web sites, many of the services they provide. A large number of banks have established Frequently Asked Questions (FAQ) sections to offer answers to many of the questions traditionally fielded by their call centers. An increasing number of banks are offering their customers e-mail notifications with their accounts. For example, an e-mail will automatically be generated when a customer's account balance falls below a specified level. In addition, many banks have now set up online automated services that enable their customers to perform certain functions so that they no longer have to go to the banks or call a customer service representative. Customers can now perform online a number of account-related activities such as reordering

checks, ordering paper copies of cancelled checks and bank statements, or requesting a stop payment on a check. Furthermore, customers can also change certain personal information, such as their addresses and PINs (personal identification numbers), easily online without having to fill out a number of forms at a local branch.

Account-Related Activities

A majority of the online bank offerings concentrate on providing customers with a wide range of account-related activities. The three most common online offerings available at most banks' Web sites include opening bank accounts, accessing account information, and initiating transactions.

Opening an account: Most banks allow their customers to initiate the account application process online by filling out an application. Some banks provide the account application forms on their Web sites, and require their customers to download and print the forms, fill them out, and either drop them off at a local branch or mail (or fax) them to the banks. On the other hand, some banks expand on this capability by allowing their customers to complete and submit their applications fully online.

Accessing account information: Once bank customers activate online banking services with their banks, they can access a variety of information related to their accounts via the banks' Web sites. They can view the account balances of their checking, savings, certificate of deposits, and other accounts. Some banks also offer their customers the opportunity to view their bank statements online. Customers can also easily determine when a particular check has cleared by simply clicking on the link associated with that particular check. Some banks' Web sites even allow their customers to view images of their cleared checks.

Initiating transactions: When bank customers sign up for online banking services with their banks, they can choose which accounts they would like to be linked online. Once the linkages have been established, customers can easily transfer payments among these accounts. In addition, many banks are now offering their customers the ability to pay their bills online. Once this feature has been activated, bank customers can schedule future payments for up to a year in advance or even set up recurring payments, such as their mortgage payments. Some banks are also bundling online bill-presentment service with their online bill-payment service. If bank customers choose to activate the online bill-presentment feature, they will be able to receive electronic bills rather than paper bills from selected billers. The bank customers can then pay these bills using the banks' online bill-payment features, which will transfer the funds from the customers' accounts to the billers' accounts.

ONLINE BANKING SECURITY CONCERNS

As the variety and complexity of online banking offerings increase, many offerings are also fast becoming targets for unauthorized activities, which exploit the nature of online banking services and the flaws in the systems that

host the applications and platforms used to offer these services.

Each of the three areas of online banking offerings can be vulnerable to tampering. For example, a bank's Web site can be hacked and contents on the Web sites modified, which means that the integrity of the Web sites as sources of information has been compromised. Fraudulent e-mails can be sent to bank customers, notifying them that their accounts have been compromised, which undermines a bank's use of e-mail as a communications channel with its customers. Furthermore, many of these fake e-mails often provide links to spurious Web sites that look strikingly similar to the bank's Web site. The intention of the phony Web site is to extract information from the bank's customers so that the information can be used later to access their accounts or to commit other acts of identity theft.

A number of security breaches related to online banking have occurred since the late 1990s, when an increasing number of bank customers began to take advantage of such offerings from their banks. The most common security breach is associated with an e-mail fraud in which customers are requested to reactivate their online accounts and thus reveal sensitive personal and financial information. Cases of e-mail-related fraud have been on the rise. In 2003 alone, customers of Citibank, Wachovia bank, Bank of America, and Commonwealth Bank of Australia were targeted by e-mail scams (Hall, 2003; Secure Science Corporation, 2003). However, some of the online banking security breaches are the result of banks offering their services without fully testing their systems. For example, in 1999, X.com Bank, which is a division of First Western National Bank, unintentionally allowed its customers to transfer funds from any person's account in the country into their accounts as long as they had that person's account number and routing number (Markoff, 2000).

These security breaches are undermining the confidence of many bank customers in online banking services. According to a June 2003 report from Tower Group, concern about security is the number one factor that kept many bank customers offline (Hall, 2003). In addition, banks are also more concerned about security breaches as online banking transactions have become more complex and involve increasingly higher account values. Although bank customers have always been concerned with confidentiality, even in the pre-electronic era, the advent of automated teller machines (ATMs), voice response units, and other self-activated technologies have perpetuated an increasing concern about the loss of financial wealth and the loss of identity. Of foremost notoriety and concern is the loss of identity, or "identity theft." Until recently this threat, or rather its urgency, was seldom emphasized. However, with the proliferation of e-commerce and the expansive electronic access and transmission of data prevalent today, the opportunity for theft of critical customer information (i.e., social security numbers) has become of paramount concern to customers. In addition, other sensitive information, such as account information, has also become a major concern, especially in light of the amount of online shopping and online business transactions occurring today. The final, and maybe the most obvious, events that have heightened customer concern over the

protection of their information are the Y2K scare and, of course, 9/11. These two independent events alone have raised the attention level to its present state.

Banks, on the other hand, while sharing the concerns of customers, have a more expansive set of issues and focuses. As financial institutions, banks are considered fiduciaries with respect to their customers. As such, they are not only privy to a wide range of sensitive customer information, but also to information that is important to the functioning of the bank. In addition to expanding legal liability on the part of the board of directors for the protection of such information, banks also have an obligation to their shareholders to establish the controls and mechanisms which will protect client information. In this regard, banks' information security concerns are far-ranging, encompassing a large volume of both internal and external threats that have the potential to compromise their ability to protect customer information, and are an ongoing concern.

Internal threats are those risks that emanate from within the bank or within the network of the bank that could compromise systems or information. External threats, on the other hand, are those originating outside of the bank and attempt to access, maliciously, the systems to manipulate, destroy, or render systems and information unusable. Banks are predominantly concerned with mitigating risks and therefore must perform risk assessments to understand and identify all of the risks that might affect the bank and its functioning. In general, the risks that affect a bank are those specific concerns that would impair the bank's ability to deliver on their objectives or function as an ongoing concern. Among the variety of specific adverse risks affecting banks are loss of corporate image, financial loss, loss of customer trust (which could cause a run on the bank), loss of shareholder trust (resulting in a sell-off of stock), inaccurate customer or bank information, and legal liability. As part of the risk assessment process, banks must be concerned with the risks and the controls relative to three risk attributes: assets, threats, and impacts.

Assets

Assets represent the myriad of tangible and intangible items of value that a bank possesses that could be adversely affected by a threat to its utility. Assets range from a variety of things including, but not limited to, information, physical technical devices, brick-and-mortar buildings, and equipment.

Threats

Threats are potential sources of harm, which could cause an impact to one or more of the bank's assets. Major threat categories include the following:

Technical. Technical threats are those sources of harm that are precipitated by the utilization of some form of technology. The most prevalent of these are computer viruses. Computer attacks and "hacking" are among the major concerns of any bank that has an Internet presence and conducts business or presents information about the bank through a Web interface. These threats are voluminous and occur with a high degree of frequency. As

a result, it is imperative that safeguards be instituted to prevent penetration and preclude an effect on bank assets.

Human. Human threats generally emanate from four predominant sources: outsiders (terrorists), customers, partners, and insiders. These threats can vary in type; however, their common feature is direct human involvement that affects a bank's assets in some way. This could be through sabotage and espionage (both internal and external), as well as through partners who may be privy to information and other assets, which could constitute a risk. Terrorist activities, similar to the events involving the World Trade Center, are the most obvious of the human threats. With this recent example, the risk from human threats has grown tremendously in importance and focus for banks and other organizations alike. Customers, as well, can impact a bank's assets through physical access and exposure to information and other assets.

Natural. The final category of threats affecting banks is composed of those that occur naturally. Tornados, storms, fires, snow, and ice all constitute likely threats to bank assets. Although these events can and do occur randomly in the environment, they nevertheless must be addressed to avoid affecting key bank assets.

Impacts

Impacts represent the outcomes or the consequences of a particular threat. Because a threat (any of those identified) will affect a bank's assets in some way, one or more of the following will occur as a result:

Unauthorized disclosure of information. Banks are always concerned with the disclosure of sensitive bank or client information to other parties not authorized to view it and who could be in a position to use that information in ways to cause harm. This can occur through negligence or outright attempts at obtaining information.

Unauthorized modification of information. Once information is accessed by unauthorized sources, the information may be subject to modification in some way, which could result in negative consequences to the customer or bank. Examples of modification include manipulation of monetary amounts or displayed information to cause harm, to create advantage, or simply to disrupt.

Unauthorized destruction of information. In some cases information is accessed by unauthorized sources with the sole intent of destroying it or rendering it unavailable to authorized individuals. This impact is severe, greatly exposes the bank to legal liability, and can threaten the bank's existence.

Unauthorized use of information or systems. This impact is more subtle but equally as dangerous, if not more so, than the others. In this case, information that is accessed by unauthorized sources is used in ways to create advantage where none existed, to discredit, or simply for the purposes of theft, such as in the case of identity theft. The use of the information, in this regard, would appear to be appropriate and normal on the surface; however, the user of the information is not.

Improper use of information or systems. This refers to gaining unauthorized control of information and/or systems in such a way as to use them for unintended purposes. Taking control of a Web site and displaying

information or messages not intended by the bank is a good example of this.

Unavailable systems. Natural threats and human threats (terrorist activities) are probably the most obvious sources that could render systems unavailable. Tornados and fires, for example, could destroy servers or central computers, which could cause the loss of data, affecting customers and the bank. Terrorist activities could be as blatant as the destruction of a physical site or as subtle as a computer virus that renders the computer unusable. In any situation, the net result is the inability to use a system that was previously relied upon.

All of these relate to the broad categories of integrity, confidentiality, and availability of information previously discussed. The purpose of risk assessment is to understand where threats may come from (sources), the effect on the bank (unauthorized disclosure, modification, or destruction of information), and to determine the appropriate controls necessary to mitigate these risks (authentication controls, password controls, etc.).

DEFINITION OF SECURITY

According to *Webster's Dictionary*, security is "freedom from risk or danger; safety." In the context of this chapter, this definition is expounded upon with an emphasis on "information security," in contrast to physical security. Physical security relates to protecting or securing the physical branch or location and access to sensitive material and/or negotiable instruments, such as bearer bonds, CDs, and endorsed checks. Information security, on the other hand, is the "process by which an organization protects and secures systems, media, and facilities that process and maintain information vital to its operations" (Federal Financial Institutions Examinations Council, 2002). As a discipline, information security has grown in importance, particularly with the proliferation of the Internet and applications for banking. At the turn of the 21st century, bank regulators were intensely focused on the issues attendant to transitioning and recovering information that possibly could have been impaired because of outdated code. Since that time, the focus has shifted from merely recovering data to a more comprehensive focus centering on information and protecting the integrity, confidentiality, and availability of customer information.

In 1999, the Gramm-Leach-Bliley Act was passed, which documented requirements for protecting the privacy of customer information. This laid the foundation for the development of a much more sophisticated means of defining and mitigating information security risks on the part of banks. More specifically, section 501(b) of the act outlines detailed requirements of what member financial institutions must do to protect client information. This section further requires regular communication and oversight responsibility on the part of the board of directors and mandates compliance.

Information Security Objectives

In 1999, the Office of the Comptroller of the Currency developed very specific guidelines for bank information

systems departments to follow. The development of these standards resulted in URSIT, the Uniform Rating System for Information Technology (Office of the Comptroller of the Currency, 1999). URSIT not only standardizes the basis by which financial institutions' information technology (IT) departments are evaluated, but also provides effective guidelines for understanding the objectives of information security. URSIT, as a rating system, comprises four areas of focus (Office of the Comptroller of the Currency, 1999):

1. The adequacy of the bank's risk management practices.
2. Management of IT resources.
3. The integrity, confidentiality, and availability of automated information.
4. The degree of supervisory concern posed by the institution.

Although all four areas are a focus of the bank exam, the third item most specifically outlines the objectives for sound information-security practices and represents the key areas of focus as it relates to "customer" information.

Data integrity. This objective refers to both data and systems and attempts to define policies and procedures to ensure that neither have been altered or manipulated by unauthorized individuals, which could comprise the information or systems themselves. Data integrity is concerned with ensuring that systems and information have not been comprised by unauthorized individuals or access. Controls to mitigate risks in this area include separation of duties, balancing and reconciliation activities to check input and output, master file controls, changing management controls for system changes, access levels consistent with job functions, and strong authentication and password management (Office of the Comptroller of the Currency, 1999).

Data confidentiality. Data and system confidentiality refers to protecting sensitive information from unauthorized access and/or use while in transit or otherwise. This objective is at the heart of the Gramm-Leach-Bliley Act with regard to privacy of information. The goal of this objective is to avoid the disclosure of client data unintentionally, which could compromise the system and/or customer. Controls include intrusion detection systems, encryption of data, and monitoring mechanisms to detect and prevent unauthorized access (Office of the Comptroller of the Currency, 1999).

Data availability. Data and system availability ensures that systems and data are accessible to customers and other authorized users. Data availability is the closest to recovering data and therefore is concerned with backup procedures, redundancy, and other mechanisms that prevent the loss of access to data when needed. Controls include business resumption contingency policies and plans, event management procedures (including incident response), physical access to information and sensitive areas, virus protection, and backup and recovery procedures (Office of the Comptroller of the Currency, 1999).

The defined security objectives, in conjunction with URSIT, established the structure for information security and risk management for financial institutions. Banks are

regularly reviewed, during their "safety and soundness" audits, to ensure adherence to these guidelines with the overall objective of protecting the privacy of the customer.

SOURCES AND CONTROLS OF EXTERNAL INFORMATION SECURITY BREACHES

Definition and Problem Statement

External threats can occur at any time. As outlined previously, threats fall into three categories: technical, human, and natural. Each of these threats represents a concern for the bank with regard to protecting client and sensitive bank information, as well as the uninterrupted functioning of the bank. In today's environment, external threats are a way of life and will continue to be perpetrated against banks intentionally and/or through natural occurrence. Regardless of the threat, banks must be prepared and establish the appropriate controls to avoid the effects on the bank and customer information.

From a customer's perspective, with the expanded use of the Internet, external threats against the bank are not merely concerns of the bank but equally concerns of the customer because of the potential for loss or unauthorized use of the customer's own information. As a result, the bank must enact a wide array of controls to protect against these threats.

Sources and Controls of External Threats

Threats, as previously outlined, emanate from technical, natural, and human sources. The actual occurrence of a threat, resulting in an impact to the bank, is manifested as an "event." Events are noticeable changes affecting systems. Externally, any and all of these are possible and therefore must be considered when protecting the bank's information. Table 1 summarizes the sources, controls, and effects of external threats, although a more detailed explanation of each is outlined below.

Technical threats. For the most part, technical threats affecting banks represent attacks on the bank's Web site and/or network with the purpose of performing specific functions on behalf of the perpetrator. These originate from the outside and consist of the following types:

1. *Malicious code:* These are programs developed and perpetrated by hackers and crackers to actually capture information, determine passwords, modify information, or even to "mask" the occurrence of the virus and prevent its detection from audit logs or other monitoring techniques. The most common types of malicious code are computer viruses and worms.
2. *Unauthorized access:* Unauthorized access events permit the hacker access to a wide range of information. These events could be direct access to a customer's account (both a customer and bank concern) or to other parts of the bank's network to access and read network packets as well as other subversive access that may not easily be detected and/or lie dormant awaiting use. Of major concern, obviously, is the access to critical bank and customer information that would permit

Table 1 External Information Security Breaches

Sources	Effects	Controls
1. Technical threats <ul style="list-style-type: none"> • Malicious code • Unauthorized access • Information probing • Disruption of service • Misuse • Espionage • Hoaxes 	<ul style="list-style-type: none"> • Unauthorized modification, destruction, and/or use of information • Improper use of information 	<ul style="list-style-type: none"> • Firewall • Intrusion detection • Server hardening • Antivirus software • Virus patches • External penetration testing
2. Human threats <ul style="list-style-type: none"> • Unauthorized access • Inadvertent viewing of sensitive information • Sabotage • Theft of information • Terrorism 	<ul style="list-style-type: none"> • Unauthorized disclosure, modification, destruction, and/or use of information • Improper use of information • Unavailable systems 	<ul style="list-style-type: none"> • Awareness/education • Key/card access security systems • Automatic “time-out” features • Oversight management of third parties/partners • Social engineering testing • Strong authentication
3. Natural threats <ul style="list-style-type: none"> • Ice • Fire • Earthquake • Tornado • Storms 	<ul style="list-style-type: none"> • Unavailable systems 	<ul style="list-style-type: none"> • Identification of critical systems • Risk assessment and impact to the bank • Hot sites • Redundant systems • Recovery procedures and testing

the hacker to review and modify information for profit or pleasure.

3. *Information probing*: Probes are less obtrusive but nevertheless constitute an invasive action on the part of the perpetrator. Probes can be technical or nontechnical. In the technical world, the program sent is designed to be similar to “bug” or monitoring devices, which gather information that can be used at the convenience of the hacker. Probes are designed to be silent and undetected but nevertheless constantly gathering information. Nontechnical probing, on the other hand, is a human threat and is discussed under that category.
4. *Disruption of service*: Another name for these types of threats are “denial of service” (DOS) events. Denial or disruption of service is exactly what the name implies, an attack designed simply to disrupt. DOS events literally can preclude the bank, or customer, from accessing information or services. Some DOS attacks flood networks with spurious information, which indirectly prevent legitimate information from getting through to the server or to the database to conduct business. Essentially, depending upon the success of the DOS attack, this threat can virtually render a bank inoperable.
5. *Misuse*: This threat can be both internal and external. Misuse occurs when the perpetrator (either outside or inside of the bank) accesses the bank’s systems for the

purpose of conducting personal or other business unrelated to the bank. This could involve utilizing the bank’s database or Web site to conduct business, without authorization.

6. *Espionage*: This threat relates more to terrorist activities than others, although it is not limited to this source. Espionage relates directly to theft and the theft of information for the purpose of causing harm to the bank or to a customer; in other words, direct intent to cause harm to the enterprise.
7. *Hoaxes*: A hoax is a fraudulent or false reporting of viruses or other attacks that actually do not exist. The purpose of a hoax is to disrupt, even though the presence of the actual threat is not real. This type of event is more common and much easier to perpetrate because the technical development of an actual program to do what it is alleged to do is not required. Nevertheless, the harm and disruption they can cause are quite real.

Controls to monitor and prevent the external threats that may occur against the bank can take a variety of forms. The Federal Financial Institutions Examination Council provides, if not mandates, the development and implementation of specific controls to protect information from attack. The objective of the controls, used in this vernacular, is designed to provide layers of techniques

to filter, detect, prevent, and ultimately stop attacks from affecting sensitive servers (Federal Financial Institutions Examination Council, 2002) Unfortunately, there is no one technique or control that can guarantee success. As a result, controls occur at various levels so that if one does not stop the attack, the next may, and so on. Among the more common techniques used to protect against external threats are these:

1. *Firewall*: First and foremost, if a bank has an externally available Web site, whether through an outsourced provider or not, the Web site and other devices on the network must be protected from attack from the outside. Firewalls are devices designed specifically to monitor and restrict (or stop) various types of attacks and information flows that are not defined within the rule sets established for the firewall itself. Firewalls actually stop information, programs, viruses, and other attacks from hitting the Web server or others. Unfortunately, the firewall cannot be engineered to prevent all types of attacks and still permit the flow of normal business. For this reason other techniques are necessary to prevent compromise.
2. *Intrusion detection*: Intrusion detection systems are “appliances” that reside on the network of the bank. Their purpose is to monitor and report on the presence of attacks, but not to prevent attacks. This is a monitoring device that can detect defined attack profiles and report that they have occurred and have penetrated the firewall. Because they do not stop the attack, alert processes are normally established along with these devices so that appropriate bank personnel can be alerted to immediately assess the impact of such attacks. Intrusion detection is based upon an in-depth analysis of prevalent attack profiles in the environment that would trigger an alert. Because new attack profiles continue to evolve in the environment that have not been defined, constant updates to profiles are critical. Unfortunately, new attack profiles are constantly occurring; therefore, other controls are also important to mitigate the risk of attack.
3. *Intrusion prevention*: Because of the shortcomings of intrusion detection, another, more direct control mechanism (and relatively new) is intrusion “prevention” software. These systems are designed to stop or prevent attacks from entering the bank environment in contrast to merely monitoring and reporting. Systems of this nature are designed to assess the characteristics of the traffic patterns and to detect aberrant type behavior and stop or prevent it from accessing the sensitive systems.
4. *Server hardening*: File servers are the predominant technical devices that house the systems, programs, and information that attacks are directed against. If an attack is able to get through the firewall undetected by intrusion detection devices and is not stopped by the intrusion prevention software, then the file server is vulnerable and exposed. At this point, the only protection against compromise would be the “hardening” of the server itself. Hardening generally refers to ensuring that the appropriate patches and other protection means are completely up-to-date and are at the

ready for stopping attacks and preventing compromise. This generally involves antivirus software, among other controls.

5. *Antivirus software*: Antivirus software is installed locally at the personal computer or file server level. The software protects the computer from viruses that may enter the system via diskette, network, or other means. Although the bank may have a firewall, intrusion detection, or even intrusion prevention systems, antivirus software is still needed because viruses do get through. The reason for this is that hackers are prolific; that is, new viruses are constantly being developed that may pass undetected through a firewall or intrusion protection system. When this occurs, the last defense is antivirus protection that is designed to protect the device from compromise. Unfortunately once the software is installed, it is already out of date. Therefore, a mechanism to automatically update the software with the latest virus signatures must be a part of this control to protect systems from the very latest virus.
6. *Virus patches*: The final step in the process is patching. Patches are “fixes” for a particular virus that may be prevalent in the environment. It is not enough to simply have antivirus software installed and even to have the latest update; patches must still be distributed and installed. Patches protect against a particular virus from reoccurring and reinfected the device, without which the risk of reinfection is high even though the virus may have been previously eradicated.
7. *External penetration testing*: Although not in itself a control, external penetration testing is typically conducted periodically by a third party of the bank. This testing is designed to attempt to electronically gain access, technically, to the bank’s Web site, files, or other devices on an unauthorized basis. The results from these tests will highlight vulnerabilities and guide the bank in establishing the appropriate controls.

Human threats. Banks are very much concerned with human threats that may affect the client and/or bank information. These threats emanate from outsiders, partners, and customers. The difficulty with human threats, unlike technical threats, is that the bank can protect the perimeter through the myriad of controls previously mentioned but it is difficult to protect against the human interaction and traffic that is necessary to conduct business. Banks typically partner with many organizations to supply them with equipment, forms, electronics, and even money. Human threats involve unauthorized access or inadvertent viewing of sensitive information, sabotage of physical devices, theft of information or documents, and so forth. These threats occur because banks have branches that are open to outsiders, customers, and partners and therefore create some level of exposure to the bank and the systems the bank manages.

Controls of human threat over and above those in place to protect against external technical threats consist of the following:

1. *Awareness/education*: Security awareness programs can be very useful and important for bank customers. These programs outline the threats and define what

customers can and should do to protect themselves as well as their information from external threats and the theft of information. Banks can accomplish this through periodic seminars, Web site updates, or other brochures.

2. *Key/card access security systems:* Areas that are sensitive or contain devices that house critical bank or client information must be secured and protected from casual access. This relates specifically to central computers, servers, or mainframes that contain customer data files and/or the Web server. By restricting access to only authorized personnel using this mechanism, exposure and personnel access to these critical systems are limited and therefore the risk is mitigated.
3. *Automatic "time-out" features:* Because banks are public places, and because bankers have computers on their desks, the opportunity for inadvertent disclosure of information that may be left on a computer screen while the banker is away from his or her desk is high. Therefore, a control to prevent this type of disclosure is a program that automatically "logs off" the banker after a short period without activity. Presumably, if a banker steps away and leaves a client's account information on the screen, a security risk occurs. To guard against this threat, after time intervals of 10–15 minutes of inactivity the system will automatically log the banker off, thereby reducing the risk of unauthorized access to information.
4. *Oversight management of third parties/partners:* Bank partners generally have access to banks and bankers for a variety of reasons. As a result, the risk is not only while they are on the bank premises but also through the information or service they provide. Banks must manage partners to ensure that they have appropriate security controls in place to protect them from the same risks and threats banks face. The reason for this is that it may indirectly (or directly) affect the bank if the partner has unknowingly been compromised. Because the bank may rely on the services of the partner, compromised information or systems may be spread to the bank inadvertently. As a result, the only control is to closely and periodically review the partner and their respective security controls to gain comfort or assurance that they have done all they can to prevent compromise. Covenants can also be included in the contract to ensure that the partner adheres to certain parameters; otherwise, the bank will cease to continue doing business with that partner.
5. *Social engineering testing:* Although not a control per se, social engineering testing is conducted by a third party on behalf of the bank to test against outsiders calling or attempting to obtain information that they are not privy to. This can occur through the phone or through e-mail scams that attempt to entice the recipient to disclose information, such as a social security number or other sensitive information, about a customer or other bank data. This relates also to internal controls, in that internal awareness training (discussed later) is a reasonably effective means for controlling this.
6. *Strong authentication:* A bank's requirement of complex and not easily cracked customer passwords is

another method of controlling unauthorized access to data. Bank customers, themselves, represent a threat in that they are users of the bank's systems. As such, they too can be enticed to take advantage of the access they have by attempting to gain access to other information. By establishing strong authentication controls for system access, this risk can be mitigated. Strong authentication involves methods to access sensitive information using various techniques that cannot easily be "cracked" or guessed. Passwords are merely one means of authentication; many more exist today. Because most users tend to develop passwords that make it easier for them to remember (e.g., birth dates and anniversaries), it is relatively easy to guess someone's password, even by a complete outsider. Strong authentication for passwords consists of incorporating symbols, alpha and numeric characters, and upper and lower case letters. In this way, passwords would be virtually impossible to crack. Because complex passwords are also difficult to remember, other devices such as tokens are used to eliminate this concern and enhance authentication. Tokens such as SecurID cards have PINs that change every ten seconds. Other more advanced techniques for strong authentication include fingerprints, voice imaging, digital certificates, and electronic signatures, all designed to strengthen authentication and prevent casual determination.

Natural Threats. Natural threats, which occur in the environment, include fires, storms, tornados, and other physical threats to the bank and the bank's information. Because these cannot be predicted, they expose the bank to a loss of both information and services to the customer. Among the predominant services that customers may lose are Internet banking, ATMs, and voice response systems.

Controls for these threats pertain more to protecting "data availability" than the other concerns outlined previously. Because one cannot entirely control the threat of fires, storms, and tornados, all that can be accomplished is to establish a mechanism for the protection and recovery of information. Most banks have, or should have, well-organized disaster recovery plans. The purpose for these plans is to outline how data can be recovered quickly and how services can be restored to the customer to ensure continued and uninterrupted banking. Specific controls include the following:

1. *Identification of critical systems, locations, and functions:* The first step that banks would follow includes the identification of the most critical systems within the bank that house client and other sensitive information. In addition, bank locations that house critical systems and functions must also be included and/or identified in the event that they become completely inoperable because of a natural disaster.
2. *Risk assessment and impact to the bank:* The second control is to understand the relative financial risk the critical system, function, or location represents to the bank and whether its loss or impairment would or would not have a negative impact on the bank. Once determined, specific recovery and action plans can take place based upon the criticality of the system.

3. *Hot sites:* Hot sites can be established for specific enterprise-related critical functions or systems in the event the location becomes inoperable. These sites are established to back up critical functions such as call centers or other functions that require physical setup to be used on short notice.
4. *Redundant systems:* Particularly in the case of Internet banking, redundant Web servers or other database servers can be deployed at alternate sites to be activated in the event a server is destroyed, impaired, or even compromised.
5. *Recovery procedures and testing:* Recovery procedures and testing are the final steps and actions to be taken in the event that the location, device, or function is impaired in any way. These procedures typically would be tested once or twice per year to ensure that they are effective in the event of a disaster.

SOURCES AND CONTROLS OF INTERNAL INFORMATION SECURITY BREACHES

Definition

Internal sources of security breaches may fall within the broad categories of technical, human, and natural threats, as with external sources. Because these have been outlined in some detail in the External Sources section, they will not be repeated here. In lieu of those, other internal sources that may be more obvious to the bank will be discussed. Internal sources of security breaches affecting the bank involve, predominantly, the employees of the bank and the functions they perform. Because bank employees have a wide variety of access to systems, the potential for security breach emanating from this source can be relatively high. In addition, the threat that employees of the bank may inadvertently disclose information that may have been coaxed from them through fraud or deception is also present. Nevertheless, internal sources of security breach are those that emanate from within the bank or the bank's systems. Table 2 provides a synopsis of the sources, controls, and impacts of internal threats, with more detailed explanations of each contained in subsequent sections.

Sources of Security Breaches

1. *Negligence:* Security breaches can and do occur through employee negligence. Employees, while performing their jobs, may inadvertently leave sensitive

documentation out and available for casual observation by customers, outsiders, or other unauthorized individuals. Another form of negligence is discarding information, in paper form, that could be easily retrieved in the trash by unauthorized individuals. The last form of negligence on the part of employees is not adhering to internally derived end-user policies that protect the bank regarding Internet use, e-mail policies, and strong authentication of passwords.

2. *Sabotage:* Internal sabotage can occur by disgruntled employees that potentially have some access to servers. Another form of sabotage is making available sensitive customer information to outsiders, competitors, or others who can gain value from the information. This could consist of client lists and other types of information.
3. *Deception:* Deception occurs when calls are placed or e-mails are sent to internal staff requesting information fraudulently. This can occur in many forms but most often would be through the telephone or e-mail.

Controls

Controls should be enacted internally to ward against the threats and/or risks that can occur from within the bank. Unfortunately, these threats are equally as lethal as those that occur externally but often do not get as high a priority as those emanating from external sources. Nevertheless specific controls are available, and recommended, to mitigate the risks the bank faces. Among these are

1. *Employee awareness programs:* Employee awareness is paramount to the success of risk mitigation. Employees often are not adept at the nuances of hackers, viruses, or the subtleties of a sensitive document left available on the desktop. The purpose of awareness is not so much education as it is sensitization. Employees do not generally, in a busy workday, consider logging off and onto their systems, as this is construed to be non-productive or is simply not considered. Employees, as a rule, tend to open e-mail attachments when reading mail. The objective of awareness is to cause employees to consider or rethink routine functions in the course of completing or executing their jobs, so as to prevent the aforementioned effects of unauthorized disclosure, modification, use, or availability of information or systems.
2. *Separation of duties:* As part of URSIT, separation of duties creates an "arm's length" distance in functional

Table 2 Internal Information Security Breaches

Sources	Impact	Control
<ul style="list-style-type: none"> • Negligence • Sabotage • Deception 	<ul style="list-style-type: none"> • Unauthorized disclosure, modification, destruction, and/or use of information • Improper use of information • Unavailable systems 	<ul style="list-style-type: none"> • Employee awareness • Separation of duties • Rapid disablement of security access for terminated employees • End-user policies • Internal penetration testing

areas that have authority for monetary and other sensitive transactions affecting clients and the bank. One means of mitigating this risk is taking care to analyze functions to ensure that an independent staff member has review capability to check the work of another. In this way, the opportunity for internal misuse of information or systems can be thwarted.

3. *Rapid disablement of security access for terminated employees:* Employee resignations and terminations occur relatively frequently in large organizations. It is imperative that the bank have a process to immediately terminate passwords and user identification numbers quickly to prevent the possibility of unauthorized access or use of information during this transition.
4. *End-user policies:* Security breaches can easily occur through infected diskettes and other devices brought into the bank from the outside. The bank can protect itself by establishing strict policies that define what can and cannot be used from the outside. Policies are not absolute assurance, however. This requires that the bank consider having an annual review and sign-off of these policies to ensure awareness and compliance; a zero-tolerance approach may also be considered to enforce the policies.
5. *Internal penetration testing:* Although not a control itself, internal penetration testing is used to test the internal controls the bank has established. Similar to external penetration testing, a bank typically engages a third party to periodically perform these tests to provide the bank with guidance and areas where vulnerabilities exist.

CONCLUSION

Overall, external and internal sources of security breach are common in the banking world today and are growing. Bank regulators are very focused on the risks to the financial industry and therefore have incorporated very specific guidelines into their ongoing examinations of banks to uncover and mitigate these risks. However, even with intensified regulatory examinations, the business of risk management is a dynamic one. As new technologies evolve, so too will new avenues of breach and therefore the need for expanded controls. With the proliferation of file servers and databases housing a myriad of sensitive client and bank data, banks must be focused on not only protecting the perimeter but also ensuring that every data reservoir in the bank is completely hardened against attack. In the long run, customers will demand this to do business with the bank.

Need for Customer Assurance

When ATMs arrived on the scene, it took some time before customers became comfortable with using them as an alternative to a live teller. Even today, many bank clients are reluctant to deposit funds in an ATM for fear of loss of deposits, yet most will withdraw funds. The Internet and online banking is progressing in a similar direction. The lessons learned from ATMs can be helpful to banks in helping customers to gain comfort with this evolving

delivery channel. In many ways, the reason bank branches have not gone away, and in fact have grown in demand, is due primarily to the need for face-to-face contact or, possibly, security of transactions. Monetary transactions are very sensitive and few people are willing to expose hard-earned savings to risk of loss or theft resulting from insecure channels of delivery. Because of these concerns, banks must focus on addressing customer needs through both education and possibly guarantees.

Education. Similar to the steps banks are taking internally to educate employees, the same is necessary for bank clients. Training ATMs can be found in bank branches that educate customers on the usage of ATMs, while at the same time alleviating the fear of loss of funds through use of these devices. Kiosks are now growing at branch locations with the sole intent of breaking down fears of Internet banking and helping clients to become more comfortable with this evolving avenue. Unfortunately, client education is challenging. A means of communicating to clients that will be used by clients is necessary to educate them. This can be done through the Web site itself; however, with the amount of information already contained on the Web site, this may not accomplish its purpose unless done properly.

A possible approach to client education may have to originate from the federal government rather than banks. The preparation for Y2K (at the turn of the century) was well communicated and adopted by the federal government, through bank regulators, to prevent customers' adverse actions, resulting from lack of education. The national communications helped to prevent bank runs and other negative actions that would have dramatically affected the banking industry and thus our economy. Similarly, it may become necessary for bank regulators to do the same thing to guarantee security. This is all part of client education, which will become completely necessary as the Internet becomes no longer an interesting new technology but rather a commodity.

Guarantees. Another option to increase customers' comfort is to provide some level of guarantee of transactions, particularly transactions that might be compromised. The credit card industry, through the Fair Credit Lending Act, provides customers with avenues to address fraudulent purchases that may occur, without loss to the cardholder. The same will likely be required for Internet banking. This could be manifested in association with organizations that become recognized, that guarantee "secure" transactions, and that provide insurance that the customer will be protected from financial loss should it occur.

The future is left to be seen. As banks have come to alter their view of Internet banking, from a unique product to now another delivery channel, Internet banking will become a necessity for banking. Similar to ATMs, Internet banking will become, and is, a necessity for customers to do business with a bank. Banks that do not offer ATMs, debit cards, or now Internet banking will not attract and maintain their client base. In this regard, information security, risk management, and the controls banks develop will play a major role in the growth of online banking in the years to come.

GLOSSARY

Authentication The process of permitting access to a particular system or information via means of a password, a secure device, and so forth, which is constrained to the individual using it. Authentication is the process that compares the method used to access the data with the “accepted” access defined for the user.

FFIEC (Federal Financial Institutions Examination Council) It is a “formal interagency body empowered to prescribe uniform principles, standards, and report forms for the federal examination of financial institutions by the Board of Governors of the Federal Reserve System (FRB), the Federal Deposit Insurance Corporation (FDIC), the National Credit Union Administration (NCUA), the Office of the Comptroller of the Currency (OCC), and the Office of Thrift Supervision (OTS) and to make recommendations to promote uniformity in the supervision of financial institutions” (Federal Financial Institutions Examination Council, 2003). The agency provides guidance, in terms of policies and procedures, to member banks to develop and maintain internal controls on a uniform basis. Not all financial institutions are examined by the same examiners indicated here. However, the FFIEC, through their Web site and the aforementioned policies and procedures, provides a uniform set of materials that are adopted by all of the examining bodies and incorporated into their procedures. In this way a reasonably uniform method of controls is established for commercial banks, savings institutions, and credit unions. The FFIEC, within this context, has provided very detailed explanations of risks and controls for the management of information security, among others, within these financial institutions.

Firewall Electronic devices (appliances) that sit in front of a bank’s network and Web server. They are designed to filter incoming Internet traffic and stop unwanted traffic and/or viruses from compromising bank systems.

Intrusion Detection An electronic “appliance” placed on the bank’s network, behind the firewall, to monitor viruses and other types of attacks that are perpetrated against the bank’s Web site. Intrusion detection does not stop attacks, but merely monitors their existence and reports them.

Intrusion Prevention Software installed on file servers that relies on specific defined patterns to monitor and assess traffic and actually stop it in the event that the pattern of behavior is not considered “normal” or is not following a predefined pattern.

Retail Banking Bank sales are generally divided between “commercial” and “retail” sales. Commercial refers to business banking, which includes small business, large businesses, and even cash management services, in some cases. Commercial sales are focused on providing seasonal and other lending services to the business community. Retail, on the other hand, is centered on providing bank products (e.g., checking accounts, savings accounts, money markets, installment loans, etc.) to individual consumers (customers). This group of clients uses, in many cases, individual

products based upon need and does not have any corporate or business affiliation.

URSIT (Uniform Rating System for Information Technology) A rating system used by bank regulators to evaluate the effectiveness of banking information technology practices.

INTRODUCTION

Defining Digital Libraries

A digital library (DL) combines the advantages of digital access with the services and quality information traditionally found in a library. Digital libraries can be characterized as the “high end” of the Internet: that sector of the Internet that maintains a tradition of shared resources and easy access while offering quality content from authoritative sources, such as libraries and universities.

The author has developed the following definition of a digital library: a system that permits, via the Internet and the World Wide Web (WWW), easy access to a collection of high-value, quality digital content, which has been selected and organized to facilitate use, and is supported by appropriate services. The digital content may reflect the traditional textual orientation of many libraries or take advantage of the WWW’s facilities to deliver graphics and multimedia.

Texts for the field offer the following definitions of digital libraries:

Digital libraries are organized collections of digital information. They combine the structuring and gathering of information, which libraries and archives have always done, with the digital representation that computers have made possible. . . . [T]he digital library must have content; it can either be new material, prepared digitally, or old material, converted to digital form. (Lesk, 1997, pp. xix, 2)

An informal definition of a digital library is a managed collection of information, with associated services, where the information is stored in

digital formats and accessible over a network. A crucial part of this definition is that the information is managed. . . . Digital libraries contain diverse collections of information for use by many different users. Digital libraries range in size from tiny to huge. They can use any type of computing equipment and any suitable software. The unifying theme is that information is organized on computers and available over a network, with procedures to select the materials in the collections, to organize it, to make it available to users, and to archive it. (Arms, 2000, p. 2)

The common feature of these definitions is that a digital library must contain content. A site which simply points toward informational resources, a Yahoo!-style system, cannot be considered a true digital library. Three parallel terms exist: digital, electronic, and virtual libraries. These are normally used interchangeably (Saffady, 1995). In practice, digital library is the general term in North America whereas electronic library is preferred in Europe. Schwartz (2000) analyzed no fewer than 64 different formal and informal definitions of “digital library.” Chowdhury and Chowdhury (2003) devote an entire chapter of their *Introduction to Digital Libraries* to definitions and characteristics of the field.

Categories of Digital Libraries

Despite their short history, digital libraries already demonstrate remarkable diversity. This overview is abbreviated; for a more detailed discussion, see this author’s recent article in *The Internet Encyclopedia* (McCarthy, 2004).

Multimedia Collections

As digital libraries use computers as their interface, they can present a variety of materials, such as books, photographs, film, audio, and other media, with equal facility. A major multimedia collection, and one of the world's most important digital libraries, is the American Memory project, the Historical Collections of the National Digital Library, maintained by the Library of Congress (Figure 1; <http://memory.loc.gov/>). This now includes more than 100 collections, a total of 7 million digital items, including photographs, manuscripts, rare books, maps, sound recordings, and moving pictures.

Another source of multimedia content in a digital library is the Berkeley Digital Library SunSITE (<http://sunsite.berkeley.edu/>), by the Library of the University of California at Berkeley in collaboration with Sun Microsystems. Their Jack London collection, for instance, offers multiple approaches, such as the full text of many of London's books, reproductions of letters and documents, photographs, and audio (<http://sunsite.berkeley.edu/London/>). The objective of *ibiblio* (<http://ibiblio.org/index.html>) is to make information freely available for the public domain. It is a collaboration of the Center for the Public Domain and the University of North Carolina at Chapel Hill and includes software, music, literature, art,

history, science, politics, and cultural studies. Apart from written texts, it also includes music and poetry archives, sports statistics, large text database projects, and software archives.

Book-Oriented Collections

Project Gutenberg, a book-oriented collection, is often considered the first significant digital library (<http://www.gutenberg.net/>). It was founded in 1971 at the University of Illinois and has always concentrated on simple presentations, originally file transfer protocol (FTP) downloads of "plain vanilla" ASCII texts, readable on almost any platform. Many of Project Gutenberg's 10,000 free texts are now available in HTML, and the volunteer-supported project has numerous mirror sites. The University of Michigan is responsible for several significant book-oriented projects, notably the Making of America (Figure 2; <http://www.hti.umich.edu/m/moagrp/>). This contains 8,500 books and 50,000 journal articles on 19th-century American social history from the antebellum period through Reconstruction. Sophisticated software offers a choice of image, text, or PDF (portable document format) files, in normal, large, and small sizes.

The University of Virginia Electronic Text Center (<http://etext.lib.virginia.edu>), founded in 1992, now offers

Figure 2: Screen from the Making of America Collection, the University of Michigan. Note bibliographic data at head of page, “page format” settings (image, text, PDF), “page size” settings (small, large, normal), and controls to move from page to page.

70,000 humanities texts, which have been downloaded more than 6 million times. The Center also offers much valuable information on digitization, and links to other English-language, full-text Web resources (<http://etext.lib.virginia.edu/eng-oth.html>). It is necessary to point out, however, that at the moment digital libraries exclude most modern commercially published books and most copyright-protected resources (i.e., exactly the texts that are generally in high demand). The Online Books Page (<http://digital.library.upenn.edu/books/>), a wide-ranging catalog of online books, covers more than 20,000 titles. The Digital Book Index (<http://www.digitalbookindex.com/>) claims to list more than 90,000 English-language book texts, of which more than 50,000 are said to be free, but many texts are available in multiple versions.

Image-Oriented Collections

A significant portion of the digital library field is dedicated to photographs and still images. The Library of Congress maintains a collection of 160,000 black-and-white Farm Security Administration photographs, focusing on American rural life during the Depression (Figure 3; <http://memory.loc.gov/ammem/fsowhome.html>). Keyword, subject, creator, and geographic indexes are available.

The Bancroft Library at the University of California, Berkeley, offers the California Heritage Collection, 30,000 images illustrating California’s history and culture (<http://sunsite.berkeley.edu/CalHeritage/>).

Manuscripts

Digital libraries have blurred the line between archives and libraries. The Library of Congress offers the papers of George Washington (<http://memory.loc.gov/ammem/gwhtml/gwhome.html>), 60,000 items; and the papers of Abraham Lincoln (<http://memory.loc.gov/ammem/alhtml/malhome.html>), 61,000 images and 10,000 transcriptions. The papers of Wilbur and Orville Wright were added in 2003 (<http://memory.loc.gov/ammem/wrighthtml/wrighthome.html>).

Ephemeral Materials

The Internet is an excellent medium for ephemeral materials, so it is no surprise that digital libraries frequently preserve and disseminate ephemera. A well-organized example is the Broadside Ballads collection of one of Britain’s oldest libraries, the Bodleian Library of Oxford University (<http://www.bodley.ox.ac.uk/ballads/>). Three thousand items of historic American sheet music from the collections of Duke University can be found at <http://>

Figure 3: Photograph from the Farm Security Administration collection at the Library of Congress. Taken by Dorothea Lang, this photograph is usually referred to as the “Migrant Mother.”

memory.loc.gov/ammem/award97/ncdhtml/hasmhome.html. Spanish Civil War posters were digitized at the University of California at San Diego (Figure 4; <http://orpheus.ucsd.edu/speccoll/visfront/>).

Audio and Motion Picture Files

The previous section on multimedia digital libraries gave several examples of systems that offer partial audiovisual content. For instance, fascinating content from the dawn of the cinema can be found in the Early Motion Pictures collection of the American Memory collection: (<http://memory.loc.gov/ammem/vshtml/vshtml.html>). The Prelinger Archives of Ephemeral Films, a series of nearly 2,000 short films, mostly illustrating various aspects of American life in the 20th century, is freely available from the Internet Archive (<http://www.archive.org/movies/prelinger.php>). A major site dedicated to audio files is History and Politics Out Loud (<http://www.hpol.org/>), with speeches of Roosevelt, Churchill, and many others.

Commercially Oriented Digital Libraries

NetLibrary (Figure 5; <http://www.netlibrary.com>), which offers 60,000 titles, has always concentrated on selling through libraries. An unusual feature is that it only

Figure 4: Spanish Civil War poster, digitized at the University of California, San Diego.

Figure 5: Opening screen of netLibrary.

permits access to a limited number of copies of each book at any one time. This appears strange in view of the Internet's capability of generating an unlimited number of copies of a digital text, but this restriction encourages publishers to join the system. Rapid printing of multiple pages is also inhibited. NetLibrary is part of OCLC (Online Computer Library Center; <http://www.oclc.org/>), a cooperative system that supplies automated cataloging data to more than 40,000 libraries.

Houston-based Questia (<http://www.questia.com/>) digitized a core collection in the humanities and social sciences and offers nearly 50,000 books and nearly 400,000 articles. There is an excellent advanced software interface and full access costs \$19.95 a month as of this writing. O'Reilly Network, a major publisher of computer related books, offers digital versions of 2,000 texts on information technology and programming to libraries through the Safari Bookshelf (<http://safari.oreilly.com/>). The Association for Computing Machinery is an outstanding example of a professional association that has been able to successfully implement a paid-access digital library, the ACM Digital Library (<http://portal.acm.org/portal.cfm/>); it has the advantage of an audience with a high level of computer literacy. Consumers in traditional bookstores have always had the right to flip through a few pages of the text. Amazon.com now permits this in an electronic environment via a digital archive of more than 120,000 books (Wolf, 2003). The entire digital text is searchable, but it is not possible to print out text and only a few pages can be viewed at a time. Usage of "Search Inside the Book" is limited to people whose credit card numbers are on file with Amazon.com.

Electronic Journals (E-Journals)

This is an area where digital penetration has been intense and often both commercially driven and controversial.

The field can be divided into three major categories: commercial, semicommercial, and free e-journals.

The commercial e-journal situation has its roots in the second half of the 20th century, when the publishing of scientific journals came to be dominated by a handful of specialized companies. They gained a reputation for constantly increasing prices, but as faculty and researchers considered journals essential for research, libraries were under pressure to keep subscribing to ever more expensive periodicals. The introduction of e-journals offered no relief: major publishers now offer both paper and electronic versions of their journals; there is often little cost advantage in subscribing to electronic versions alone. Libraries end up subscribing to bundles of e-journals, including titles in which they have little interest; prices for the bundles increase constantly and cancellation of individual titles brings little relief. Journals published by Elsevier (<http://www.elsevier.com/>) are frequently cited in this context (Knight, 2003, Carnevale, 2003a). The 121 members of the Association of Research Libraries spend about \$480 million per year on journals, an average of \$4 million each (<http://www.arl.org/create/home.html>). Elsevier maintains Science Direct (<http://www.sciencedirect.com/>), which offers controlled electronic access to 1,800 titles and 4 million articles. Other agents for e-journal subscriptions include Ebsco, long established as an agent fulfilling library journal subscriptions, which now permits libraries to access more than 8,000 e-journals and 4 million articles (<http://www.ebsco.com/home/ejournals/default.asp>), and also Blackwell's Synergy system, which permits nonsubscribers to purchase single items (<http://www.blackwell-synergy.com/>).

Semicommercial approaches are seen as a solution. SPARC, the Scholarly Publishing and Academic Resources Coalition (<http://www.arl.org/sparc/index.html>), has set up a collaborative system for academic e-journal

Figure 6: Opening screen of JSTOR, the Scholarly Journal Archive, from the University of Michigan.

production. Two important university initiatives offer reasonably priced access to members of participating academic institutions. Project Muse, of Johns Hopkins University Press (<http://muse.jhu.edu/>), has more than 200 titles. JSTOR, the scholarly journal archive (Figure 6; <http://www.jstor.org/>), organized by the University of Michigan, has 360 titles.

The Public Library of Science (PLoS) is a nonprofit organization of scientists and physicians, which treats the costs of publication as the final step of the research funding process (<http://www.publiclibraryofscience.org/>). The International Consortium for the Advancement of Academic Publication, based at Athabasca University, Canada (<http://www.icaap.org/>), offers a collaborative system for publishing specialized e-journals. Another solution to the e-journal problem is offered by preprint archive systems such as arXiv (<http://arxiv.org/>), which permits rapid access to preprints in physics, mathematics, and science.

Free e-journals have also expanded rapidly. Three thousand titles are listed at the Internet Public Library (<http://www.ipl.org/div/serials/>). An additional list of e-journals can be found at the World Wide Web Virtual Library (<http://www.e-journals.org/>). The Internet Library of Early Journals offers free access to six 18th- and 19th-century journals (<http://www.bodley.ox.ac.uk/ilej/>).

Digital Newspaper Collections

NewspaperArchive is a commercial undertaking from Cedar Rapids, which has 20 million indexed pages available online; full access costs \$12.95 per month (<http://www.newspaperarchive.com/DesktopDefault.aspx>). The Missouri Historical Newspapers Collection (<http://news-papers.umsystem.edu/archive/Skins/Missouri/navigator>.

[asp](http://www.newspaperarchive.com/DesktopDefault.aspx)) offers advanced access to local newspapers; readers are able to click on any article, photograph, or advertisement, which is then enlarged and presented in a separate window. This uses Olive ActivePaper Archive software (<http://www.olivesoftware.com/home.html>). Several newspaper-clipping collections are now available. An indexed collection of clippings from newspapers published in the Pacific Northwest of the United States is available at <http://content.wsulibs.wsu.edu/pncc/pncc.htm>. For World War II, a collection of more than 144,000 newspaper articles compiled by a Canadian newspaper has been digitized and indexed at <http://www.warmuseum.ca/cwm/newspapers/index.html>.

Electronic Theses and Dissertations

A general reference point for this field is the Networked Digital Library of Theses and Dissertations (NDLTD; <http://www.ndltd.org/>). A founding member was Virginia Tech, which now offers unrestricted access to more than 5,000 digital theses (<http://scholar.lib.vt.edu/theses/>). Experience suggests that digital availability stimulates use and promotes the author's reputation. West Virginia University reports more than 1.4 million hits on its digital theses collection (http://www.wvu.edu/~thesis/News/WVU_ETDS_Over_1_Million_Served.htm). MIT (<http://thesis.mit.edu/>) permits online reading of theses in a presentation that inhibits printing; users can buy PDF versions online or have printed copies sent by mail. ProQuest, formerly UMI, which disseminates 55,000 graduate theses each year, now accepts electronic submission of theses (Olsen, 2003a).

E-Books for Specialized Distribution Media

Systems cited in the previous sections distribute digital information via Internet browser, but some important related areas need to be mentioned. Commercially produced e-books downloaded to users' devices have had considerable effect since 2000, when half a million people downloaded Stephen King's e-book, *Riding the Bullet*. Common formats include MS Reader (Microsoft's downloadable e-book software), the well-known Adobe Acrobat PDF format, and the Palm and Mobipocket formats for mobile devices. Rosetta Books (Figure 7; <http://www.rosettabooks.com>) offers e-books in all four of these formats. Rosetta Books received considerable publicity in 2001 when Random House tried to stop them from distributing electronic versions of works by Kurt Vonnegut, William Styron, and Robert B. Parker. The judge ruled in favor of Rosetta Books, determining that e-books are a separate medium from the original product because they offer full-text searching, hyperlinking, and other electronic advantages (Stein, 2001). Older contracts in which authors had assigned rights to publish "books" would not therefore automatically cover electronic versions.

Palm Digital Media (<http://www.palmdigitalmedia.com/>) offers 11,000 titles for sale. PDABooks.org links to 2,600 texts, all of which are freely available (<http://www.pdabooks.org/>). Manybooks (<http://www.manybooks.net/>) contains more than 10,000 public domain e-books, formatted for reading on Palm, PocketPC, or other devices. The University of Virginia Electronic Text Center offers 1,800 downloadable books for Palm Pilots or

Figure 7: Opening screen of Rosetta Books, a major e-book publisher.

MS Reader (<http://etext.lib.virginia.edu/ebooks/ebooklist.html>). The variety of formats available is not an indication of the health of the e-book field. In fact, it has been a major factor in deterring readers from spending money on equipment and texts (Crawford, 2000). Consumers have demonstrated almost total lack of interest in specially designed e-book readers. In a major shakeout in late 2003, Barnes&Noble.com (<http://www.barnesandnoble.com/>) announced it was shuttering its e-books store (Albanese, 2003). Publishers say that Barnes&Noble.com's decision will not affect their e-book programs, which they maintain are still showing rapid growth. Amazon (<http://www.amazon.com/>) maintains its e-books division. Readers have to download special software to use ebrary (<http://www.ebrary.com/>) and can only view one page at a time. Major publishers, including Random House and McGraw-Hill, finance ebrary, which, like NetLibrary, seeks to sell subscriptions to libraries. The National Yiddish Book Center (<http://www.yiddishbookcenter.org/>) in Amherst, Massachusetts, maintains the Steven Spielberg Digital Yiddish Library, which has processed 14,000 texts. Digital versions are not disseminated, but paper copies are produced via a print-on-demand system for \$48 per hardcover, library-bound volume. As a result, Yiddish is the language that has the highest proportion of its literature immediately available.

Institutional and Informational Resources in the Digital Library Field

The Digital Library Federation (<http://www.diglib.org>) is a consortium of 32 major institutions, based in Washington, D.C. It maintains a guide to public access collections at <http://www.hti.umich.edu/cgi/b/bib/bib-idx?c=dlcoll>.

This offers simple searching, advanced searching, a list of more than 370 digital libraries whose descriptions can be searched, and a list of the participating institutions. An additional 460 digital library initiatives were cataloged by the Association of Research Libraries (ARL) Digital Initiatives Database, a collaboration between the University of Illinois at Chicago and ARL (<http://www.arl.org/did/index.html>).

Important general information sources for the digital library field include Berkeley's SunSITE (<http://sunsite.berkeley.edu/>). Resource pages are maintained by Ben Gross at Illinois (<http://bengross.com/dl/>), Candy Schwartz at Simmons (<http://web.simmons.edu/~schwartz/dl.html>), and Tom Kochtanek and Rafee Kassim at Missouri (<http://www.coe.missouri.edu/~rafe/iDLR/index.php>). Chowdhury and Chowdhury (2000) compares the information retrieval features of 20 important digital libraries. Major textbooks for the field have been authored by Lesk (1997), Arms (2000), and Chowdhury and Chowdhury (2003). For recent printed overviews of the field, see Fox and Urs (2002) or McCarthy (2004). Greenstein and Thorin (2002) prepared a biography of the digital library based on six case studies.

The digital library field is often financed by special government grants. Of vital importance to digital library development in the United States was the National Science Foundation's Digital Libraries Initiative. Phase 1 projects, 1994–1998, are at <http://www.dli2.nsf.gov/dlione/> and were discussed by Fox (1999). Phase 2 projects can be seen at <http://www.dli2.nsf.gov/> and were summarized by Lesk (1999). An important current source of financing for digitization projects in the United States is the Institute of Museum and Library Services (IMLS);

The Canadian Inventory of Digital Initiatives provides descriptions of Canadian information resources created for the Web (<http://www.collectionscanada.ca/initiatives/erella.htm>). Nicholson and MacGregor (2003) describe a major digitization program aimed at improving online access to U.K. cultural resources from the United Kingdom's museums, libraries, and galleries. The EnrichUK program (<http://www.enrichuk.net/>) is supported by lottery funding of \$50 million and provides free access to the country's cultural, artistic, and community resources. Digital library development in Brazil was discussed by McCarthy and Cunha (2003).

Research in the digital library field has been reviewed by Chowdhury and Chowdhury (1999). As might be expected, the digital library field is well served by e-journals. The principal U.S. e-journal is *D-Lib Magazine*, published by the D-Lib Forum (Figure 8; <http://www.dlib.org/>).

From Britain come *Ariadne* (<http://www.ariadne.ac.uk/>) and the *Journal of Digital Information* (JoDI; <http://jodi.ecs.soton.ac.uk/>). The major U.S. conference in this area is the Joint Conference on Digital Libraries (JCDL; <http://www.jcdl.org/>), sponsored by the Association for Computing Machinery and the Institute of Electrical and Electronics Engineers (IEEE). The European equivalent is the European Conference on Research and Advanced Technology for Digital Libraries (ECDL), and Asia has the International Conference on Asian Digital Libraries (ICADL).

CONSTRUCTING DIGITAL LIBRARIES

Digital libraries are complex systems that require careful planning and design; their construction involves a series of interlocking considerations of a technical and intellectual, legal, and even esthetic nature.

Copyright and Digital Libraries

Copyright laws were written to control the sale and distribution of physical objects; they adapt poorly to digital environments and represent a major constraint to digital libraries. Lesk presents the history of copyright law from the point of view of digital libraries (1997, pp. 224–229). According to the U.S. Constitution, copyright is granted for “limited times,” but terms have been continually extended, largely in response to pressures from film studios. The Sonny Bono Copyright Act, 1998, fixed copyright in the United States at the life of the author plus 70 years. Pre-1978 works in copyright are protected for 95 years from the date copyright was first secured. Most materials produced in 1923 or after are protected by copyright. Consult the “Public Domain and Copyright” page of Project Gutenberg (<http://promo.net/pg/vol/pd.html>) or “When works pass into the public domain” (<http://www.unc.edu/~unclng/public-d.htm>). Note that all works are protected—books, films, photographs, ephemera, newspapers, computer files—anything fixed in tangible form, regardless of whether anybody is interested in protecting their rights in these materials. In 1930, about 10,000 books were published in the United States; today

fewer than 200 are still available from publishers (*Brief of Amici Curiae: The Internet Archive*, 2002). The other 9,800 may well include texts that might usefully be made available to the public in digital form, but they continue to enjoy full copyright protection until 2019. No institution could risk digitizing them, for fear that rights-holders might suddenly appear. Most book publishing contracts signed in the United States in the 20th century state that rights return to the author a few years after the book goes out of print (Lynch, 2001). When the authors die, these rights pass to their descendants. This has created a huge class of “orphan books,” items for which no rights-holder can be traced. The situation is even less clear for photographs, ephemera, and sheet music. Eric Eldred, whose Eldritch Press (<http://www.ibiblio.org/eldritch/>) freely disseminates public domain texts, recently challenged the extension of copyright laws. The Supreme Court, however, found against him; CNN reported: “Decision seen as victory for movie, recording industry” (Mears, 2003).

In many cases, digital libraries find it simpler to limit themselves to pre-1923 materials, to avoid the troublesome process of identifying rights-holders. Even if a rights-holder can be identified, the digital library has to go through a lengthy, expensive, and often fruitless process of negotiating rights. One possible solution is to operate within the “fair use” provisions of current U.S. copyright law. The legal situation is complex, but fair use might be invoked when a nonprofit library or archive makes materials available for research and private study. It should be made clear that the institution does not condone further distribution or usage, such as commercial exploitation or print publication. Many digital library sites have relevant disclaimers; for example, the Library of Congress (<http://www.loc.gov/homepage/legal.html>) and Duke University’s Rare Book, Manuscript, and Special Collections Library (<http://scriptorium.lib.duke.edu/copyright.html>).

Until recently, freelance authors who wrote for newspapers or magazines did not formally surrender rights to put articles into databases, because this market was small or nonexistent. Under the 2001 Tasini decision (New York Times, 2001), the Supreme Court agreed they had rights when their materials were published in this way. Dissemination of materials via a database, in which they could be consulted individually, was considered a separate usage from print or microfilm. The *New York Times* was said to be purging from its database 115,000 articles by 27,000 different freelance writers (Stern, 2001). The decision has only retrospective effects because since the mid-1990s publishers routinely retain all digital rights for freelance articles.

If copyright materials are posted to the Internet, there must be a mechanism whereby they can be taken down, as a result of either an informal request or a formal demand made under the Digital Millennium Copyright Act. Because of their historical and academic bias, digital libraries are rarely the target of “takedown” or “cease and desist” orders. There is little interest from authors, who are, in effect, asking to be taken out of the historical record. This situation arises more frequently with search engines, which have to devote considerable effort to meeting takedown demands. The Chilling Effects Clearinghouse (<http://www.chillingeffects.org>) maintains coverage of such requests.

One solution for copyright problems is to work with copyright-free niche collections. The Government Publications from World War II digital library at Southern Methodist University (<http://worldwar2.smu.edu>) is perfectly legal, because U.S. government publications are not copyrighted. The University of Iowa maintains medical documentation on its Virtual Hospital and Virtual Children’s Hospital sites (Figure 9; <http://www.vh.org> or <http://www.vh.org/pediatric/index.html>); these are based

Figure 9: Opening screen of the Virtual Hospital, a health-oriented digital library from the University of Iowa.

on noncopyrighted government publications and texts contributed by faculty of the University of Iowa.

PubMed, set up by the National Library of Medicine, facilitates public awareness of 11 million items of medical literature (<http://www.ncbi.nlm.nih.gov/entrez/query.fcgi>); there are no copyright problems because abstracts, rather than full text, are offered. Further possibilities are opened up by licensing systems, such as Creative Commons (<http://creativecommons.org/>), which does for publications what Open Source licensing does for software. Creative Commons work can be made freely available, but attribution can be required, commercial use can be prohibited, and the original creator can demand that derivative works must also be made publicly available. The license relieves authors of liability or implication of warranty. Ashling (2003) discusses a variety of models for open access and the public domain.

Selection of Materials for Digital Libraries

Hazen and colleagues devote a short monograph to the selection of research collections for digitization (1998). The first criterion they present is, predictably, copyright. They then propose a careful analysis of the intellectual nature of the materials to be digitized, together with an estimate of current and potential users. The actual and anticipated nature of the use of the materials must be considered, as must the format and nature of the digital product. It will be essential to describe and deliver the digital product, while retaining archival copies. The relationship to other digital efforts must be considered, and, last but not least, costs and benefits need to be carefully analyzed. Collections that score well on all or most of these considerations will be given priority in the digitization process.

Digitization of Materials for Digital Libraries

Image access is used for individual visual resources, such as photographs, posters, drawings, and so forth. The classic method of offering access to these materials is by a series of three types of image. Scanning produces a high-quality archive image, which is then used to generate an access image for general public use. Finally, a small thumbnail image is produced, for quick reference (Boss, 2001; Lee, 2001). The list that follows describes these terms in more detail.

Archive image: A high-quality image, scanned directly from the original material, and destined for long-term preservation. Normally an uncompressed TIFF (tagged image file format) image is used for this; TIFFs can preserve high-quality images and a resolution of 600 dpi (dots per inch) is standard. As scanning is an expensive operation, which exposes original materials to possible damage, the archive image has considerable value and will be carefully preserved. Archive images must always exist at system level but may not always be made available to the end user. TIF files occupy significant server space and imply lengthy download times. Another factor is that some DLs will want to sell their own hard-copy prints of quality images. Frey (1997) discusses technical standards for digital imaging of photographic collections.

Access image or working image: A quality image, adequate for consultation and serious study by digital library users. This is normally a high-quality JPG (Joint

Photographic Experts Group) image, generated from the archival TIFF. JPG files are widely used on the Internet and offer quality spatial and color reproduction, together with a high compression ratio. For DL purposes, JPG images will often be generated at a resolution of 300 dpi; a size of 640 × 480 pixels is also common.

Thumbnail image: A small reference image, which gives the user an immediate general idea of the access image before it is downloaded. It is typically a medium- to low-quality JPG, generated from the access image, but about one-tenth of its size, and is commonly produced at a resolution of 72 dpi. GIF format (graphic interchange format) can also be used for thumbnails.

Detailed information by practitioners in the area is available from *Digitization Guidelines* from Arizona State Library, Archives and Public Records (http://www.lib.az.us/digital/dg_a4.html), the *Western States Digital Imaging Best Practices* from the Colorado Digitization Program (http://www.cdphheritage.org/resource/scanning/documents/WSDIBP_v1.pdf), Washington State Library's *Digital Best Practices* (<http://digital.wa.statelibrary.gov/newsite/best.htm>), and *Moving Theory into Practice: Digital Imaging Tutorial* from Cornell University Library (<http://www.library.cornell.edu/preservation/tutorial/index.html>). The Digital Library Federation offers a *Benchmark for the Faithful Reproduction of Monographs and Serials* (<http://www.diglib.org/standards/bmarkfin.htm>). Further standardization and development can be expected in this field; notably, there is increasing interest in a major upgrade of the original JPG format, known as JPEG 2000 (<http://www.jpeg.org/jpeg2000/index.html>). JPEG 2000 images offer high quality and excellent compression; they could possibly displace TIFFs in archival roles.

Books available in multiple copies may be disbound for sheet digitization. Fragile and older materials require careful handling. Automated digitizers, which can turn the pages of books and even newspaper volumes, are beginning to emerge. An early model, by 4DigitalBooks (Figure 10; <http://www.4digitalbooks.com/>), is about the size of a sports utility vehicle and can process more than 1,000 pages an hour (Markoff, 2003). This Swiss-designed robot is considered cost-effective only for projects that involve more than 5.5 million pages.

A smaller automated digitizer, based on technology developed by Xerox, is being offered by Kirtas Technologies (<http://www.kirtas-tech.com/>).

Digital libraries that offer textual content also need to convert page images to text that can be manipulated. This would now normally be HTML text, although early systems used plain ASCII text files. Conversion to text is undertaken using quality OCR (optical character recognition) software, such as OmniPage Pro (University of Virginia Electronic Text Center, 1998) or the Russian AB-BYY software (<http://www.abby.com/>). Even first-class scanning software can confuse certain words, for example clean/dean and modern/modem. Careful proofreading is therefore essential. The problem is especially acute in digital libraries that pride themselves on offering quality content but that process a large proportion of older and specialized texts, with rarely used terms, unusual spellings, unusual fonts, and so forth. Highly qualified personnel are required to proofread such texts.

Figure 10: Automated digitizer, developed by 4DigitalBooks.

An obvious way to guarantee delivery of correct text is to offer both an HTML version and a page image. The page image can be a JPEG image; medium quality is often adequate for plain text, without illustrations. It is also possible to use Adobe's Portable Document Format (PDF) for text. Results are generally satisfactory, images correctly represent the originals, certain security parameters can be easily set (e.g., to inhibit printing), and most serious Internet users have already downloaded the free Adobe reader. Several U.S. federal agencies are collaborating on the development of an archiving version of the portable document format; a standard should be defined by the end of 2005 (Jackson, 2004). For a major project that offers books in both text and page-image form, see the University of Michigan's Making of America (<http://www.hti.umich.edu/m/moagrp/>). Here, sophisticated software offers a choice of image, text, or PDF files, in normal, large, and small size. The Digital Quaker Collection (<http://esr.earlham.edu/dqc/>) contains full text and page images of more than 500 individual Quaker works from the 17th and 18th centuries.

Software for Digital Libraries

It is possible to create small-scale digital collections by hand, using standard HTML editing software. However, because of the complexity and variety of the field, software designed for this purpose is now in common use. In alphabetical order, principal options are as follows.

CONTENTdm Digital Media Management Software Suite: A high-performance storage and retrieval software

for multimedia collections, which is rapidly gaining acceptance (<http://contentdm.com/index.html>). It was developed at the University of Washington and is offered to libraries, museums, and nonprofit archives by OCLC, the major supplier of bibliographic data to libraries (<http://www.oclc.org/contentdm/default.htm>). Collections using CONTENTdm include the Louisiana Digital Library (<http://louisdl.louislibraries.org/>) and Early Las Vegas from the University of Nevada, Las Vegas (http://www.library.unlv.edu/early_las_vegas/index.html).

DLXS: DLXS is offered by the University of Michigan Digital Library eXtension Service; it is a comprehensive suite of software especially suited to indexing and presenting multipage documents (<http://www.dlxs.org/>). It has already been mentioned as being used for the University of Michigan's the Making of America collection, which has approximately 8,500 books and 50,000 journal articles from the antebellum period through Reconstruction (<http://www.hti.umich.edu/cgi/t/text/textidx?tpl=browse.tpl&c=moa&cc=moa>). An additional 3,000 books can be found in the Wright American Fiction collection, 1851–1875 (<http://www.lettrs.indiana.edu/web/w/wright2/>).

Dspace: A "Durable Digital Depository," designed to capture, distribute, and preserve the intellectual output of universities and similar institutions (<http://dspace.org/>). It is a joint project between MIT Libraries and the Hewlett-Packard Company; the original DSpace can be searched at <https://dspace.mit.edu/index.jsp>; full-text documents are presented in PDF. An open-source software,

Figure 11: Opening screen of the New Zealand Digital Library.

DSpace can be freely downloaded from <http://sourceforge.net/projects/dspace/> (Atwood, 2002; Carnevale, 2003b).

EXist: An open-source XML database created in Germany (<http://exist.sourceforge.net> or <http://exist-db.org/>). It was used for an ambitious project, The Proceedings of the Old Bailey, 1674 to 1834 (<http://www.oldbaileyonline.org/>). This is considered the largest body of texts detailing the lives of nonelite people ever published and covers more than 100,000 criminal trials held at London's central criminal court.

Greenstone Digital Library Software: An open-source suite, developed in New Zealand at the University of Waikato (<http://www.greenstone.org/>). It automatically creates organized collections of digitized documents with a standardized interface, creates automatic full-text indexes, lists titles, and so forth (Witten & Bainbridge, 2002). It handles large collections of documents in a variety of formats and works on server or desktop; it even exports to CD-ROM. It was used for the New Zealand Digital Library (Figure 11; <http://www.nzdl.org/>), notable for humanitarian and United Nations collections in a variety of languages and scripts, including Arabic and Chinese.

Greenstone is distributed free of charge under the GNU Public License and can be downloaded from <http://www.greenstone.org/cgi-bin/library?a=p&p=download>. All texts in Project Gutenberg can be searched via Greenstone at <http://public.ibiblio.org/gSDL/cgi-bin/library?a=p&p=about&c=gberg>.

Hyperion Digital Media Archive: This archive organizes and offers full-text indexing, storing, and accessing of nonbook holdings in a digital format (<http://www.sirsi.com/Sirsiproducts/hyperion.html>). It was produced by Sirsi, an Alabama company that supplies automated

cataloging and circulation systems to all types of libraries. An important application is the Civil Rights in Mississippi Digital Archive of materials on race relations, created by the University of Southern Mississippi (<http://www.lib.usm.edu/~spcol/crda/>).

Insight image management and delivery system: A system that was produced by Luna Imaging, a joint enterprise between the J. Paul Getty Trust, California, and Eastman Kodak (<http://www.luna-imaging.com/>). It is high-quality imaging software, noted for its powerful zoom capability, and is used for works of art, photographs, and maps. For an example, see the David Rumsey Historical Map Collection (<http://www.davidrumsey.com/>), which features more than 8,000 maps and won a Webby Award in 2002.

Olive ActivePaper Archive software: This software permits historical newspapers to be scanned from the originals or from microfilm, creating fully searchable digital collections. Readers can click on any article, photograph, or advertisement, which is then enlarged in a separate window. For an operational system, see the Missouri Historical Newspapers Collection (<http://newspapers.umsystem.edu/archive/Skins/Missouri/navigator.asp>). Olive Software is located in Denver (<http://www.olivesoftware.com/home.html>).

Open-source software is widely used for server software and in academic environments. It is therefore natural that it is often used for digital library database construction. Zhang and Gourley (2003) review a range of open-source software options for the management and presentation of digital collections. The best known standardized language for databases is SQL (structured query language). In the digital library field, it is normally applied via open-source, server-side database software, of which PostgreSQL and MySQL are frequently cited as powerful alternatives. A combination of MySQL with PHP has drawn much attention recently. PHP (<http://www.php.net>) is a server-side, Web-scripting language whose predefined function set easily interfaces with MySQL. The Digital Library Toolkit (Noerr, 2000) contains a useful overview of software. ColdFusion is an additional alternative; its current version is Macromedia ColdFusion MX 6.1 (http://www.macromedia.com/software/coldfusion/?promoid=home_prod_cf_082403). If the project involves querying traditional library catalogs and bibliographic databases, it will be necessary to adopt software compliant with the Z39.50 standard, which permits advanced searches using Boolean, truncation, and similar procedures (Z39.50, 2001).

Metadata

The addition of metadata, or subject terms and descriptive elements characterizing the digital object, adds significant value to digital records. The use of metadata is clearly demonstrated in Figures 12 and 13, from the LOUISiana Digital Library (<http://louisdl.louislibraries.org/>).

The value of this photograph of a famous building in the French Quarter of New Orleans is greatly enhanced by the metadata elements added to it:

Note that the metadata terms are hyperlinked; for example, by clicking on "Wrought-iron" the user is taken to other images of wrought iron.

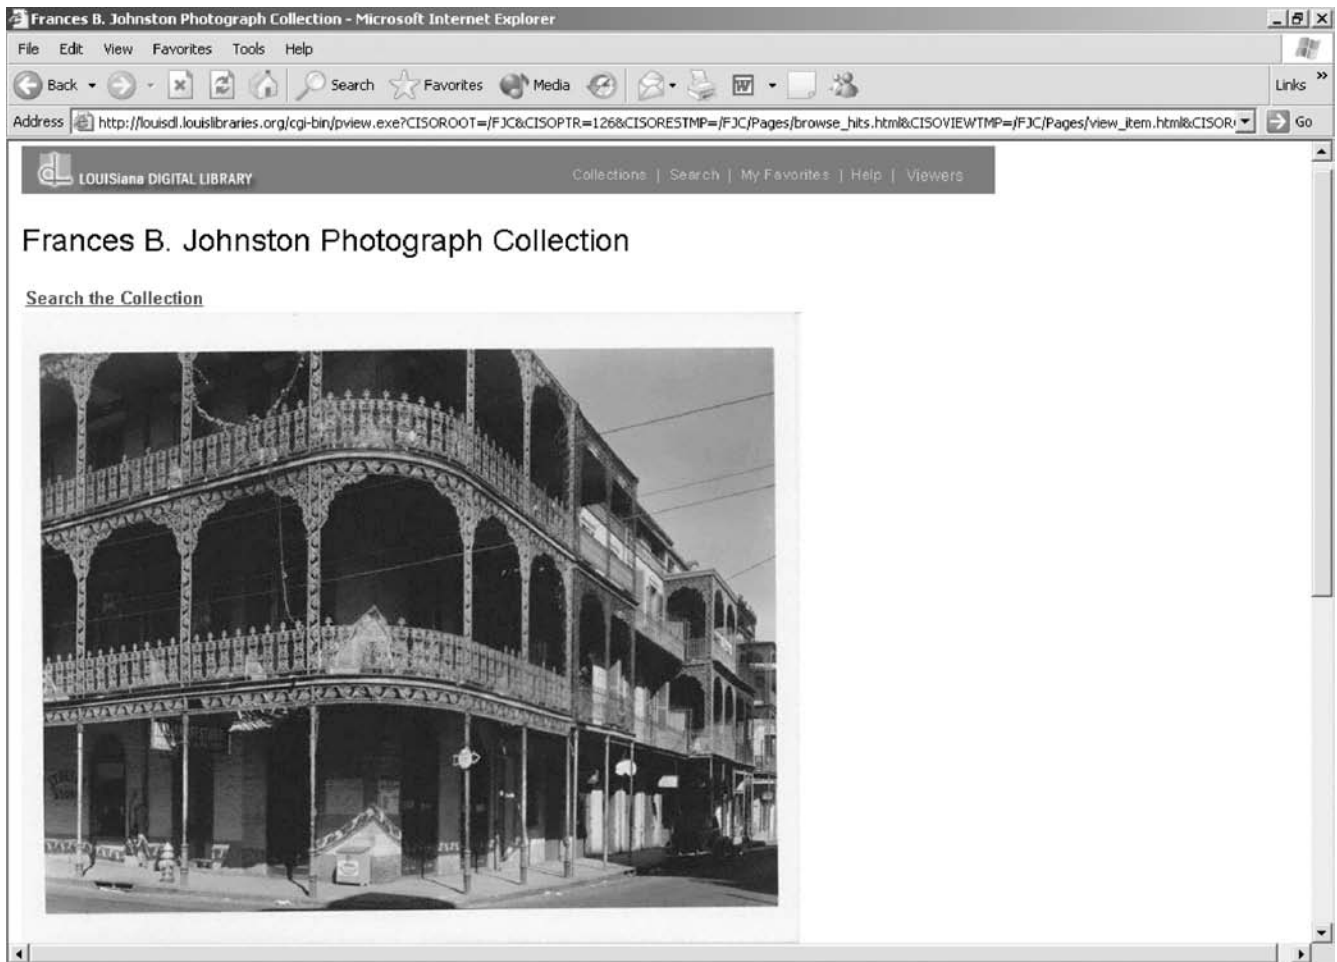

Figure 12: Photograph of a building in the French Quarter of New Orleans, taken by Frances B. Johnston, digitized by the LOUISiana Digital Library.

There are various types of metadata; typical categories include the following:

Descriptive metadata: Used for the indexing, discovery, and identification of a digital resource, such as author, title, abstract, subject headings, and so forth.

Structural metadata: The information used to display and navigate digital resources; also includes information on the internal organization of the digital resource. Structural metadata might include the structural divisions of a resource (i.e., the chapters in a book) or sub-object relationships (such as individual diary entries in a diary section).

Administrative metadata: Management information for the object, which may include technical information, such as the hardware and software used in producing the image, the resolution the image was scanned at, compression information, pixel dimensions, and so forth (*What Is Metadata?*, 2003). Technical metadata must be recorded accurately and consistently to ensure that the image files remain useable well into the future; standards are currently being developed (http://www.niso.org/committees/committee_au.html). Digital rights management information, such as contact information and rules for appropriate use of the data, is another important

element of administrative metadata (*What Is Metadata?*, 2003). Correct legal language must be employed to specify digital rights.

Metadata can be:

1. **embedded** within the resource to which it relates; for example, as HTML metatags;
2. **stored** in a data management database separate from but linked to the resource;
3. **included** in a resource discovery service, such as a library catalog, with a link to the resource (National Library of Australia, 2002).

For an in-depth discussion of metadata, see Vellucci's 1998 paper in the *Annual Review of Information Science and Technology*. Traditional library or archive systems can include entire collections of photographs on a single catalog or container record; digital presentation requires detailed metadata. The best known metadata system, specifically developed for a digital environment, is the Dublin Core, first developed at a meeting in Dublin, Ohio, in 1995. The Dublin Core Metadata Element Set (<http://dublincore.org/documents/dces/>) specifies metadata elements such as title, creator, subject, and rights (for digital

Figure 13: Metadata for a photograph of a building in the French Quarter of New Orleans; metadata generated by the LOUISiana Digital Library.

rights management information). Metadata analysts normally work with a list of acceptable terms, such as the Art and Architecture Thesaurus of the Getty Museum (http://www.getty.edu/research/conducting_research/vocabularies/aat/) or the Thesaurus for Graphic Materials, from the Library of Congress (<http://www.loc.gov/rr/print/tgm1/>). The long-established Library of Congress Subject Headings are widely used, notably in the American Memory collections. Inconsistent or locally created terms will not provide accurate retrieval, but metadata creation adds significantly to both the value and the cost of systems. Good metadata can represent half or more of project costs.

Metadata is widely available through the Open Archives Initiative (OAI; <http://www.openarchives.org/>), which is based on harvester/server architecture. Participating data stores make simple metadata available in standardized format. Information systems harvest the metadata, which is then used to power subject gateways. The metadata in thousands of systems worldwide can be collected centrally (Digital Library Federation, 2001). Lagoze and Van de Sompel (2001) outline the origins and development of the Open Archives Initiative. Nelson and colleagues (2003) describe OAI harvesting from

the NASA Technical Reports Server (<http://ntrs.nasa.gov>). OAIster, from the University of Michigan, offers a sophisticated search interface to a wide variety of freely available, academically oriented digital resources (<http://oaister.umdl.umich.edu/o/oaister>). The Experimental OAI Registry at Grainger Engineering Library, University of Illinois at Urbana-Champaign, has collected sample records from numerous OAI compliant repositories, input them to a database, indexed them, and made them searchable (<http://gita.grainger.uiuc.edu/registry/searchform.asp>).

Text Indexing

Complete, word-by-word text indexing is a valuable feature of most digital libraries. Specialized software for this area includes the XPAT search engine, part of the University of Michigan Digital Library eXtension Service (DLXS) software suite (<http://www.dlxs.org/>). This powers the Legacy National Tobacco Documents Library (LNTDL), a collection of more than 6 million documents, which were obtained through the legal discovery process for a lawsuit and relate to scientific research, manufacturing, marketing, advertising, and sales of cigarettes (Figure 14; <http://legacy.library.ucsf.edu/index.html>).

Figure 14: Opening screen of the Legacy Tobacco Documents Library, from the University of California, San Francisco.

Another specialized example is the Simple Web Indexing System for Humans—Enhanced (SWISH-E; <http://swish-e.org/>). This open-source software enables full-text indexing in many locations, including the Berkeley Digital Library SunSITE (<http://sunsite.berkeley.edu/cgi-bin/search.pl>) and even the Apache Web Server site (<http://search.apache.org/>). Another option is WebGlimpse (<http://webglimpse.net/>) from the University of Arizona. It is free to educational users and is widely used, for instance for the papers of President George Bush, Senior ([http://bushlibrary.tamu.edu/research/paper.html;test index with “saddam”](http://bushlibrary.tamu.edu/research/paper.html;test%20index%20with%20%22saddam%22)). Fluid Dynamics Software (<http://www.xav.com/scripts/search/>) is used for the Encyclopedia Titanica (<http://www.encyclopedia-titanica.org/index.php>), a well-presented collection of documents and information relating to the sinking of the Titanic. Indexing software from Master.com (<http://www.master.com/texis/master/app/home.html>) offers advanced Boolean search (AND, OR, NOT) capacity; for a digital library example, see the documents of the Chicago Women’s Liberation Union (<http://cwlulherstory.master.com/texis/master/search/?q=CWLU&s=SS&cmd=Options>).

SECURITY AND DIGITAL LIBRARIES

In the digital library area, security can be defined as “techniques and practices that preserve the integrity of

computer systems, and digital library systems and collections” (Arms, 2000, p. 281). At the most basic level, digital libraries contribute significantly toward document security because they permit the rapid dissemination of multiple copies. History has shown that documents available in a large number of copies have a much better chance of survival.

Security of Original Materials During the Digitization Process

Security problems during the digitization process are very similar to those encountered during microfilming. Old and fragile documents need to be handled carefully. Valuable materials will be digitized on-site to avoid any risks during the transportation process. The team responsible for the digitization process will carefully count and number all items before they are digitized. Digitization today may involve outsourcing, notably to countries such as India and the Philippines. This is only viable for materials that can be replaced if lost in transit. Offshore digitization has also been combined with XML markup; this, of course, requires that offshore staff be trained in XML.

Security of Online Resources

Even digital libraries that make their materials freely available to the public need to take normal firewall

precautions against hackers, crackers, and individuals who attempt to download large proportions of their content. For general overviews of IT security in higher education in the United States, see the *Effective Security Practices Guide* produced by the EDUCAUSE/Internet2 Computer and Security Task Force (<http://www.educause.edu/security/guide/>) or the IT Security in Higher Education site maintained by Syllabus (<http://www.syllabus.com/campussecurity/index.asp>). Materials within digital libraries represent the best of an institution's collection, whereas older materials may be out of copyright and could possibly be redistributed. There are many considerations in terms of potential abuse of images; if users can steal an image, the institution may lose possible use and publication fees, an important source of revenue for cultural heritage repositories.

Lesk's introductory book to the digital library field devotes part of a chapter to security (Lesk, 1997, pp. 139–142); he suggests basic security, sensible administration, firewalls, and passwords. Gladney and Lotspiech (1997) discuss the safeguarding of digital library content from the point of view of convenient security and data quality. Digital libraries should protect copyright holders, users, and themselves against misuse of content, either deliberate or inadvertent. Unobtrusive programs can provide protection without inconveniencing users. Digital libraries can be seen as a development and improvement of traditional library services while following similar principles. Authenticity in the library context becomes integrity for computer professionals; privacy becomes confidentiality and intellectual property rights are guaranteed by security systems. Collectively they ensure quality services. In a later paper (Gladney & Lotspiech, 1998), they offer specific solutions, via the use of cryptographic envelopment of document packets. This should provide end-to-end protection while demanding a lower network infrastructure and administration. Protocols can enforce information owners' rules governing how users might select, request, possibly pay for, and eventually gain access to digital materials. It is also important to note that Gladney (1998b) recognizes that technology can contribute toward digital libraries only within a framework of administrative, legal, and social practices. Technical considerations are secondary to issues of public policy, law, and ethics. Gladney (1998b) stated that computer professionals were able to design systems with sufficient flexibility to work within these constraints.

A paper by Kohl and colleagues (1997) considers that there are major advantages to retaining the library as an intermediary between publisher and customer in a digital environment. Under these circumstances, digital library services must protect transactions between publishers and users. Content must be secured, via guarantees of payment and copy and usage rights; user privacy must also be protected. This can be done using either secure connections or secure packages; the latter are considered more appropriate to a digital library environment. A further consideration might be whether the library should shoulder the cost of protection and security in these transactions. The authenticity of digital resources is discussed by Bearman and Trant (1998); this is an important aspect of security in a digital library context, because it is not

impossible to find resources apparently representing the same document at different sites. It is essential to be able to establish the relative authenticity of different representations by analyzing the methods used to transform the original into digital form. It is also essential to be able to determine the integrity of a specific digital copy. Cox (2001) discusses the user's participation in computer security from a digital library point of view. An organization such as a university computing services center should not reveal too much information about protective measures. However, users should be told about the extent of external attacks; this would give them a stronger appreciation of the value of computing services' activities and a greater understanding of the value of stable networks.

Access Control Systems

Arms (1998) offers a general approach to the problems of implementing policies for access management. Policies should cover who can access information and under what terms and conditions. Access management is required for digital libraries because of donor restrictions, privacy, obscenity, and copyright. It is also needed for electronic publications, which may require payment for use, needed because of government security, and needed for trade secrets. Commercial or academic digital library access, where copyright materials are involved, is often limited to users of specific institutions. In these cases, access is restricted to computers with specific addresses (Internet protocol identification, or IP identification) and to users with passwords. Arms also devotes a chapter of his textbook on digital libraries to access management and security (Arms, 2000, pp. 123–142). Access management procedures begin when users identify themselves; authentication procedures then validate the users, verifying that they are really who they claim to be; after validation, users can be allocated to specific categories. Digital materials also have to be identified and authenticated, whereas materials in specific subcollections or subject to varying licensing arrangements may be treated in different ways. Operations management policies may restrict extent of use (e.g., stopping downloads of large quantities of material) or inhibit subsequent use of downloaded items. Policies must be carefully drawn up, be viable and appropriate to the environment, and be clearly communicated to the end users. Trusted digital repositories are essential. Security techniques discussed by Arms include encryption, private key encryption, dual key encryption, digital signatures, and public key encryption.

In the only significant case of violation of an institutional digital library to come to public attention, 50,000 scholarly journal articles were downloaded from JSTOR (<http://www.jstor.org/>), the University of Michigan's scholarly journal archive (Olsen, 2003b). The hacker took advantage of IP authentication. The owners of JSTOR have recently posted a strong statement concerning unauthorized access (<http://www.jstor.org/about/unauthorized.html>). JSTOR is experimenting with new open-source software, Shibboleth (<http://shibboleth.internet2.edu/index.html>), which prevents such incidents by improving online authentication. Shibboleth was developed by Internet2 researchers with National

Science Foundation support; it supports interinstitutional sharing of Web resources subject to access controls.

Lesk (1997, pp. 140–142) suggests access control systems that use constantly updated passwords, or “one-time passwords,” such as the SecurID system, in which users carry a matchbox-sized token that generates a new six-digit number every 60 sec. Each user also has a personal identification number (PIN), which is entered in conjunction with the six-digit number. An alternative technology is the S/Key system invented by Bellcore. Gladney (1997) presents a document access control system developed for digital library environments by IBM. This follows established organizational practices in respect to privilege controls and makes access control information a part of ordinary objects. The resulting document access control method (DACM) scales efficiently, is functionally flexible, and can be either embedded into a library or be implemented externally. A library can establish varying policies for different document classes, for example, distinguishing between defense documents and other documents. A security key based on a credit card number was recently adopted as the basis of security at Palm Digital Media (<http://www.palmdigitalmedia.com/>). This system gives wide latitude to the buyer, who can, for instance, purchase an e-book, accidentally delete it, and then download a second copy. At the same time, illegal copying is effectively inhibited (Becker, 2004).

Intellectual property management problems at Case Western Reserve University were examined by Alrashid and colleagues (1998), who describe a series of small-scale projects that deliver supplemental instructional resources directly to student dorm rooms. Rumsey (1999) describes a smart card application called TOLIMAC (total library management concept), which is designed to control access to electronic library services; it was developed by a Belgian, French, and British consortium. Networked digital system security and firewalls are discussed from a digital library perspective by Peacock (1999). He suggests running applications in a restricted environment that the client would visualize as a “full” machine. Any attacker would only be able to damage the restricted environment. Guenther (2001) examines ways for librarians to authenticate users of their digital collections, emphasizes the importance of authentication, and discusses methods of authentication, including user name and password, cookie files, smart cards, and biometrics. Saeednia (2000) presents a brief overview of two main network security problems related to digital libraries, privacy and authentication, and proposes practical solutions that are applicable to digital libraries of any type and size, such as a key exchange protocol and an identification scheme whose security is based on the difficulty of computing discrete logarithms and factoring large integers.

Distributed access control and secure content distribution in the context of digital libraries are examined by Yagüe and colleagues (2002). They present a system that combines the use of an external authorization infrastructure, together with a software protection mechanism and a modular language, to control access to content. Solbakk (2003) describes basic architectural choices for the access to and preservation of digital objects at the National Library of Norway. A digital repository is the core element

for the handling of both access to and preservation of the digital objects. Strategies for giving access to the complete holdings include the use of a powerful search engine and the OAI protocol to harvest metadata from conventional catalog systems to make textual or structured indexes. Access management for the subject portals set up to provide the United Kingdom higher education community with access to distributed resources in the areas of biomedicine, engineering, humanities, physical sciences, and social sciences are examined by Pinto (2003). Each hub is able to customize a portal for its specific needs, while offering common functions, such as access management, user profiling, and cross searching. Users will have streamlined access to subject-specific datasets and personalized services, while being able to obtain authorization to access protected remote resources.

Sturges and colleagues (2003) discuss the other side of digital library security, the privacy of users. With digital technology, libraries can archive detailed information about users; this information is generally considered confidential but could be of interest for law enforcement, security, and commercial organizations. Their project at Loughborough University, England, during 2000–2002 found that users were not concerned about privacy when using libraries because they expected that libraries would not pass on personal information. Librarians respected user privacy but did not rank it as a primary consideration. A significant minority of libraries needed better data protection; the project developed guidelines for privacy policy.

Commercial Digital Library Systems

Herzberg (1998) discusses charging for content by digital libraries and other providers of online content and offers an overview of a variety of different charging mechanisms, both existing and proposed. Charge card payments involve minimal fees, as well as delay, which makes them inappropriate for very small purchases. It is possible to provide free content and finance it via advertising revenues, but these tend to be limited in the digital library area. It is also possible to package content and sell access, for instance, in the form of subscriptions. In practice, relatively few users are willing to subscribe, and fees often have to be shared with intermediaries. There has been considerable interest in the use of micropayments, or payments whose value is too small to justify the cost and delay of a charge card transaction (roughly speaking, under one dollar). They are an attractive option in theory, but their widespread adoption depends on the creation of mechanisms capable of rapid transfer of small amounts of money at a low cost per transaction. Herzberg also examines the requirements for successful charging mechanisms. Credit card charging mechanisms using the SSL protocol were the most common at that time; the SET (secure electronic transaction) standard for charge card payments was also outlined. The MiniPay micropayment mechanism for charging small amounts “per click” is compared to other micropayment mechanisms. Herzberg helped develop both SET and MiniPay, which are IBM systems. A content management system that detects users who attempt to make illegal copies of materials

in fee-charging digital libraries was created by Mun and colleagues (2002); they define a set of rules that permit the identification of abnormal access behavior patterns.

A recent development is that commercial digital library systems are forced to adopt a series of precautions to protect themselves when they offer access via credit card, even when they are only selling technical or academic documents. Should a commercial system accept a stolen credit card number, it will make an inappropriate charge against the cardholder. This can be easily annulled, but if this occurs frequently, the credit card company may charge the digital library heavily. Another problem may arise when commercial digital libraries offer trial access to collections to credit card holders. Credit card preauthorization is not normally a problem, because it only costs the digital library a few cents per card. However, if foreign scammers use automated systems to generate credit card numbers and submit several thousand numbers to verify their validity, significant charges may be incurred. To protect themselves against these problems, commercial digital libraries may automatically refuse requests from IP addresses located in foreign countries known for “scams” of this type. An alternative would be to insist on address verification for credit card transactions, which will limit their sales to North America.

Watermarking

Watermarks are a security technique familiar to all users of paper currency, but they can be easily transposed to the digital environment. A classic watermark would be a visible subsidiary image inserted in a protected image. In the digital field, watermarks may be coded so as to be invisible to the end user. Visible watermarks are routinely used to mark the sample images that can be examined free of charge in commercial photograph collections, such as that at the New York Times (<http://www.nytimes.com/nytstore/photos/index.html>) or Corbis (Figure 15; <http://pro.corbis.com/>).

Mintzer, Lotspiech, and Morimoto (1997) are responsible for a seminal paper on watermarking in a digital library environment. They define “digital watermarks” as imperceptible, or barely perceptible, transformations of digital data. They are mostly applied to digital images but can be applied to other forms of digital data, for example, videos and music. The term “invisible watermarks” can be used to describe digital watermarks that are imperceptible but that can be extracted by a computer. When the imperceptible watermarks themselves contain data, the term “data hiding” is used. A password may be needed to extract the digital watermark; this is called a “watermark key.” Mintzer and colleagues do not consider watermarking to be a total solution for digital library security; better security can be achieved by combining it with encryption and digital signatures. The paper describes a variety of technologies, including some that were relatively unproven at that time. Mintzer also collaborated on a major paper describing the application of watermarks to images of priceless materials in the Vatican Library (Gladney, Mintzer & Schiattarella, 1997). IBM collaborated with the Vatican in an early experiment to explore the technical, financial, and practical challenges of making illustrated medieval

Figure 15: This sample image, from the Corbis image agency, has been protected by a clearly visible watermark.

manuscripts accessible via the Internet. Gladney and colleagues note that making images and text available via WWW or CD-ROM is quite easy; the challenge is to do so in a way that enhances and preserves the value of the materials. The situation is especially difficult when libraries need to make new services pay for themselves. Safeguards are nearly always imperfect, but digital watermarks can make misuse economically unattractive.

Komatsu and Tominaga (1990) suggest embedding a digital watermark in each document image sold; it would therefore be possible to track illegal copying. Video steganography, or how to secretly embed a signature in a picture, is discussed by Matsui and Tanaka (1994). Zhang and colleagues (2002) propose a novel watermarking scheme for still images in digital libraries. The image is decomposed, and a logo watermark is embedded into the low-frequency band. They provide a detailed technical description of the method, which they consider more robust than conventional approaches. Sasaki and Kiyoki (2003) propose to systematically protect digital library materials, especially images, by using patentable content-based retrieval processes.

Audio watermarking is less common but was discussed in a digital library context in two papers relating to the National Gallery of the Spoken Word (NGSW; <http://www.ngsw.org/>). Seadle and colleagues (2002) approach the problem from the general point of view. The development of audio watermarking technologies is an important research consideration for the NGSW, which considers audio watermarking a particularly desirable method of intellectual property protection. Even the courts accept watermarks as legitimate means of copyright protection. Watermarking facilitates redress, while representing a protective technology that can be used by universities without prejudice to their mission to disseminate knowledge. Intellectual property techniques adopted by the NGSW are described by Deller and colleagues

(2001); their discussion centers around an audio watermarking algorithm called \textit (transform encryption coding; TEC), which offers several advantages.

PRESERVATION AND DIGITAL LIBRARIES

Although their major objective is to increase access to materials, digital libraries serve an important preservation function by reducing the need to handle the original every time somebody wants to view it or read it. All digital library policy and design should be influenced by considerations of preservation, both of the original materials and of the digital surrogates. For instance, even when the public will have access only to working JPEG images, provision should be made for the long-term storage of high-quality archival images.

Preservation of Original Materials

Originals of photographs and broadsides will normally be retained, even after digitization. Books, which may be printed on brittle paper and may have been unbound to facilitate digitization, can be more difficult to preserve. Microfilm has been the standard answer, but libraries have recently been criticized for failing to retain the originals of microfilmed newspapers (Baker, 2001). In the future, there will, no doubt, be strong pressure on libraries to preserve originals after digitization, especially when they are the last available copies. A series of difficult decisions will have to be made. Will minor restoration work, such as mending tears, be undertaken before digitization? The cost of restoration work can rarely be included in digital library projects. Should images be processed to restore original color? The aim of digitization will normally be to faithfully represent the original as it is now.

Preservation of Digital Materials

Protection of digital resources is essential to preservation activities. Libraries have traditionally thought in terms of centuries, whereas computer software only lasts a few years before being replaced by new, and often incompatible, systems. All types of digital information are at risk. Software and hardware quickly become obsolete, and file formats and versions constantly change, rendering important data unusable. Even simple data formats are in danger because of the degradation and obsolescence of computer media. As a result, high-quality information resources, such as databases and e-journals, can become entirely or partially unreadable. By the time the problem is detected, it may be too late to save them (Ray et al., 2002).

Arms devotes a chapter of his textbook on digital libraries to repositories and archives (Arms, 2000, pp. 245–262). He offers criteria for the evaluation of repositories, storage of metadata, and interoperability. Digital archival operations are seen in terms of refreshing and migrating data; he also discusses digital archeology, or the process of recovering data from superseded systems. Arms is careful to distinguish between migration and emulation:

Migration: The “preservation of digital content, where the underlying information is retained but older formats and internal structures are replaced by newer.”

Emulation: “[T]he replication of a computing system to process programs and data from an early system that is no longer available” (Arms, 2000, p. 276–279).

Chowdhury and Chowdhury’s textbook also devotes a chapter to digital library archiving and preservation (2003, pp. 214–226). They discuss problems and strategies for digital preservation and outline principal projects in the area. A general overview of the preservation landscape is offered by Abby Smith (2004) of the Council on Library and Information Resources (CLIR). She points out that the fundamental questions of stewardship (what is to be collected and preserved, for whom, for how long, and by whom) have changed significantly. Key questions include these: is it possible, or even desirable, to select or preserve rapidly growing Web resources? Is it possible for institutions to collaborate in collection development, metadata creation, or preservation services? How can institutions such as libraries preserve digital informational resources that are owned by commercial rights-holders and simply licensed for use by the library? Who is going to pay for preservation in the digital age? Is it possible to envision a rights regime that provides an incentive for good stewardship?

Gould and Ebdon (1999) conducted a survey for the International Federation of Library Associations (IFLA) and United Nations Educational, Scientific and Cultural Organization (UNESCO) on the digitization and preservation policies of major libraries worldwide. Sixty-four percent of the libraries or archives that digitized materials had a preservation policy for digitized documents. A large majority, 83%, continued to allow access to the original document after digitization. Sixty-seven percent of the libraries and archives surveyed stored the originals in special conditions. Slightly more than half of the respondents had a policy for migrating data to more recent platforms. In all cases, when data were migrated, all data were processed. Data migration was always an internal procedure; it was never contracted out.

Digital files must be carefully refreshed at regular intervals. Simple steps that any webmaster can take to safeguard digital resources are outlined by the National Library of Australia in *Safeguarding Australia’s Web Resources: Guidelines for Creators and Publishers* (2002). For a British initiative in digital preservation by CURL (Consortium of University Research Libraries), see CEDARS (CURL Exemplars in Digital ARchiveS). This project lasted from 1968 to 2002 and generated numerous papers and the prototype of a distributed digital archive. Documentation is still available via the University of Leeds (<http://www.leeds.ac.uk/cedars/index.html>).

The Digital Library SunSITE at Berkeley suggests four levels of collecting; each level implies a different commitment to preservation:

Archived: The material is hosted here, and the library intends to keep the intellectual content of the material available on a permanent basis.

Served: The material resides here, but the library has not (yet) made the level of commitment to keeping it available that it has for “archived” materials.

Mirrored: A copy of material residing elsewhere is hosted here, and the library makes no commitment to archiving. Also, an institution other than the library has

primary responsibility for the content and its maintenance.

Linked: The material is hosted elsewhere and the library points to it at that location. Therefore the library has no control over the information.

Material in any category except Archived may be redesignated from one level to another as required to meet changing information needs, remote server accessibility or responsiveness, local resource demands, etc. Material that receives the Archived designation cannot be downgraded to a lower status. (<http://sunsite.berkeley.edu/Admin/collection.html>) The Digital Library SunSITE at Berkeley offers additional resources on preservation at <http://sunsite.berkeley.edu/Preservation>.

Lorie (2001) discusses the technical, social, and organizational challenges that have to be overcome to guarantee the long-term preservation of digital data. Technical challenges involve ensuring that today's information can survive changes in storage media, data formats, and devices. He suggests distinguishing between the archiving of data files and the archiving of programs. Program behavior would be reenacted in the future, because the original executable object code would be saved alongside the specification of the processing required for each original machine instruction. Data files would be preserved, together with a specification of the processing that needs to be performed on the data so as to return the information to a future client. Processing would be based on a universal virtual computer model that would be general in nature and sufficiently basic to remain relevant in the future. A logical view of the data would also be archived. In a follow-up paper to a later digital library conference, Lorie (2002) continued his discussion of long-term archiving of digital data using a universal virtual computer (UVC). To render archived data comprehensible to a future client, a certain amount of information must be preserved indefinitely to guarantee that the client will be able to recover the information. Lorie calls this a "Convention" and presents the first version of one in his paper, together with the architecture of the UVC.

Rothenberg (2000) discusses emulation as an option for a major European library. His report was issued as part of the NEDLIB (Networked European Deposit Library) project (<http://www.kb.nl/coop/nedlib/index.html>), which had as its objective the long-term storage of European digital publications. Holdsworth and Wheatley (2001) discuss emulation as a preservation technique. They describe the CAMiLEON project, a joint undertaking between the Universities of Michigan (U.S.) and Leeds (U.K.) to develop and evaluate a range of technical strategies for the long-term preservation of digital materials (<http://www.si.umich.edu/CAMILEON/index.html>). Its best known achievement was the rescue of the data in the BBC Domesday Project (<http://www.atsf.co.uk/dottext/domesday.html>). A mass of information on life in Britain in the 1980s was recorded on large videodiscs, using an unusual format that could only be read by an obsolete computer (<http://www.si.umich.edu/CAMILEON/domesday/what.html>). There was great relief when the data were finally recovered (*Digital domesday book unlocked*, 2002).

A distributed, object-based design for digital library repositories is described by Lagoze (1995). He proposes inter-operable secure object stores (ISOS) and defines interfaces to secure repositories that permit interoperability with other repositories, with clients, and with other infrastructure services. The interfaces to ISOS are defined as classes in a distributed object system, using network interoperability protocols such as CORBA (common object request broker architecture) or OLE (object linking and embedding). Lagoze also defines an extension to CORBA security that can be used by repositories to secure access to themselves and to their digital objects.

Tennant (2001) discusses disaster protection in the digital library context. He recommends RAID (redundant array of inexpensive [or independent] disks) technology. RAID level one involves mirroring data or making one complete copy. RAID level five distributes data across several physical disks. Uninterruptible power supplies and fire and alarm systems constitute necessary disaster infrastructure. Data also need to be backed up at a distant location.

The preservation of digital content at one of the world's major digital libraries, the National Digital Library Program (NDLP) of the Library of Congress, is discussed by Arms (2000). All files offered by the Library's servers are currently on magnetic disk, with built-in mirroring capability. Full backups of the entire system are made to magnetic tape cartridges in a robotic "library" on a 2-week cycle; backups of files that have been modified or created are made nightly. Two new features were planned: snapshot archives of digital collections and an off-site location for an additional robotic backup facility; this would be accessible via the storage network. In December 2002, the U.S. Congress approved NDIIPP's Preserving Our Digital Heritage: Plan for the National Digital Information Infrastructure and Preservation Program, making it possible for the Library to proceed with the work of developing an infrastructure for the collection and preservation of digital materials (National Digital, 2002). Another national library, the National Library of Australia, maintains an important Web site for digital preservation. PADI: Preserving Access to Digital Information (<http://www.nla.gov.au/padi/>) covers strategies, data documentation and standards, sources of information, and a series of other topics. In the United States, the Online Computer Library Center (OCLC) offers practical support to libraries and maintains a digital archive that permits members to store their digital assets either item by item or as entire collections (<http://www.oclc.org/digitalarchive/default.htm>).

The Internet Archive and the Wayback Machine (Figure 16; <http://www.archive.org/>) permit nostalgic surfing through the Web of several years ago and access to special collections recording specific events.

In view of their role, it is interesting to note their archival procedures. Their hardware consists of PCs with clusters of IDE (integrated device electronics) hard drives. Data is stored on DLT (digital linear tape) and hard drives in various formats (<http://www.archive.org/about/about.php>). Although DLT is rated to last 30 years, the industry rule of thumb is to migrate data every 10 years;

The screenshot shows the Internet Archive website. At the top left is the 'INTERNET ARCHIVE' logo with a classical building icon. Navigation links include 'Web', 'Moving Images', 'Texts', 'Audio', 'Software', and 'Patron Info'. A secondary row of links includes 'Internet Archive Home', 'Forums', 'FAQs', 'Contributions', 'About IA', 'Terms, Privacy, & Copyright', 'Contact', and 'Jobs'. A search bar is present with a 'GO!' button and a dropdown menu for 'All Media Types'. On the right, it says 'Anonymous User (login or join us)'. Below the navigation is a 'Universal access to human knowledge' slogan.

the Internet Archive expects to migrate more frequently. Web data are stored in 100-MB WWW archive (ARC) files designed to meet the specific demands of the system (<http://pages.alex.com/company/arcformat.html>). Each archive file contains many individual files and multiple copies are stored in different locations. The Internet Archive also collects software and emulators that will aid future researchers, historians, and scholars in researching the history of the Internet and social communication patterns.

For a unique, open-source approach to archiving digital materials at a library level, see Lots of Copies Keep Stuff Safe or LOCKSS, implemented at Stanford University (<http://lockss.stanford.edu/index.html>). This permits libraries to maintain local archive copies of the Web journals to which they subscribe; the system polls the Web journals regularly and downloads new material to a local cache. These are the procedures libraries have always adopted with periodicals, now updated to a digital format. Lavoie (2000) discusses the preservation process for electronic scholarly journals from the point of view of a major intermediary, the Online Computer Library Center (OCLC).

Cooper and Garcia-Molina (2001) discuss the creation of cooperative trading networks, which could protect digital archives against failure by maintaining copies at remote sites. Simulations assist in calculating space requirements and the optimum number of partner sites. A paper at the same conference by Crespo and Garcia-Molina (2001) points out that it is difficult to design an archival repository because there are many possible alternatives, all with different levels of reliability and cost. They analyze the cost of these repositories and suggest evaluation criteria that permit the selection of the most reliable

and cost-effective procedures. They have developed a simulation tool that aids in the decision process. Chapman (2003) discusses the cost of digital preservation and compares the centralized repositories of Harvard University Library and the Online Computer Library Center (OCLC). Both organizations recover operational expenses by charging owners; Harvard Depository assesses rates for analog storage per billable square foot; OCLC assesses rates per gigabyte for storage of digital objects. Formats are significant factors in deciding preservation costs; the definition of content integrity and tolerance for risk are important variables that can change over time.

Preservation of CDs and DVDs

The archival TIFF files produced directly from original materials are of great value and must be carefully preserved. It is common practice for digital libraries today to save these on a series of CD-Rs (compact disc, readable). Even relatively small systems may have more than 1,000 CD-Rs. Byers (2003) produced a comprehensive guide to the care and handling of CDs and DVDs for librarians and archivists that covered topics such as the types of media in use, how they are made and how they work, the care of optical media, their longevity, and conditions that affect their life expectancy. The "write-once" CD-Rs used to record digital data in DLs should have a life of at least a hundred years, if well looked after. More serious problems arise with mass-produced audio CDs, which may have a life of only 20 years, even when carefully stored. The Library of Congress' Preservation Research & Testing Division recently examined preservation problems of CDs (Library of Congress, 2003). Program objectives included developing storage guidelines and using an accelerated

aging procedure to estimate the lifetime of CDs. If the rate at which optical and physical changes occur can be determined, it is possible to anticipate when discs will need to be reformatted. Samples of the CD collections of the Library of Congress are monitored periodically. These problems recently came to wide public attention when a music enthusiast noted that 15–20% of his audio CDs suffered from “CD rot” and would no longer play (Baig, 2004).

An additional problem with handling thousands of CD-Rs is that information has to be carefully organized so that specific images can be quickly retrieved when necessary. This requires careful planning, especially with simplified systems where file names may be limited to eight characters.

Legal Deposit of Digital Materials

Legal deposit of books with national libraries has long been the cornerstone of bibliographic preservation. The concept is now being extended to digital works. The International Federation of Library Associations (IFLA) and the International Publishers Association (IPA) recently made a joint statement on the archiving and preserving of digital information (International Federation of Library Associations, 2002). They pointed out that an increasing amount of the information published only in electronic form has enduring cultural and documentary significance. It is just as important as more traditional information, and action must be taken to guarantee its long-term availability. Both organizations would work to add long-term archiving and preservation to international agendas. Industry standards, systems, and research for digital archiving and preservation are essential for the success of this program. Libraries are in a good position to take responsibility for long-term archiving, working with publishers. National libraries are experimenting with the acquisition of digital publications and should take the lead in long-term archiving of digital publications.

UNESCO recently promulgated the important *Charter on the Preservation of the Digital Heritage* (UNESCO, 2003). This states that member nations need to secure and protect their digital heritage via appropriate legal and institutional frameworks. Archives legislation and legal or voluntary deposit in libraries, archives, and other repositories are key elements of national preservation policy and should embrace national digital heritage. Adequate access should be assured to legally deposited digital heritage materials. It is essential that appropriate legal and technical frameworks be created to guarantee authenticity and prevent manipulation or intentional alteration of digital materials. For archival work, it is essential that electronic materials should be verifiable.

The British Library has begun a project that may eventually lead to the archiving of all U.K. Web sites (Marson, 2004). A trial project to preserve 6,000 U.K. Web sites was announced by the U.K. Web Archiving Consortium, led by the British Library and including the National Archives and the Scottish and Welsh national libraries. All types of Web content, from government documents to blogs, will be covered. The British Library will not censor the material and ultimately would like to archive all U.K. Web sites. Because of U.K. copyright laws,

permission is needed to archive a site, but the British Library is asking the government to extend the law to permit preservation of the U.K. Web. A British Library Web site (<http://www.bl.uk/news/webcase.html>) somberly predicted that “Without new legislation to ensure non-print materials are saved for future generations, the 21st century will be seen as a cultural Dark Age which failed to archive a substantial and vital part of the nation’s published heritage.” It is interesting to compare digital and audio materials in this context: the United States only introduced legal deposit for sound recordings in the 1970s; as a result, many early recordings are not in the Library of Congress (Lesk, 1997, p. 179).

PANDORA (Preserving and Accessing Networked Documentary Resources of Australia) is Australia’s Web archive, created by the National Library of Australia in 1996 (<http://pandora.nla.gov.au/index.html>). Because of the lack of legal deposit provisions covering online publications in Australia, PANDORA seeks permission from publishers before including materials in the archive (<http://pandora.nla.gov.au/legaldeposit.html>). An assistant director-general of the National Library of Australia has given an interesting account of archiving the Web in Scandinavian countries (Cathro, 2001). Progress has been made in Finland, Norway, Sweden, and Iceland, but serious legal obstacles still need to be overcome. The first efforts of the French National Library to archive the French Web are described by Abiteboul and colleagues (2002). Specific problems included the exact definition of the perimeter of the French Web and the specification of appropriate intervals for the production of successive archive copies of regularly updated Web pages.

CONTINUITY OF DIGITAL LIBRARIES

Continuity of Resource Identifiers

The problem of “dead links” is a familiar source of annoyance to all Internet users. Digital libraries, which offer quality materials, should make special efforts to maintain their URLs over time. Many digital libraries contain links to outside resources. These links have to be checked regularly, biweekly, weekly, or even daily. Dead links have to be removed or updated, often a laborious process. Simple approaches include organizing Web sites so that it is unnecessary to move resources, or even maintaining older materials on the Web site (National Digital Information Infrastructure and Preservation Program, 2002).

One solution is to use persistent identifiers, such as PURLs (persistent URLs; <http://purl.oclc.org/>). To the end user, a PURL looks and functions like a URL. However, instead of pointing at an Internet resource, a PURL points to an intermediate resolution service. The PURL resolution service associates the PURL with the current URL and returns that URL to the client, who is switched seamlessly via a standard HTTP redirect.

Gladney (1998a) discusses methods of unambiguously identifying each digital library item needing protection. The best-known operational system uses digital object identifiers or DOIs (<http://www.doi.org/index.html>). DOIs consistently identify content objects in a digital environment, permitting persistent identification, management of intellectual content, and links between users and

content suppliers. Information about a digital content object may change and its location on the network may be altered, but the DOI will remain the same. DOIs are presented in the form “DOI:Directory.Registrant/Suffix.” In the example “DOI:10.1234/999ABC,” “10” represents the directory of DOIs for a specific geographic region or industry, “1234” is the registrant’s prefix, which identifies the company or institution supplying the content, and “999ABC” is the suffix, a unique identifier supplied by the company. The suffix can be an existing product number or code. The director of the International DOI Foundation, writing in *D-Lib Magazine* in June 2003, stated that 10 million DOIs have been distributed, mostly for textual content objects (Paskin, 2003). Articles in *D-Lib Magazine* (<http://www.dlib.org/>) receive DOIs that commence with “DOI:10.1045”; the DOI of Paskin’s article is “DOI:10.1045/june2003-paskin”; this can be used to retrieve the paper via a search engine, such as Google.

Continuity of Digital Libraries as Institutions

Digital libraries are relatively new and are often created by institutions with solid foundations, such as universities. As a result, almost all the systems implanted appear to be still operational. It is easy to find a listing of dead search engines: Notess (2004) lists about 20. However, there is no listing of dead digital libraries. The few closures that have occurred are related to changes in government policy. The U.S. Department of Energy used to maintain PubSci (formerly at <http://pubsci.osti.gov>), a site that permitted researchers to examine more than 1,000 peer-reviewed journals free of charge through a single interface, instead of searching multiple Web sites. This was closed on the grounds that it duplicated commercial services (Foster, 2002). The ERIC database (<http://www.eric.ed.gov/>) of 1.2 million documents and journal articles on education research and practice, founded in 1966, is one of the world’s best known information resources. In 2003–2004, it underwent major transformations; notably contracts with its 16 clearinghouses were not renewed (ERIC, 2004). ERIC users expressed concern about the changes (Potter, 2003).

McArthur and colleagues (2003) review work on sustainability of digital libraries within the NSF-supported National Science Digital Library (NSDL) program. In the digital library environment, sustainability can be visualized as covering a wide range of topics, from technical issues relating to digital preservation to social questions concerning long-term accessibility of resources. The Institute of Museum and Library Services (IMLS) continually stresses the importance of sustainability. Its *Framework of Guidance for Building Good Digital Collections* presents as the third principle of successful collection building the following statement: “A collection should be sustainable over time. In particular, digital collections built with special funding should have a plan for their continued usability beyond the funded period” (<http://www.ims.gov/pubs/forumframework.htm>). IMLS proposals normally include a section on sustainability; for an easily viewed example, see *Connecticut History Online* (<http://www.cthistoryonline.org/project/IMLSproposal.htm#sustainability>).

CONCLUSION

An important paper by Lynch (2001) points out that the new technologies have a potentially steep social price, because they provide new levels of control, monitoring, and usage restrictions for digital books. The paradox is that unless publishers are able to establish what they consider adequate levels of control, in-print books may not move to digital form. They certainly will not migrate quickly or in large numbers. It is likely that publishers will favor appliance book readers, but it is also possible that print-on-demand publishing (POD) will occupy a significant niche in the future. As this chapter went to press, there were encouraging signs of growth in e-book sales (Becker, 2004). Adoption is expected to continue to be gradual, because the book publishing business is traditional and decentralized. Current growth in e-books has been fueled by users reading them on devices they already have: PCs, laptops, and handheld computers, or personal digital assistants (PDAs). As equipment of this type becomes ever more common, the demand for digital materials can be expected to grow. The long-term potential for digital libraries seems excellent. Kurzweil (1999) published a seminal book, *The Age of Spiritual Machines*, in which he forecast that paper books and documents would rarely be used by the year 2019; all documents and multimedia would be digitized by the year 2029. Libraries will, no doubt, continue to make quality and older materials available. As demonstrated in this chapter, much in the digitization of cultural materials by institutions such as libraries and archives has already been achieved in a few years. This is an important beginning, because, over the next few decades, a major aim of humanity will be the digitization of our cultural heritage. There will, of course, be significant costs, not only in creating, but also in maintaining, digital archives of this scope. If publishers are able to develop secure business models that guarantee significant commercial returns from digital information, they will, no doubt, migrate in force to the digital environment and contribute significantly to this process.

Digital publications are still in their earliest stages, equivalent to print books at the time of Gutenberg. They have little more than a decade of life and will doubtless develop rapidly in the near future. At the moment, the digital library field is unequally developed and characterized by a bewildering variety of systems. Standards are urgently required and will doubtless evolve rapidly. The same is true of security and preservation measures in the digital library field.

GLOSSARY

Access Controls Procedures to control access to digital libraries, based on use of passwords, recognition of IP addresses, and similar features.

American Memory The Historical Collections of the National Digital Library, maintained by the Library of Congress (<http://memory.loc.gov/>); one of the world’s largest digital libraries, with more than 100 collections and a total of 7 million digital items, including photographs, manuscripts, rare books, maps, sound recordings, and moving pictures.

Digital Library A system that permits, via the Internet and the WWW, easy access to a collection of high-value, quality digital content, which has been selected and organized to facilitate use and is supported by appropriate services. The digital content may reflect the traditional textual orientation of many libraries or take advantage of the WWW's facilities to deliver graphics and multimedia.

Digital Preservation Process of guaranteeing the long-term preservation of digital objects by storage of files in secure repositories, migration to other platforms, and other means.

Digital Rights Management Procedures that ensure that holders of digital rights are clearly identified and receive the stipulated payment for their materials; they may also impose further restrictions on use of digital objects, for example, inhibiting printing or prohibiting further distribution.

Digitization Process of converting analog documents (e.g., paper, film, maps) to digital form.

Electronic Journals (E-Journals) Journals, such as scientific and professional journals, available in digital form.

Electronic Theses and Dissertations (ETDs) Theses and dissertations available in digital form.

Emulation The replication of a computing system to permit the processing of programs and data from an earlier system that is obsolete or no longer available.

Indexing The process of systematically generating pointers or keys to the content of texts to permit readers to go directly to pages that contain specific words or deal with specific topics.

Metadata Data about data. Keys, guides, or indications of the content of a document or dataset and stipulations of appropriate use.

Migration Transfer of digital data from one format or platform to another; normally, digital data are migrated from an older format or platform to a newer format or platform to guarantee preservation.

Multimedia Digital Library Digital library that delivers content in a variety of formats: text, photographic images, audio, short films, and so forth.

Project Gutenberg One of the longest running digital libraries (<http://promo.net/pg/or> or <http://gutenberg.net/>), founded in 1971. It has always concentrated on simple, copyright-free texts that can be read on almost any computing platform. Now offers more than 10,000 texts and is supported by a network of mirror sites.

Sustainability The capacity of a digital system to continue operating for the foreseeable future. Sustainability depends on factors such as organizational or governmental commitment, a secure financial model, adequate protection from external attack, use of appropriate formats and platforms, and collections that are of lasting interest or capable of being updated.

INTRODUCTION

E-mail and IM systems are the two main categories of software described in this chapter, and emphasis is placed on security issues and solutions. After a brief introduction to electronic mail and instant messaging, a more detailed look at each system is presented. In today's world of increasing cybercrime, security in e-mail and IM environments is an important concern. Security issues and possible solutions are examined in depth for both e-mail and IM. Following this discussion, e-mail and IM usage policies are suggested. The conclusion is followed by a glossary of key terms and a list of references.

ELECTRONIC MAIL

Electronic mail is ubiquitous in communication today. Before the usefulness of e-mail was perceived, the Internet was widely employed initially for military and academic use. The growth in popularity of the Internet was due, in part, to e-mail. Compared to other modes of communication such as postal mail, e-mail is cheaper, faster, and more convenient. The ability to forward communication to many people and to address more than one recipient, as well as the asynchronous nature of the communication, makes e-mail popular. The advent of mailing lists and address books added convenience and ease of use, leading to an upsurge in the use of e-mail.

Definition of E-Mail

Per the popular usage of the term, e-mail can be defined as mail sent via electronic means. According to Lombardi (2003), e-mail messages use standard conventions for addressing and delivering content across the public Internet. An e-mail has two mandatory parts: a header and a message. Other components, including attachments, are optional. In the beginning of e-mail history, all e-mails were in text format. As e-mail systems evolved, different formatting styles other than plain text began to be used. The e-mail header contains information on where the

e-mail originated, the route it has traveled, and to whom it is addressed. Although most e-mail users may dismiss the header as irrelevant to their communication, technical staff needs to know the source, destination, and route of the e-mail in case of problems.

Brief History of E-Mail

Ray Tomlinson adapted an existing internal e-mail program to the ARPAnet file transfer technology and sent the first e-mail message from one computer to another in 1971 (Griffiths, 2002). After the first message, "Testing 1-2-3," was successfully sent and received by two different computers, Tomlinson sent a message to all ARPAnet users and gave them instructions for sending and receiving electronic mail. The convention `username@hostname`, which is the basis for e-mail today, dates from this time.

Initially, e-mail was cumbersome and user-unfriendly. However, most of the modern e-mail features were implemented within a year of the first e-mail transmission (Griffiths, 2002). The ability to delete, forward, and save messages, together with a standard protocol to transfer messages between programs, was established by 1972. Thus, e-mail evolved along with the network now known as the Internet. In 1977, a standard specification of e-mail was published in a document called RFC 733, which was revised in 1982 to describe domain name syntax explicitly for the first time (Crocker, 2003).

Eric Allman developed the sendmail program in the 1980s, which was derived from e-mail relaying on the UNIX operating system at the University of California at Berkeley. In 1988, Vinton Cerf sent the first commercial e-mail by connecting MCI Mail to the NSFnet (National Science Foundation network). This event marked a milestone in the history of e-mail because it paved the way for network service providers America Online and Delphi to connect their proprietary e-mail systems to the Internet. The exponential growth in e-mail use can be traced to this moment when the benefits of e-mail were globally recognized.

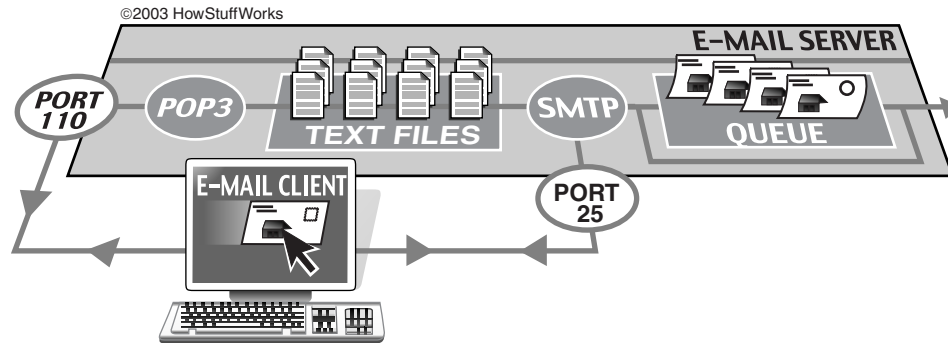

Figure 1: How e-mail works.

Advantages and Features of E-Mail

Some people consider one of the advantages of e-mail to be its informal style of communication. Although people expect typed letters to be formal and perfect, no such expectations exist for e-mail. E-mail became more popular because of its relatively low cost, high reliability, and almost instantaneous delivery as compared with regular mail (Living Internet, 2003). E-mail provides a high level of informality, a sense of community and sharing, wide tolerance of spelling and typographical errors, and brevity of expression. It has been theorized that the style of e-mail communication was a factor in its early and continued success. Also, e-mail does not demand an immediate response, unlike the telephone (Griffiths, 2002).

Scientists and researchers working in the ARPAnet (precursor to the Internet) community started to recognize the immense promise of e-mail to change the way people communicate in all sectors of society, including the academic, business, and cultural sectors (Myer & Dodds, 1976). Productivity gains were realized by businesses through the use of e-mail. Today, e-mail has become indispensable in academic, governmental, and business organizations around the world because of ease of use, convenience, low cost, asynchronous nature, range of features, and communication efficiency.

Current E-Mail Systems

An e-mail system has three components: the transport agent and the delivery agent on the server, and the user agent or client (Preetham, 2002). Popular graphical-user-interface-(GUI-) based e-mail clients such as Eudora, Mozilla, Microsoft's Outlook and Outlook Express, and Pegasus incorporate features such as e-mail forwarding, read receipts, e-mail filtering, and spam blocking. Besides the GUI-based e-mail clients mentioned previously, popular text-based e-mail clients include elm and pine. An e-mail client can use either the post office protocol (POP) or the Internet mail access protocol (IMAP). Whereas POP copies e-mails from the server to the computer on which the client resides, IMAP works by copying e-mail headers to the client computer—actual e-mail messages are not copied unless selected (Nevis, 2004).

On Outlook for Microsoft Exchange server, messaging application programming interface (MAPI) can be used for retrieving e-mail. For sending e-mail, simple mail transfer protocol (SMTP) is the de facto standard

for transmission, whereas multipurpose Internet mail extensions (MIME) is another popular protocol available for e-mail clients (Wikipedia, 2004). For server software, Exchange and sendmail protocols are popularly used. On Linux, qmail is a widely used protocol on the e-mail server. Other chapters in this *Handbook* present more information on these e-mail protocols (MIME and SMTP). Howstuffworks.com has simple diagrams (reproduced in Figures 1 and 2) that provide a clearer understanding of the e-mail transfer process and SMTP protocol. Figure 1, How E-mail Works, and Figure 2, How SMTP Works, are both available at howstuffworks.com.

E-mail addresses can be grouped together into mailing lists. A manager program automates the tedious maintenance of the list by adding, modifying, and deleting users and their e-mail addresses. Most corporations use standard naming procedures to make e-mail administration and management easier (Tittel, 2002). Popular e-mail server software can be categorized into proprietary intranet solutions such as Microsoft's Exchange program and the Internet-based sendmail program. Web-based e-mail software abounds and providers make these clients available to users for free. For instance, Yahoo! and Hotmail provide free e-mail quotas of 100 MB and 250 MB to each user.

Disadvantages and Vulnerabilities of E-Mail

Although more detail can be found in the chapter "E-Mail Threats and Vulnerabilities," this chapter provides a high-level perspective on e-mail vulnerabilities and disadvantages. The very advantages of e-mail can be construed as disadvantages under certain circumstances. The asynchronous nature of e-mail results in disadvantages such as the lack of face-to-face presence that is vital to effective communication. Terse messages can mislead the recipient, especially if previous threads to an e-mail conversation are not attached. E-mail is hampered by the lack of visual cues that are sometimes necessary to understand what the sender really means (Counseling, 2003). Some people find it ineffective to communicate solely via e-mail because its asynchronous nature means there is an absence of immediate, real-time responses.

Today's e-mail systems are more vulnerable to attacks than earlier ones because of the many additions made to the basic model. Advanced formatting such as hypertext markup language (HTML) and the sending of attachments

Figure 2: E-mail transfer and communication.

via e-mail contribute to the propagation of viruses and spam. It is also easy to impersonate others via e-mail. Recipients may be led to believe that the e-mail is from someone they know, but the sender's name and e-mail address could have been impersonated by a crook.

Standard procedures and default configurations are vulnerabilities in e-mail systems. For example, standard naming procedures that ease e-mail management are predictable and thus exploited by hackers. Malicious users hide their identity by using anonymous addresses of publicly available Web-based e-mail providers such as Yahoo! and Hotmail (Kruse & Heiser, 2002). Source addresses can be spoofed. Even if the sender's Internet protocol (IP) address is logged, the hacker might be using a computer in a public place, such as a library or an airport.

Other threats to e-mail include interception and modification of messages and distortion of message headers and content to hide the source and route of traversal (Pfleeger, 1997). Sophisticated protection systems exist today to resolve these threats. E-mail filters work in conjunction with firewalls and intrusion protection systems to create layers of blocking measures for potential malicious software. Sender identity and e-mail privacy are resolved by security measures such as public/private key encryption and digital signatures.

The chapters in this *Handbook* titled "Encryption Basics," "Secret Key Cryptography," "Data Encryption Standard (DES)," "Advanced Encryption Standard (AES)," "Hashes and Message Digests," "Number Theory," "Public Key Algorithms," "Elliptic Curve Cryptography," "IBE (Identity Based Encryption)s," "Cryptographic Protocols," "Quantum Cryptography" and "Digital Signatures

and Electronic Signatures" have detailed information about encryption and digital signatures.

Spam, or unsolicited e-mail (often undesirable), is an ever-growing problem and has surpassed legitimate e-mail in volume. In July 2004, spam constituted 65% of all e-mail messages (Greenspan, 2004). Because of this record increase, spam filters for e-mail have grown in popularity. Employee productivity and network bandwidth are adversely affected if spam is not blocked. Commercial implementations of spam filters include SpamAssassin and BrightMail. Spam filters use many techniques for preventing false positives, that is, legitimate e-mails flagged as spam. Bayesian learning techniques, bouncing spam back to the sender, Turing test filters, and e-mail stamps have been used successfully against spam.

The Bayesian spam filter has an initial time period to "learn" user preferences about spam e-mails and legitimate e-mails (Graham, 2002). Spam filters also exist that can send a fake bounce message to the spammer after simulating an e-mail delivery failure. The Turing test filter requests a human response for a potential spam e-mail before placing it in the inbox (Knight, 2003). With e-mail stamps, a charge can be imposed before allowing the spam messages to go through to the sender.

Malicious people such as virus writers usually exploit the features of e-mails to spread their destructive payload. An e-mail virus usually spreads from computer to computer by automatically mailing itself to all the e-mail addresses in the victim's address book. The Melissa virus of 1999 spread through Microsoft Word documents attached via e-mails (Brain, 2004). Social engineering attacks are also common via e-mail. The "I Love You" virus

that spread in 2000 was an example. Another example is the recent spate of “phishing” attacks that exploit e-mail’s ubiquity in order to harvest confidential data of unsuspecting users who click on an apparently genuine URL in an e-mail purportedly from a legitimate authority (FTC, 2003).

A key concern is the confidentiality of e-mail communication. Because an e-mail can pass through many servers from source to destination, it can be stored and/or retrieved at any point along its route. Network administrators and high-level managers have the right to read all e-mail passing through their networks. Employees may not be aware that e-mail communication is neither private nor confidential. Law enforcement officials can confiscate e-mail on servers and backups for investigative purposes. Later in this chapter, e-mail use policies are described that elaborate on the procedures necessary to alert employees about e-mail communication.

Safeguards for E-Mail: Filters and Usage Policies

Several vulnerabilities posed by e-mail communication make the presence of monitoring systems inevitable today, especially in large corporate environments. According to Lyris, a provider of e-mail filtering services, the process of monitoring e-mail and taking certain actions based on predefined criteria is referred to as e-mail filtering (Lyris Solutions, 2003). E-mail that is monitored can be incoming or outgoing; messages need to match predefined criteria, which can be changed at any time. E-mail filters can help sort, forward, and delete incoming and outgoing e-mail. On an organization-wide level, e-mail filters might be installed:

- 1) to disinfect viruses from attachments,
- 2) to block unsolicited e-mail (spam),
- 3) to block confidential information from going outside the company,
- 4) to block incoming and outgoing offensive content, and
- 5) to prevent unauthorized usage of corporate e-mail systems (Bhagyavati, 2004).

E-mail filtering software is currently available from Lyris, SurfControl, and MailWasher. Although e-mail filters are necessary to monitor spam and offensive e-mail, their implementation can have unintended consequences, such as blocking legitimate e-mail or blacklisting naïve users accused of sending unsolicited e-mail. Cross-compatibility issues among e-mail filters and antivirus software may cause unintentional propagation of viruses. Monitoring and matching measures add extra time to the delivery of e-mail. These security measures also inhibit the free flow of communication that is vital for research and creativity in organizations. The unintended effect of these filters could cause a shift away from e-mail by annoyed employees (Koprowski, 2003). The Chapter “Spam and the Legal Counter Attacks” provides more details about spam and legal countermeasures.

Because e-mail is frequently used to communicate with colleagues, peers, and superiors, a lack of usage guidelines

can lead to confusion over appropriate content and message form. Lack of an e-mail use policy can have serious consequences in cases of inappropriate communication. If corporations do not have policies on e-mail use, employees can misuse corporate-owned e-mail systems without fear of consequences. In creating a written e-mail policy, all “do’s and don’ts” need to be included. The chapter on “E-Mail and Internet Use Policies” can be perused for more information regarding e-mail and Internet use policies.

Employees must also be trained fully to understand why policies are important. Implementation of the rules can be monitored by management tools (EmailReplies.com, 2001). Professionalism, efficiency, and liability protection are the primary reasons for an organization to implement etiquette rules and train its employees on them. Sending e-mails in uppercase letters, attaching unnecessary files, making grammatical and spelling errors, and requesting read receipts frequently are all etiquette policy violations. Consequences for policy violations vary widely by state and by demographic segment. Sample policy guidelines follow (SANS, 2004).

- 1) Office e-mail may not be used for commercial purposes or for personal gain. Distribution of spam or flame e-mails is not tolerated from office computers.
- 2) Confidential and sensitive information should not be sent via e-mail, unless it is encrypted. Because e-mail communication is free and open, anyone can obtain such sensitive information. Encryption makes the message impossible to read if the deciphering key is not available.
- 3) E-mail communications on office systems will be monitored for appropriateness of use.
- 4) Due diligence needs to be practiced while communicating via e-mail; although an e-mail has been deleted by the recipient, it can be retrieved and used against the sender or the workplace.
- 5) Inappropriate and offensive material, which is not suitable for distribution otherwise, should not be transmitted through e-mail. For example, off-color remarks, racist comments, pornographic material, and other unsuitable material should not be sent through office e-mail.
- 6) E-mail communication needs to be concise and work-related. Incidental personal use is only permitted if it does not interfere with office operations.
- 7) E-mail recipients should be limited to only those with a need to know the contents of the communication. Forwarding and copying to everyone in the workplace should be avoided.
- 8) If copyrighted information or trademarks are sent via e-mail, the recipient must have a need to know the information and should be able to securely receive the e-mail.
- 9) Use of office e-mail implies that the sender acts as an agent on behalf of the employer. Appropriateness of tone, style, content, and form of e-mail will ensure that high standards of work and professionalism are maintained.

INSTANT MESSAGING

Instant messaging systems extended the chat service available on time-shared computers to the Internet. IM client programs on users' computers connect to specialized servers that monitor all IM users and maintain buddy lists for each user. America Online (AOL) popularized the IM service with its AIM (AOL Instant Messenger), which is freely available for download from its Web site. IM can be thought of as an online, real-time version of e-mail (Day, Rosenberg, & Sugano, 2000). In today's fast-paced corporate environment, employees do not wish to wait for recipients to check e-mails and then respond; instead, real-time and interactive responses are expected. The use of instant messaging grew exponentially in the late 1990s (Ralston, Reilly, & Hemmendinger, 2003).

Definition of IM

Instant messaging is a type of real-time communication via the Internet that enables a user to create a private chat room with another user (Webopedia, 2004). Whereas e-mail can be compared to postal mail, IM can be compared to a telephone conversation. However, a telephone conversation is voice-based, whereas an IM conversation is largely text-based. The IM system allows a user to create and maintain a buddy list of other users; the system alerts the user when any of the buddies is online. The user is then free to initiate an IM session with the buddy. For IM to work, both users must download and install an IM client, and both users must be logged on to the Internet at the same time.

Brief History of IM

Internet Relay Chat (IRC) was a messaging program invented in 1988 that was IM-like in its functionality. More about IRC can be found in the chapter titled "IRC (Internet Relay Chat)." In November 1996, four Israeli programmers introduced ICQ ("I seek you"), which was a free instant-messaging utility that anyone could use by downloading a client capable of real-time communication (Tyson, 2004). Because of the sense of community it created, online services were popular even before the growth in popularity of the Internet.

America Online, long considered the pioneer of the online community, had provided chat rooms for its users before it introduced AIM, its version of IM services. Although AIM uses proprietary protocols to enable users to IM each other, non-AOL users can talk to AOL users; this explains the dominance of AIM in the IM marketplace. The development of standards and protocol specifications by the Internet Engineering Task Force popularized the use of IM and pushed the technology to the mainstream (Day, Rosenberg, & Sugano, 2000).

The future of instant messaging appears promising because of heightened interest among the business and common user community. Predictions by Gartner that IM use is anticipated to be 60% of all real-time communication in 2004 has resulted in several organizations trying to develop security solutions for IM's loopholes, such as file sharing and transfer vulnerabilities (FaceTime,

2004). Companies have recognized the promise of IM and are planning to deploy the next generation of secure IM products for internal and external communications in the workplace.

Advantages and Features of IM

IM appears attractive to people on projects that require more real-time interaction than e-mail can provide. Employees on team projects need not check their e-mails frequently; instant messaging provides interactive and real-time contact among them (Deutschle, 2003). Synergies of work and a boost in productivity are usually reported when an organization deploys IM. Communicating in real-time streamlines interactions saves time and money. In addition, free IM client software implies reduced licensing and contractual fees for communication. Employee frustration can also be minimized because IM facilitates immediate access to colleagues.

Long-distance telephone bills can be reduced by using IM. Spam can be reduced because the sender and recipient communicate in real time. IM provides an opportunity for employees to hold conferences and chats (IM-Age, 2002). It also speeds up internal and external communications and provides network-independent access to communication. However, several corporations are hesitant to deploy IM because of inadequate security. Corporate policy sometimes may not deter employees from using public domain IM clients without IT approval. This activity may result in inadvertent disclosure of confidential corporate information.

Current IM Systems

Although AIM and ICQ are the leaders in the IM race, other popular IM systems include Microsoft's MSN Messenger and Yahoo! Messenger (YM). Utilities such as Odigo and Omni allow the user to combine multiple IM services in one application (Tyson, 2004). MSN Messenger and YM allow users to talk via IM just like via the telephone, provided both parties have the necessary equipment, such as microphone and speakers, to access the voice feature. Today's IM programs also incorporate file sharing and file transfer capabilities. Mobile devices such as handhelds, tablet personal computers (PCs), and Internet-enabled cellular telephones are capable of communicating via instant messaging systems.

There are two main categories of second-generation secure IM products: (a) IM clients with security features built in and (b) IM management software that can monitor any of the products currently popular among users. Zone Labs' product "Integrity" and IM-Age's "Policy Manager" management solution belong to the latter category. These products do more than secure IM; they handle policy management and provide centralized security (Zone Labs, 2004; IM-Age, 2002). For example, Zonelabs' IM Policy Manager authenticates internal IM users, blocks file transfers, and monitors employee communications. Niksun's "NetDetector" can detect anomalies, reconstruct IM sessions, and archive IM for long-term storage (Niksun, 2002). The diagram in Figure 3, How IM Works, appears in Learnthenet.com and shows an IM system.

Figure 3: How IM works.

Disadvantages and Vulnerabilities of IM

Basic IM is not a secure way to communicate. The content of instant messages and information about user (network) connections are maintained on servers controlled by the IM provider. Although most of the large IM providers offer encryption, user logs have been captured by malicious hackers in the past (Deutschle, 2003). The perception among employers is that IM is uncontrollable; therefore the whole network becomes compromised. Buffer overflow vulnerabilities in IM clients can lead to attacks that result in denial of service and/or execution of arbitrary code. Open ports can be found by hackers via file transfer on IM. Malware can be spread using file sharing and transfer.

Proprietary client software, word limits on messages and sessions, potential for employee misuse, and security concerns have managed to restrain the popularity of IM in the business environment. Because IM does not leave an audit trail, the corporation cannot monitor the conversation. Proprietary consumer products such as MSN Messenger and ICQ are unsuited for enterprises because they allow unencrypted data and bypass the virus protection at the corporate network's gateway servers. The file transfer capability of IM is especially insecure in this regard.

Service providers such as AOL and Sprint have developed separate enterprise versions of their proprietary IM solutions that address corporate security concerns.

Safeguards for IM and Usage Policies

Buffer overflow vulnerabilities found in popular instant messaging applications such as Yahoo! Messenger and AIM serve as a reminder that hackers can take control over other machines for coordinated attacks at a later time (Weber, 2004). Because consumer-level IM programs do not use encryption, these programs cannot be used in corporate environments without modification. IM also allows hackers to become aware of user presence, that is, whether the user is online or offline. Social engineering, which can lead to identity theft, is also common because of poor authentication practices. Security concerns are, therefore, paramount in presence-aware IM environments.

According to security experts, insecure IM is the new target for hackers who seek to steal sensitive corporate information. Firewalls and intrusion detection systems are not useful unless they are integrated with IM-security software (Gaudin, 2002). Employees sending non-corporate information on IM can waste network bandwidth. IM can

also cause easy distraction and loss in productivity. Offensive jokes propagated through IM can lead to harassment suits. Because of legal and ethical ramifications of IM use, an enterprise needs to structure IM use policies and train employees before deploying the IM solution. Sample policies include the following:

- 1) Confidential and sensitive information should not be sent via IM unless it is encrypted. Because IM communication is insecure, anyone can obtain such sensitive information.
- 2) IM communications on office systems will be monitored for appropriateness of use.
- 3) Inappropriate and offensive material, which is not suitable for distribution otherwise, should not be transmitted through IM. For example, off-color remarks, racist comments, pornographic material, and other unsuitable material should not be sent through office IM.
- 4) IM communication needs to be concise and work-related. Incidental personal use is only permitted if it does not interfere with office operations.
- 5) Use of office IM implies that the sender acts as an agent on behalf of the employer. Appropriateness of tone, style, content, and form of IM will ensure that high standards of work and professionalism are maintained.

SECURITY IN E-MAIL AND IM ENVIRONMENTS

Security is a significant area of concern in an e-mail environment because e-mail is the most crucial form of communication medium available on the Internet (Preetham, 2002). To ensure the integrity of e-mail communication, various measures have been implemented. Not caring about e-mail security could result in the sender's identity being compromised, the recipient's identity being compromised, or leakage of sensitive information. If the transfer agent and client of an e-mail system can be secured on the network, the service provider can secure the delivery agent. Encryption software can ensure security on the communication channel. Security measures can also guard against address spoofing and anonymous e-mail.

Features of secure environments include confidentiality of message content, authentication of sender and recipient, and assurance of message integrity (Kurose & Ross, 2003). Public key cryptography (more detail in later chapters, e.g., chapter 67), symmetric key cryptography, digital signatures (chapter 179), message digests (chapter 112), message integrity checks, trusted key distribution, and certificate validating authority are essential to secure all e-mail communication within the environment. Because IM clients are used on mobile handheld devices such as PDAs and cellular telephones in addition to desktop and laptop computers, the security risks are higher because of the inherent vulnerabilities of wireless transmission. The lack of secure environments exacts a productivity and monetary toll.

More detail on public key cryptography can be found in the chapters "Public Key Standards: PKCS (Public-Key Cryptography Standards)," "Public Key Algorithms," "Elliptic Curve Cryptography," "Cryptographic Proto-

cols," "Quantum Cryptography" and "Public Key Standards: SSH (Secure Shell)." Digital signatures can be studied in greater depth in "Digital Signatures and Electronic Signatures" and "Encrypting E-mail." Message digests can be explored in the chapter on "Hashes and Message Digests."

E-Mail Security: Issues and Practices

User awareness and training are probably the most important tools to secure e-mail. Deleting unsolicited messages, not opening suspicious attachments, encrypting sensitive information sent via e-mail, and using spam filters are effective practices for ensuring the security of e-mail communications (Weber, 2004). Corporate policies will not amount to much if users are not trained on implementing the policies and made aware of the consequences of violations. Security-savvy users can thwart social engineering attacks that try to obtain login and password information from them.

Other security measures to follow in an e-mail environment include using proxy servers to forward e-mail to the clients and employing an updated antivirus program to check all incoming and outgoing e-mail. Modern antivirus programs are capable of heuristic analysis of viruses by safely monitoring their behavior under controlled conditions (Sandhu, 2002). Installation of antivirus software must be augmented by prompt updating of virus definitions and patterns; otherwise, the antivirus software will not be effective against newly generated viruses and other malware, such as Trojan horses and worms, which may infect application software.

IM Security: Issues and Practices

Patch management and avoidance of spying software are the first steps in securing IM systems. Antivirus software and intrusion detection and protection programs will limit the security vulnerabilities of IM systems. However, corporate entities can ensure IM security by not allowing their employees to use public domain IM systems such as AIM and YM. Proprietary solutions combined with end-to-end security provide a better defense than freeware.

Solutions such as the Enterprise IM Management Suite from FaceTime Communications, Inc., have managed to allay the fears of some corporate IT departments regarding the use of IM among employees. These providers claim that viruses sent through IM will be detected, unintentional transmission of sensitive information will be controlled, and the IM security solution will be integrated with preexisting antispam, content scanning, and encryption programs (FaceTime, 2004). For example, if unauthorized IM or P2P (peer-to-peer) connections are detected, they are blocked and logged.

Realizing that the corporate environment was not ready to accept insecure IM systems, service providers such as AOL and Sprint developed enterprise versions of their IM clients, specifically tightening or adding security features. AOL's Enterprise AIM service allows system administrators to manage IM use from behind the corporate firewall (Deutsche, 2003). Although the security features come at a steeper price than the virtually free consumer-end versions, companies are expected to invest

in IM's long-term advantages. Other security-hardened IM products include IBM's Lotus Sametime and Bantu's Presence Platform. An encrypted version of Sametime is used by the U.S. military and some academic institutions.

Security providers such as Zone Labs have developed management platforms for securing IM in the enterprise. Zone Labs' product, IMsecure Pro, is advertised as ensuring privacy for IM communications (Zone Labs, 2004). This program is independent of the IM client and can execute equally well on AIM, MSN Messenger, and YM. According to Zone Labs, this product is compatible with its firewall product, so both can be integrated to form an end-to-end solution. Featuring IM encryption, spam blocking, password protection, and security logging, this product is geared toward the security-conscious corporate marketplace. Other vendors such as IM-Age and Niksun have also developed secure IM products or IM management software.

CONCLUSION

E-mail has become one of the primary means of communication for people today (Tyson, 2004). E-mail clients that allow users to send, receive, and manage their messages evolved from different formats and storage systems. E-mail clients differ in how they track e-mail and where they store archived data (Nelson, Phillips, Enginger, Steuat, 2004). Hence, no single security solution can be provided for their varying vulnerabilities and differing reactions to threats.

Because of its ubiquitous nature, several viruses now use e-mail as a distribution and reproduction mechanism because of its potential for rapid, worldwide spread. Security concerns must be weighed critically before sending confidential data through the system. Behavior-based monitoring of virus activity, integrity checks, detection of changes in content and sources and destinations of e-mail, signature-based searches, and heuristic, real-time scanning can mitigate security risks (Slade, 2004).

The Gartner Group, in October 2001, opined that IM, like e-mail, could cause a company to operate as a real-time enterprise if it is properly managed and integrated into the underlying infrastructure. Today, IM is being used by more than 210 million people; 10% are using IM at workplaces (Goldsborough, 2004). Although IM is perceived to be ephemeral, every message can be stored by the service provider or the organization. These archives can be monitored and even used in evidence. Hence, it is prudent to exercise care in sending e-mail and IM messages.

GLOSSARY

Antivirus Software Software programs that detect and eliminate viruses, worms, Trojan horses, and other malware.

Authentication The process of ensuring that the individual is who she says she is.

Confidentiality The act of keeping sensitive information secretive.

Demilitarized Zone (DMZ) A computer or a subnet-

work that is installed between a trusted internal network and an untrusted external network.

Digital Certificate An attachment to an e-mail used for security purposes such as verifying the sender's identity to the receiver.

E-mail An asynchronous communication tool analogous to postal mail; it is used to transmit messages via the Internet.

Encryption The process of translating data into a secret code; it is the most effective way to achieve data confidentiality.

Filter Software or hardware that monitors and blocks incoming and outgoing e-mail traffic.

Firewall Hardware and/or software designed to prevent unauthorized access to or from a private network.

Instant Messaging An interactive, synchronous tool for engaging in real-time communication via the Internet.

Intrusion Detection System A system that inspects all inbound and outbound network activity to identify suspicious patterns that may indicate an attack.

Malware and Spyware Malicious software designed to damage a system. Spyware is software that gathers user information through the Internet connection without his or her knowledge, usually for advertising purposes.

Message Integrity This refers to the validity of e-mail transmissions.

Nonrepudiation When the recipient of a communication has the ability to ensure that the sender is unable to deny the sending of the message or the authenticity of its signature on the communication.

Patch Management Process of updating and managing patches and temporary fixes on a frequent and regular basis so as to remain current on the latest updates of the software.

Proxy Server A server that sits between a client application and another server; it intercepts all requests to the actual server. Proxy servers improve efficiency and filter harmful traffic.

Spam Electronic junk mail or unsolicited, targeted advertisement via e-mail.

Use Policies Policies regarding employee use of organization-owned computers for e-mail and IM.

Virtual Private Networks A private network developed by using public wires to connect nodes. A virtual private network employs encryption and other security mechanisms, thus ensuring that corporate data is safe traveling on the public Internet.

Viruses, Worms, and Trojan Horses Malicious software that infect a host computer, then replicate and spread to other computers via the network to cause more damage.

Vulnerabilities and Threat Assessment A process of proactively identifying vulnerabilities (weaknesses) in computers of a network to determine if and where a system can be exploited and/or threatened (attacked).

SECURE COMMUNICATION USING INTERNET RELAY CHAT

Defining Statement

Internet Relay Chat (IRC) is a worldwide system of synchronous, text-based conferencing on the Internet. IRC was the first online chat system to achieve widespread adoption, and despite the increasing popularity of Web-based chat rooms and instant messaging systems, it continues to be the synchronous medium of choice for many Internet users. Numerous sites on the World Wide Web contain IRC tutorials, network information, and software downloads. Because IRC is based on a client-server networking model, users simply install client software on their local computer and access the Internet to create a new channel (chat group) or join an existing channel. Using established network protocols, messages travel from an individual's computer to an IRC server, and then are relayed through other servers if necessary before being delivered to the designated recipient(s). IRC supports private, one-on-one conversations (analogous to real-time e-mail) as well as the simultaneous distribution of messages to all users in the channel (analogous to a real-time Listserv or newsgroup). Interactions on IRC channels involve users from all over the world, take place in many different languages, and focus on a wide range of topics. Most interactions on IRC are casual and "chatty" in nature, but sometimes they involve specific personal, academic, or organizational communication objectives. At any given moment, tens of thousands of IRC users are conversing about sports, science, technology, academics, news, recreation, and entertainment, as well as engaging in spontaneous personal and social interaction.

Historical Development

After the earliest experiments in real-time chat systems in the 1960s and 1970s, IRC was created in 1988 by Jarkko Oikarinen, an engineering student at the University of

Oulu, Finland. By extending the features of an early UNIX-based function called Talk, Oikarinen's innovative technology allowed multiple users at different geographical locations to enter designated channels and engage in synchronous, online discussion. By 1990, the system had expanded to include 38 IRC servers located at universities in Scandinavia and the United States (Hamman, 1999). IRC gained notoriety as a strategic global communication system in 1991, when real-time messages were received from IRC users inside Kuwait during Iraqi occupation. In 1993, IRC enabled computer users in Moscow to communicate with outsiders during the uprising against President Yeltsin. Following the terrorist attacks in New York and Washington, D.C., in September 2001, IRC networks became extremely active, initially to support communication with survivors and rescue workers, and later to allow users from around the globe to vent their feelings, rally support for victims, and engage in political and ideological debate. When other communication systems failed or became congested during these international crises, computer users with access to the Internet used IRC for up-to-the-minute interaction with external parties.

In recent years, rapid growth in the number of individuals with Internet access has contributed to rapid growth in the use of IRC. At the beginning of the 21st century, hundreds of thousands of users were communicating via IRC networks. Charalabidis (2000) reported that the total number of IRC users was increasing as much as 30% annually, and that the largest IRC networks had tens of thousands of channels and sometimes experienced more than 50,000 simultaneous connections. Although many Web users gravitate to popular, easy-to-use messaging systems such as ICQ ("I Seek You") and Instant Messenger, IRC continues to appeal to the more technology-oriented specialist. In fact, "newbies" (newcomers) may find the IRC communication climate to be unfriendly or hard to understand at first. IRC commands and interfaces are not especially complicated, but casual Web users are often more accustomed to the very simple interfaces of

browser-based Web chat systems. Furthermore, experienced users on some networks adopt an exclusivist attitude by refusing to communicate with newbies, or by using vague or highly specialized jargon that is unintelligible to outsiders. On these networks, newcomers are more likely to obtain advice and direction from channels devoted to IRC help.

STRUCTURE AND OPERATION

Infrastructure

Because IRC works on the client-server networking model, the IRC server is the central point of communication through which all messages pass en route to individual client computers. In the simplest IRC network structure, the computer of each user runs a client program to connect to a common server. The server runs an application called an IRC daemon (ircd), which allows connections from individual users and relays messages from one client to another by passing them through the server. Some IRC chat systems consist of a simple network in which a single server manages connections and communications among all its clients. However, most IRC servers are connected to other IRC servers, thus opening the IRC system to potential communication among all users with connections to all the servers on the network. Originally, there was only one IRC network, consisting of a few servers, but as IRC grew in popularity and complexity, it splintered into multiple networks. Today, there are hundreds of IRC networks that are constantly evolving through expansion and redefinition. They range in size from very small, family-oriented chat networks to global networks such as EFnet or the expansive IRCnet, which links more than 100 servers and supports thousands of chat groups, or channels (see Table 1). Channel names are fairly stable, but channel topics change regularly, and the announced topic frequently bears no relation to the conversation actually occurring on the channel.

To engage in IRC, users select an IRC network and connect to one of the available servers, using a nickname (e.g., *SuperTig*) rather than their real name. Using the `/list` command, users can consult a list of public channels currently available on that server. The channels listed as `#channelname` are global and can be accessed through any server on the network; channels listed as `&channelname` are available through that server alone. Some channels are

designated “secret” and not open to others. By entering the command `/join #channelname`, users join a channel and usually receive the MOTD (message of the day) containing some basic information from the server’s database about current activity on the channel (topic, nicknames of current users, etc.). The new user is then ready to communicate with others by sending a message that will appear more-or-less synchronously on the screens of all channel participants (see Figure 1). Newbies can usually find help on the channel `#irchelp`, and other help channels may be listed in the MOTD. The command `/leave` or `/part` will terminate the connection to the channel, and the command `/quit` will terminate the connection to the network. In reality, connecting to an IRC server is not always simple, especially for newcomers. Connection may be prevented if the user enters an incorrect server name, chooses an unacceptable nickname, or has been *K-lined* (specifically banned from the server for some reason). Users who connect to the Internet through large, popular ISPs (Internet service providers) may find some channels closed to them, based on the stereotype that such subscribers are probably newbies and therefore unwelcome on certain channels.

When using text-based IRC client software such as ircII, users manually enter commands in the typical command-line format familiar to UNIX users. When using graphical interface client software such as mIRC and Ircl, users click the mouse on an icon to generate the same result. Because the original IRC source code was not copyrighted, some networks have developed proprietary functions and features unique to their IRC system. The result is that all commands are not standardized across all IRC networks. Most of the basic commands are recognized by all IRC servers, however, and users who frequent a network typically learn specialized commands quickly through observation and by inquiring on a channel devoted to IRC help.

Although most users connect through IRC servers, the major IRC client programs also allow a direct client connection (DCC). Two clients who are connected to the same IRC network can initiate a direct connection between themselves. IP (Internet protocol) addresses are typically used to establish the DCC connection, and messages or shared files pass directly from one client to the other without being relayed by the IRC server. Many of the more experienced users prefer to use DCC for their one-on-one interactions and file transfers, because DCC frequently results in faster message exchange, a higher degree of privacy, and avoidance of network problems such as lags and netsplits. Netsplits occur when one or more servers are disconnected from the network.

IRC networks are not immune to problems of congestion or breakdown. As with all other packet-switching Internet communication systems, users sometimes experience delays in the transmission of electronic messages. This delay (known to IRC users as “lag”) is irritating to all Internet users, but it is especially problematic in synchronous communication systems characterized by real-time interaction. A 10-second lag can dramatically change the timing and effectiveness of some types of online interaction, as threads of conversation become entangled and users appear to be “talking over” one another. The jumble

Table 1 Some of the Largest IRC Networks

	Number of Servers	Help Site and Server List
Efnet	40	http://efnet.org
IRCnet	>120	http://www.ircnet.com
DALnet	30	http://www.dal.net

GalaxyNet	30	http://www.galaxy.net
WebNet	15	http://www.webchat.org
NewNet	15	http://www.newnet.net
ChatNet	15	http://www.chatnet.com

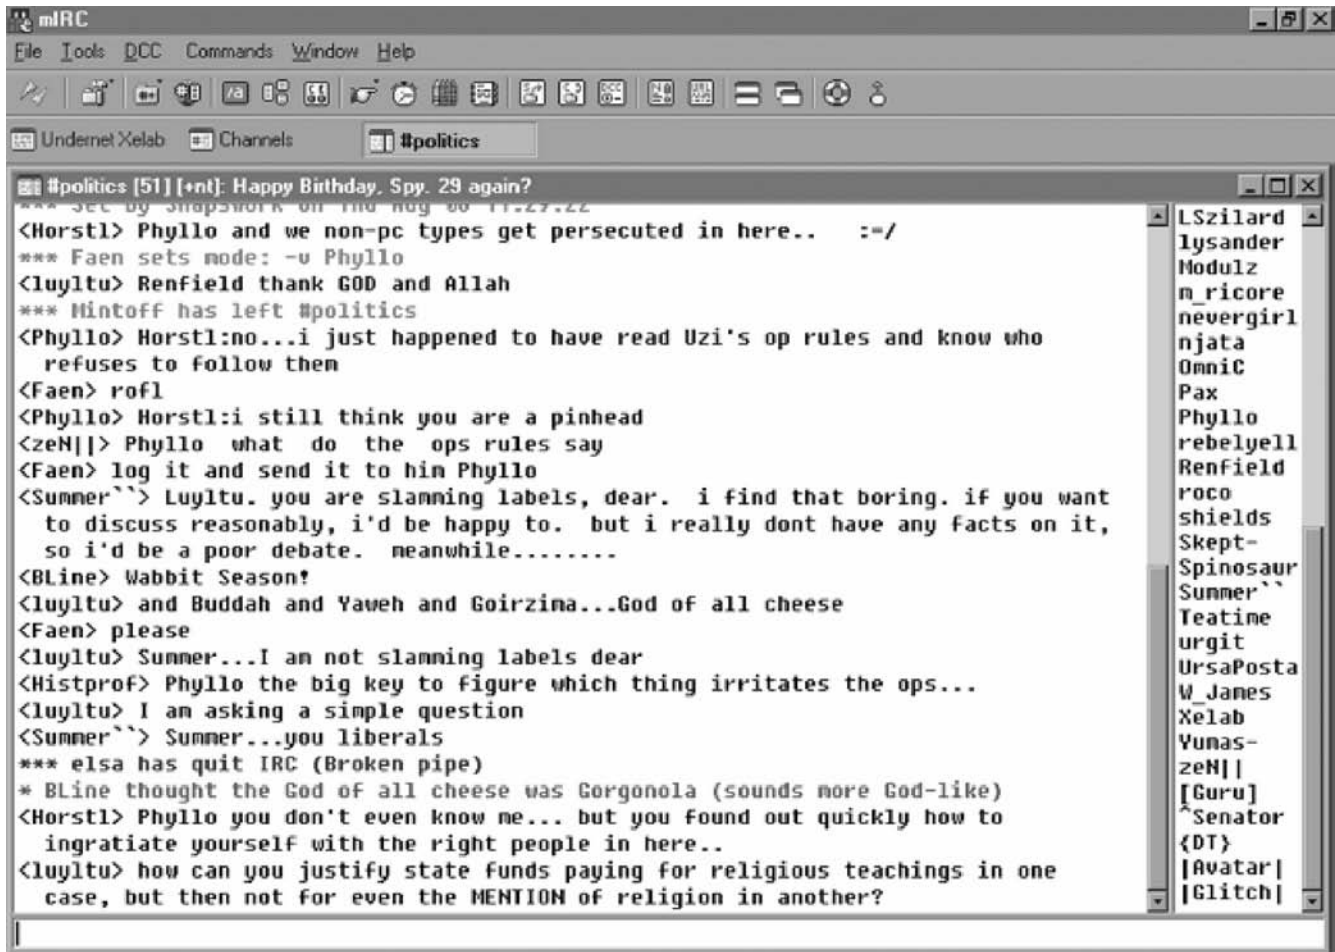

Figure 1: Screenshot of online interaction using mIRC.

of multiple conversations is a common characteristic of interaction on public IRC channels (Herring, 1999a), and lag serves to exacerbate the problem. Increased lag may be caused by heavy traffic on the Internet or IRC network, a malfunctioning server, flooding, or a denial of service attack (see following sections). Lag is sometimes related to a netsplit, which occurs when one or more IRC servers lose their connection to the network. Netsplits fracture the network and effectively create separate network fragments that may or may not continue to operate separately. Netsplits often result in a buildup of packets queued for delivery to servers that are no longer available. After a netsplit, servers sometimes reconnect to the network and are able to update the server with activity that occurred during the netsplit. Sometimes a netsplit results when an IRC operator revises the network connection to other servers to achieve a more efficient or more desirable network configuration.

Software

To engage in online communication using IRC, users need access to the Internet through an ISP or direct network connection. They must also install a communications software program called an IRC client. The client software serves as the interface between the individual computer

(the client) and the IRC server (serving the needs of multiple clients). The IRC client processes the commands that are typed or clicked by the user and then employs network protocols, such as TCP/IP (transfer control protocol/Internet protocol) to transmit them to the server.

IRC supports communication across different operating platforms, enabling the flow of messages between PC and Macintosh computers, as well as UNIX-based computing systems. IRC clients for these and other operating systems are readily available, and free downloads or demonstration copies can be found on most of the major FTP (file transfer protocol) sites on the Internet. Some IRC clients are available as shareware, meaning that if users wish to continue using it after a free trial period, they are asked to purchase the software or pay a modest registration fee. Generally, the cost of IRC client software is quite reasonable.

Text-Based IRC Clients. Early IRC users were almost exclusively UNIX-based, and the majority of today's IRC servers are UNIX servers. Individual computer users who use a terminal emulation program to establish a dial-in connection to an organization for Internet access effectively turn their computer into a terminal by use of a shell account on the UNIX system. The most common IRC client for UNIX and related systems (such as

shell accounts and Linux) is ircII. This full-featured, text-based client was the first widely used IRC client and still serves as a reference standard for essential commands and functions. More advanced users sometimes use ircII's scripting language to create scripts that streamline complex processes, generate customized output, or perform certain functions automatically when prescribed conditions occur.

Graphical Interface IRC Clients. The majority of online communicators connect to the Internet through Windows-based PCs or Macintosh computers. IRC clients have been developed for both platforms, offering the point-and-click ease of use characteristic of graphical user interfaces (GUIs). The major GUI clients receive ongoing attention from their developers, and excellent support is available for learners. The client of choice for many PC users employing Windows operating systems is mIRC, a powerful, intuitive, and reliable application. Because PC users outnumber those on UNIX and Macintosh platforms, mIRC is probably the most widely used IRC client on the Internet today. Easy-to-use menus and buttons, customizable functions, and extensive user support contribute to the popularity of mIRC (see Figure 1). The most widely used IRC client for Macintosh computers is Ircle. A stable, full-featured IRC client, Ircle provides buttons, menus, and icons to facilitate common IRC functions. Ircle users may also employ AppleScript to modify the client to their custom specifications. Good user support and innovative features place IRC interactions within easy reach even for beginning Ircle users.

Users

The IRC system hierarchy of networks, servers, channels, and clients is reflected in an administrative hierarchy of people who oversee each level of the system. End users who direct their IRC client to connect to a network should be aware of the scope of authority and control exerted by IRC operators and channel operators. Newbies sometimes embarrass themselves and irritate others by inappropriately posing questions or filing complaints with the person they perceive to be in charge of a channel or server.

IRCCops. IRC operators generally oversee the operation of an IRC server, maintain routing functions in relation to other servers on the network, modify server settings, and monitor general activity on the server. Sometimes the original server administrator fulfills the role of IRCCop, and sometimes the administrator selects one or more experienced and qualified users to serve as IRCCop. Servers typically have more than one operator, to ensure constant observation of activity on the server. In the event of a server failure or network fault, IRCCops work to restore network connections. They also enforce the policies and procedures of the server they oversee. If a user violates policy or misbehaves in some way, the IRCCop usually issues a warning. Users who are reprimanded by an IRCCop are sometimes unaware of the power the operator has to control activity on the server. For example, an IRCCop can issue a `/kill` command that effectively bans the offending user from further access to the server and, in some

cases, the entire network. Determining the identity of a server's IRCCops is not always easy. When they are listed in the MOTD (message of the day) or active user lists, their "user mask" (nickname plus host name) is usually marked with an asterisk (**Stinkbug!skb220@rhl.net*). The command `/stats o` may be used to identify active operators, and some IRC clients support the command `/who -oper`. Many IRC users never have direct communication with an IRC operator unless their activity on the server violates accepted practice and attracts the operator's attention. IRC operators do not exert control over channel activities; they leave those functions to the channel operators.

Chanops. Each IRC channel (chat group) is initiated or overseen by a channel operator, or chanop. Channel operators exert management and control over the channel's topic, mode, and settings, and they regulate how many users and specifically which users are allowed to interact on the channel. If users misbehave, become obnoxious, or irritate the channel operator, most chanops do not hesitate to ban them from the channel. Any user may become a chanop by creating a new channel or by being given operator status by a chanop on an existing channel, so it is not uncommon for chanops to misbehave as well (Herring, 1999b). Chanop status is valid only for the duration of the current IRC session, and when chanops leave the channel, they ordinarily lose their operator status. However, if operators are registered as super-ops with an IRC channel service, they can effectively maintain control over a channel even during their absence. Many IRC channels have several operators active at any given time, but occasionally a channel may function without an operator at all. Channel operators are usually identified with an @ sign before their nickname (*@SuperTig*). Most IRC clients support the command `/who -chops` as a means of identifying channel operators.

Chanops can remove users from a channel and ban them from future access. On password-protected channels, they can invite users to join and can issue them the key to enter. On moderated channels, chanops can give selected users a voice that allows them to post messages to the channel while other users can only receive messages. Channel operators can grant chanop status to other users, and they can remove chanop status from other operators. Any IRC user who creates a new channel with the `/join #channelname` command automatically becomes the operator for that channel. When a new channel is created, some basic channel modes and settings should immediately be set to establish guidelines for the activity allowed by users and operators on the channel.

Users. Users get to choose their nicknames and can use them as long as they are the first to log into a channel with that nickname. If someone else is using it, then users can either choose another nickname or ask the incumbent user to give it up. If the incumbent user refuses, then the user is best advised to choose another nickname. This same etiquette applied when there was a universal nickname registry for IRC called "NickServ," a service operated in Germany until it discontinued in 1994. There is no evidence that NickServ will resume IRC nickname registration operations.

Table 2 Basic User Commands

<code>/join #channelname</code>	Joins the user to a global channel on the network, unless the user is banned or the channel is restricted (invite-only, secret, etc.)
<code>/join #channel1,#channel2</code>	Allows the user to simultaneously participate in both of the channels listed
<code>/mode MyNickname + i</code>	Sets the mode of the user "MyNickname" to invisible, enhancing privacy and security
<code>/list</code>	Produces a list of channels on the server; often used with various flags and parameters
<code>/set hold_mode on</code>	Prevents a long list from scrolling beyond the monitor's limits
<code>/names</code>	Shows a list of nicknames of users currently on the network (potentially a huge listing, so always use parameters)
<code>/names #channelname</code>	Shows a list of nicknames of users currently on the channel (also very large on some channels, so use parameters)
<code>/who #channelname</code>	Lists nicknames, usermasks, and other information about current users on a channel
<code>/whois NewName</code>	Produces basic information from the server's database about the user "NewName"
<code>/msg NewName</code>	Sends a private message to the user NewName; messages to all users are entered without the <code>/msg</code> command
<code>/dcc chat NewName</code>	Requests Direct Client Connection with the user "NewName"; if NewName accepts, a direct private chat will bypass the IRC server (may be more private, less lag)
<code>/nick othername</code>	Changes a user's nickname to the one specified
<code>/ignore badguy</code>	Blocks or ignores messages from user called "badguy"
<code>/part</code> or <code>/leave</code>	Signs a user off of a channel, may be followed by a parting comment
<code>/quit</code>	Terminates connection to the network, may include a brief comment

Commands

Table 2 contains a sampling of user commands commonly employed across different IRC clients and servers. Users of text-based clients enter these commands manually, whereas users of GUI clients usually click on icons or drop-down menus to engage the function, and the client automatically generates the command. Some commands contain specific parameters or are qualified by "flags" that set the limits of the command output. Table 3 contains the most common commands used by channel operators.

SOCIAL FACTORS

IRC and Online Community

As with all online communication systems, IRC is more than a network of computers relaying electronic files among themselves. Fundamentally, IRC systems are composed of humans who utilize the computer network to exchange information or conversation with others. As a somewhat specialized online community, IRC has drawn those who are more technically proficient, whose computer skills enable them to easily perform such tasks

Table 3 Basic Channel Operator Commands

<code>/join #NewChannel</code>	Creates a new channel with the specified name
<code>/mode #NewChannel +o l m v t</code>	Sets the channel modes to Operator (chanop status can be assigned or removed), Limit (limits the number of users allowed at one time), Moderated (all users receive, but only some can post messages), Voice (grants selected users the ability to post messages), and Topic (set by operators only); several other modes are available
<code>/mode #NewChannel</code>	Reveals all the current mode settings for the channel
<code>/mode #NewChannel +o mybuddy</code>	Gives the user "mybuddy" operator status
<code>/mode #NewChannel -o mybuddy</code>	Removes chanop status from the user "mybuddy"
<code>/mode #NewChannel +l 20</code>	Limits the number of users on NewChannel to 20
<code>/mode #NewChannel -l</code>	Removes the limit on number of users
<code>/mode #NewChannel +v angelbaby</code>	Allows the user "angelbaby" to post messages to NewChannel
<code>/topic #NewChannel IRC clients</code>	Changes channel topic to "IRC clients"
<code>/kick #NewChannel satanson</code>	Kicks the user "satanson" off the channel
<code>/invite mybuddy #NewChannel</code>	Invites the user "mybuddy" to join NewChannel

as the following: downloading and installing software from an FTP site; learning intuitively the features and functions of new software applications; using line commands, scripting, or hand coding to accomplish tasks; adapting to the specific styles and conventions of online communication forums; and maintaining sufficient safeguards to protect their personal privacy and system security.

Many individuals "meet" regularly on IRC channels where, in much the same way as with instant messaging and Web chat, they develop close relationships and a true sense of community. On some channels, the basis for commonality is the agreed-upon topic (such as advanced applications of certain software), and participants willingly share techniques and resources in mutual support of one another. Other channels are predominantly social in nature, marked by spontaneous, casual conversation. In both types of IRC communities, casual, online acquaintances are the norm, but significant one-on-one relationships sometimes develop. There are reports of IRC users who decided to move their relationships offline and meet face to face, and some have become business partners or marriage partners (e.g., Hoff & Hoff, n.d.) Of course, the majority of IRC relationships are restricted to the online context, but they constitute legitimate relationships that fill meaningful social roles for many users. Friends made on IRC are not only "virtual" friends but also "real" friends.

Communication researchers study the social, relational, and communicative dynamics of online communication forums such as IRC. Overall, these studies indicate that computer-mediated communication systems do support the development of meaningful relationships, effective decision-making groups, and a legitimate sense of community (Finholt, Sproull, & Kiesler, 1990; Reid, 1991; Walther, 1996, 1997; Wood & Smith, 2001). Nevertheless, research has also identified some important differences between face-to-face and online communication. For example, in face-to-face interactions, people normally communicate interpersonal liking through such nonverbal cues as eye contact, smiles, proximity, touch, open body positioning, and vocal expressiveness (Richmond & McCroskey, 1999). Because the usual nonverbal behaviors are absent in the online context, a greater responsibility is placed on verbal messages for feedback, affect, and nuances of meaning. Typically, IRC users attempt to replace nonverbal messages through various means (Werry, 1996), such as using acronyms like IMHO ("in my humble opinion") and LOL ("laughing out loud"), or by inserting affect cues <grin>, demonstrative punctuation (no!!!!!!!!!!), or emoticons such as the smiley face :-) and its many variant forms. The absence of nonverbal communication cues led some early researchers to judge online communication as incapable of conveying subtle relational messages and therefore an unsatisfactory medium for meaningful interpersonal exchange (Kiesler, Siegel, & McGuire, 1984). However, in the intervening years, online skills have improved and online communication norms have evolved, with the result that modern communicators routinely use IRC and other computer-mediated communication systems to engage in effective and meaningful interaction of all types.

IRC and Relationship Development

As IRC users employ new communication strategies, they sometimes find relationship opportunities in the online community that do not exist for them in face-to-face contexts. For example, research has shown that the decision to initiate face-to-face interaction with someone may be directly or indirectly affected by the other person's physical appearance, nonverbal behaviors, vocal attributes, age, gender, or ethnicity (Berscheid & Walster, 1978). It may seem unkind or unfair, but people often choose whether or not to interact with others on the basis of these traits. When people go online to engage in conversation on IRC or Web chat, however, these physical characteristics are obviously not visible. Many users choose a nickname that is not gender-specific and avoid revealing details of personal identity when queried for their "ASL" (age, sex, location). Because physical attraction is a less influential factor in computer-mediated communication than in face-to-face interaction, unattractive people can relate as equals with the beautiful and handsome; those with vocal or speech problems can engage in fluent expression; those who painfully experience bias or discrimination in face-to-face encounters may confidently enter chat groups as social equals, perhaps for the first time in their lives.

Therefore, computer-mediated communication systems may actually enhance the potential for long-term relationship development by expanding the ways interpersonal relationships develop. An example is seen in the "matching hypothesis" (Walster, Walster, & Berscheid, 1978), which theorizes that people usually date and marry someone with approximately the same physical attributes as themselves (e.g., both are attractive or both are plain in appearance). By contrast, couples who first met on IRC may vary considerably in physical attractiveness. Online relationships can deepen over time through self-disclosure, empathic "listening," and progressively more intimate communication. When existing online relationships are moved offline for face-to-face meetings, differences in physical appearance may seem relatively unimportant in comparison with the many points of commonality already discovered. In such cases, IRC may provide a more just and balanced communication context than traditional meeting places.

Anonymity and Virtual Identity

The relative anonymity that enhances relationship development on IRC might also introduce an element of deception. Obviously, users may project a virtual identity very different from their true identity. Their intent in doing so might be harmless and recreational, or it might be deceptive and dangerous (Donath, 1999). IRC, like all online communication systems, occasionally draws users who are malicious, misleading, or mentally unstable. For example, pedophiles frequently pose as youngsters in forums frequented by children, hoping that a child will trust them with information or engage in conversation with them. According to accounts in the popular press, some long-term relationships that seemed healthy and secure online turned out to be dangerous when the couple met face to face, because one of the parties had been projecting a virtual identity to conceal unwholesome motives.

SECURITY AND LEGAL ISSUES

Hate and Harassment on IRC

The anonymous nature of online communication systems such as IRC may contribute to the use of aggressive or inflammatory verbal abuse in the form of harassment or hate speech. Most IRC interactions involve the use of nicknames only, and users rarely reveal their true identities. This anonymity may contribute to a perception of low accountability, with the result that some IRC users may verbally lash out against individuals or groups in ways that are offensive and illegal. For example, Herring (2002, 2003) documented instances of flagrant sexual harassment on IRC and posited that male-dominated online environments are often hostile to participants whom they perceive to be female.

For American citizens, First Amendment (free speech) privileges extend to IRC interactions, but so do criminal laws preventing hate speech, inciting violence, and stalking. U.S. federal laws expressly forbid cyberstalking and online harassment (Executive Order 13133, Unlawful Conduct Using the Internet), which occur when a user annoys, abuses, threatens, or repeatedly initiates unwanted communication with another. Responsible channel operators seek to eliminate such activity on IRC by banning the offending user and, if necessary, reporting them to legal authorities. Occasionally, however, chanops themselves engage in unethical communication behaviors (Herring, 1999b). IRC communications are subject to surveillance by law enforcement authorities acting pursuant to lawful court orders. IRC service providers, including operators, are required by law to cooperate with law enforcement authorities to effectuate the surveillance. Of course, many IRC participants are not U.S. citizens and not constrained by American laws, which points to the ethical and legal complexities of global communication networks.

Children and IRC

Although a significant percentage of overall Internet users are under the age of 18, the percentage of minors on IRC may be relatively smaller. In truth, IRC is not especially suited to the needs and concerns of children. The more widely known Web-based chat systems maintain terms of service that restrict certain activities and topics of discussion. Offenders in these chat rooms can be quickly and effectively removed by administrators. IRC channels, on the other hand, are generally not restricted, and people may talk about anything they choose. It is not infrequent to encounter adult conversations and offensive language on IRC that would be unsuitable for children. On moderated channels, chanops can always remove a user's "voice" and disable the offender's ability to contribute to further discourse, but such censorial functions are not characteristic of most IRC channels. IRC is perceived by many to be spontaneous, free-wheeling, unrestricted, and unpredictable—a kind of "wild West" communication context.

In carefully controlled and appropriate IRC channels, children may benefit from online conversation with other children from around the world, with teachers and classmates, and with extended family members or parents who

are traveling. Unsupervised, however, children on IRC may encounter such risks as cyberstalking, which could possibly lead to physical stalking if the child reveals personal information; offensive and harmful conversations with unwholesome characters such as pedophiles; and exposure to sexual content, viruses, or other harmful material if the child accepts a file transfer from an unknown IRC user. Numerous laws and regulations exist to protect minors on the Internet, and responsible IRC users should immediately report any suspicious activity involving a minor on IRC. Since 1997, the FBI has vigorously investigated and prosecuted online pedophiles and stalkers of children through its "Innocent Images" program. Agents go online and pose as children to attract the attention of these criminals. Once these criminals make their moves on what they think are vulnerable children, they are arrested and brought to justice. The program has already produced several hundred convictions.

Scripts and Viruses

Informed IRC users are aware of the many risks involved with file transfers, through both hard media and the Internet. When users install new software, download Web pages, or receive files from external sources through either networking or hard media such as disks or compact discs (CDs), some degree of security risk is introduced. It is a rare occurrence, but even respected commercial software has been distributed with inadvertent flaws that damage systems. More common is the intentional or unintentional passing of a virus or harmful script from user to user through various Internet connections, including IRC. Responsible users minimize these risks by maintaining awareness of current security threats, practicing discretion when networking, and taking steps to keep applications and operating systems up to date.

Most viruses are in .exe or .ini files, but they can also be concealed in zipped files or embedded in completely unrelated files such as .jpg or .gif files. When launched by an unsuspecting user, viruses can cause irreparable harm to individual computers and potentially spread throughout entire systems. Some viruses are not destructive but merely irritating, such as those with pop-up messages of a humorous or salacious nature. Others may disable or destroy hard drives, data files, operating systems, and peripheral components or create havoc throughout entire networks.

People who share word processing files, script files, graphics, or other types of files on IRC may potentially be spreading viruses, Trojans, or worms. Trojans (or Trojan horses) are spread by users who transfer seemingly benign files that contain harmful concealed code. Worms are viruses that propagate themselves and migrate from one application to another within a computer, and from one computer to another within a network.

Scripts represent another source of external control and increased security risk. Scripts are files containing macros (or mini-programs) that enable an application to combine or automate various functions. IRC users have created scripts for such tasks as completing nicknames from typed initials, automatically performing ping operations, generating automated "away" responses, and

customizing the output of IRC interactions. Some early IRC users enhanced the function of their IRC clients by writing scripts that have subsequently been incorporated into more recent versions of the software. Within the IRC community, techniques of scriptwriting constitute a frequent topic of conversation, and the sharing of scripts among users is relatively common. A number of Web sites or FTP download sites serve as archives or clearing houses for the open sharing of scripts and script paks (sets of coordinated scripts) for various IRC clients. When an IRC user downloads a script file from an archive or another user, however, there is always risk that the file may contain concealed or deceptive code that may launch unexpected or harmful functions in the receiver's system.

Most IRC clients include options to limit or disable the automatic or unintentional running of scripts, just as the major Web browsers include settings to control scripting functions encountered on the World Wide Web. Because harmful functions can be inserted into otherwise legitimate scripts, cautious IRC users run scripts only after proofreading every line of the code. Safe practice also calls for the careful screening of IRC users before accepting from them any files of any type. Common practice states that files should never be accepted from an unknown person, and file transfers from known parties should always be scanned for viruses before being opened.

Mischief and Sabotage on IRC

Many people use IRC safely and never experience viruses, takeovers, or threats to their security. It is not uncommon, however, to encounter less serious offenses allegedly launched by mischievous youngsters known as "script kiddies." (For a more serious perspective on "script kiddies," see Gilboa, 1996.) Anyone who has been on IRC very long has probably observed attempts by an aggressive user to take charge of a channel or disrupt the flow of messages on a channel or network. "Channel taking" may be accomplished if a user is granted chanop status or deceptively uses an operator's nickname, then "de-ops" the other operators and indiscriminately bans users, kicks them off the channel, or silences their voices by turning the channel into a moderated one. Sometimes malicious users simultaneously send multiple files to another user, a practice known as "flooding." If practiced on a large scale, flooding can significantly increase lag on a channel or entire network. Most IRC clients include optional settings that limit flooding to that client.

A more serious form of sabotage exists in denial of service (DoS) attacks, which involve harmful data packets that sneak through loopholes in an operating system's security and launch erroneous messages from or to the client. DoS attacks, sometimes called "nukes," are against the law and can cause the host to disconnect from the Internet, freeze, or crash entirely. IRC can be exploited to facilitate a DoS attack by sending scripts called "bots" to unsuspecting users. Bots use vulnerabilities in the operating system to initiate the attack simultaneously from multiple computers. Engaging in such destructive practices violates federal law, specifically the Computer Fraud and Abuse Act (18 U.S.C. § 1030), as well as many state

statutes. As a result of these laws, even first-time offenders can get jail time and stiff fines.

Because internal security is especially critical to certain types of organizations, some companies or institutions have restricted the use of IRC and other Internet functions through the use of firewalls that prohibit any computer in their network from connecting to an IRC server. For any IRC user, whether institutional or private, the best defense against mischief and sabotage is to refuse to accept file transfers or DCC chat requests from unknown individuals, to carefully peruse every line of script code before launching it, and to maintain updated security files for operating systems, IRC clients, and virus protection software.

Ensuring Privacy and Security

All Internet users should take three basic steps to maximize privacy and security when connecting to IRC, the World Wide Web, or any other online communication network. First, the user's operating system should be kept current by logging onto the publisher's Web site (e.g., <http://www.windowsupdate.com>), scanning for updates, and downloading and installing modifications as advised by the publisher. Such updates are usually free and consist of security patches (minor adjustments that close potential breaches) or more substantial service packs that modify file architecture or essential processes. Failure to keep the operating system current could expose the host computer to intrusion, including unauthorized access to the data it contains or the takeover of the computer to launch denial of service attacks.

Second, users should install and continuously run a firewall to protect the host computer from unauthorized intrusion while connected to IRC or other parts of the Internet. A firewall is software that provides an intrusion detection system to manage and monitor the ports or connection points between the host computer and the Internet. Although some firewalls can be found on the Internet and downloaded for free, many users prefer to purchase full-featured programs from well-known software publishers, thus entrusting their system's security to major players in the Internet security marketplace. The routine use of a firewall is important for all users but absolutely essential for those who maintain continuous connection to the Internet (e.g., through cable or DSL connections). A continuous Internet presence provides potential hackers with uninterrupted access to probe the host computer's ports in hopes of gaining a point of entry. Users who spend time communicating with others on IRC channels but who do not continually run a firewall to monitor the connection place themselves at greater risk of a security breach.

A third important security component is the installation and maintenance of virus detection software, which scans incoming and outgoing data transfers such as IRC messages, e-mail, Web pages, graphics, and attachments. If a known or potential virus is found during these file transfers, the virus detection program isolates the file before it damages the computer, alerts the user to the presence of a suspected virus, and offers tools to clean both the file and the user's system, should it become infected.

Fortunately, virus protection software is inexpensive and readily available on all operating platforms. Major publishers market these programs and maintain them on an ongoing basis with newly developed virus definition files. After installing the program, registered users are encouraged to log onto the publisher's site frequently and download the latest data files to combat new viruses as they emerge. This update service is usually free or available at minimal cost, and the crucial nature of maintaining up-to-date virus protection justifies the time and expense required. It is frequently reported that as many as half of all Internet users do not run virus detection software at all, and many of those who have installed the software do not conscientiously update the virus definition files. In summary, IRC users can minimize the likelihood of privacy or security breaches by routinely updating their operating systems, running reputable firewalls, and using up-to-date virus detection software continually during on-line interactions.

FUTURE OF IRC

Organizational Applications

In some organizations, real-time, online communication systems such as IRC are viewed as little more than a novelty. In fact, use of the word "chat" in serious organizational contexts may cause some institutional leaders or educators to grimace and assume that the medium only promotes idle chit-chat. As a generic communication medium, however, synchronous communication systems such as IRC, instant messaging, and Web chat can assist modern communicators in reaching important organizational and personal communication goals. For example, these systems are used in many organizations to support real-time collaboration among employees at different geographic locations, thereby contributing to productivity while keeping down long-distance communication costs. Probably the most common computer-mediated communication (CMC) mode selected for these purposes is instant messaging, which most people find easier to use and generally more secure and private than IRC. In fact, security concerns have prompted some organizations to install firewalls that prevent the use of IRC and other external file-sharing applications on their networks. Of course, an organization could choose to maintain an internal IRC server with no connections to outside networks, or to use moderated or secret channels on existing networks.

Individual Applications

IRC was the first synchronous text-based conferencing system to gain widespread use by individual Internet users, and the number of IRC users continues to grow at a rapid pace (Charalabidis, 2000). Nevertheless, in recent years, the use of IRC for interpersonal interaction has been largely supplanted by instant messaging systems that provide easy access or quick integration with Web browsers. Not only are command-line systems such as IRC less familiar to Internet users today, but there is a growing perception that IRC is frequented by those who engage in pirating or illicit file sharing, and that the medium has become quite risky.

In the years ahead, as new communication technologies emerge to support increasing demands for private and secure communication networks, IRC will face the challenge of evolving into a medium capable of serving the legitimate needs of 21st-century communicators. Otherwise, it may be relegated to the Internet history books or lose its place of respectability as a safe and effective network available to the entire Internet community.

GLOSSARY

- Ban** Status of a user forbidden by a chanop to enter a channel.
- Channel** A virtual chat group in which users interact, discussing specific topics or engaging in general conversation.
- Chanops** Channel operators; they monitor and maintain a channel by setting the parameters and inviting or expelling users.
- Client** Software run by the local computer of an IRC participant, which converts the user's actions into commands recognized by an IRC server.
- Daemon** (IRC daemon, or *ircd*) Software run by a server connected to the Internet, accepting connection requests from clients and relaying messages among users.
- Direct Client Connection (DCC)** Connection established between two users that allows them to bypass the network for increased privacy and faster connection.
- Flooding** Simultaneously sending many messages to a single user, thus "flooding" a channel or an entire network with unwanted messages and probably increasing lag.
- Internet Relay Chat (IRC)** Real-time, text-based communication medium that employs a network of servers to connect geographically separated users.
- IRCops** IRC operators who monitor and maintain IRC servers; they generally have very little to do with the operation of channels.
- Lag** A delay in the transmission of messages among users or between a user and a server.
- MOTD (Message of the Day)** An automated confirmation message containing certain information about practices relating to a channel, its activities, and its current participants.
- Netsplit** Disruption in the connection among servers that results in the fracturing of the network into subdivided parts and the disconnection of some users.
- Newbie** A newcomer to IRC or other online contexts.
- Nickname** An invented name that uniquely identifies the user on the network.
- Scripts** Files containing code that enables an application to combine or automate various functions.

INTRODUCTION

The Internet was not invented as a social technology, but it has turned out to be one. From the earliest days of the ARPAnet (a network of communicating computers established in the late 1960s with U.S. government funding), people have shaped and used the technology for social purposes. Today, millions of people use the Net as a means of making and maintaining connections with other people who share a common experience, interest, or concern. The Net-based social contexts range from family e-mail to fantasy games with hundreds of thousands of players. This chapter focuses on a subset of Net-based social contexts, which in recent years have come to be called "online communities." These are large voluntary online groups, composed primarily of people who have no pre-existing ties with one another and who may never meet face-to-face. Their members interact with one another primarily, if not exclusively, via the Net. Online communities range in technical sophistication from Usenet discussion groups to complex multiplayer fantasy games supported by proprietary software. They range in purpose from entertainment to developing free software to political dissent. They range in accessibility from totally open to completely hidden behind corporate firewalls. Some express no concern for security and privacy. Some, particularly those whose focus is on medical or psychological conditions, are concerned about member privacy. A few have as their common interest the topic of Internet security or Internet fraud.

This chapter describes how technical and social factors mutually interact to produce and sustain online communities. It also begins to offer a differentiated view of online communities. Online communities share some underlying attributes and processes, but they differ in member interests, goals, processes, and consequences for their members, sponsors, and society. A more differentiated view will make possible more productive theorizing, research, and design.

DEFINITION AND ATTRIBUTES

Definition

Communities in the physical world are defined as collectivities based on members' shared experience, interest, or

conviction, and their voluntary interaction in the service of member welfare and collective welfare (Bender, 1978; Etzioni & Etzioni, 1999; Knoke, 1986). Examples include neighborhood communities; religious communities; civic and social communities, such as youth scouting or service clubs; and collections of like-minded enthusiasts, such as sports fans. Communities in the physical world can be described by structural attributes such as rules, roles, and resources that exist independent of any member (e.g., Lin, 2001). Thus, one can talk about the size of a community, membership requirements and obligations, resources and amenities, member characteristics, and interaction patterns. Communities can also be described by psychological attributes internal to their members, such as feelings of trust, alienation, identification, and commitment. Both structural and psychological attributes exist along a continuum, so one can find more or less well-structured communities with more or less committed members. In casual usage, the term "community" usually suggests positive feelings, prosocial behavior, and choice. (People rarely talk about a prison community even though its inmates interact and have experiences in common.) Analytically, however, the term is a neutral one. Communities can do physical and economic damage to their members, neighbors, and enemies, just as they may produce beneficial outcomes.

The definition of online community is also based on shared experience, interest, or conviction, and voluntary interaction among members in the service of member welfare and collective welfare. An online community is defined as a large, voluntary collectivity whose primary goal is member or collective welfare; whose members share a common interest, experience, or conviction; and whose members interact with one another primarily via the Net. Online communities can have more or less structure and more or less committed members. They may yield positive or negative consequences for their members, sponsors, and society. This definition excludes electronic work groups and virtual teams, whose primary goal is economic gain, whose members are paid, and whose size is relatively small. It excludes ad hoc friendship groups and buddy lists, which are relatively small and unstructured and whose members interact primarily in the offline world. These two exclusions highlight our focus on

common-interest groups of large size with voluntary members. It also excludes nominal groups such as “all –the –people –who –use –Google” (who neither share a common interest nor interact with one another), “all –the –people –who –donate –cycles –to Seti@home,” and “all –the people who read a particular Web log” (who may share a common interest but do not interact with one another). This exclusion highlights our focus on social interaction around a common interest. It is difficult to tightly bind the concept of community because human interaction occurs in a continuum of social organization—from the dyad to the nation state. Nevertheless, the definition of electronic community used in this chapter excludes some forms of electronic social interaction for reasons of focus and because they are deserving of consideration in their own right. Others who have offered definitions of electronic communities include Figallo (1998), Kim (2000), Powazek (2002), Preece (2000), Rheingold (2000), and Werry and Mowbray (2002).

Until the mid-1990s, almost no one used the term “online community.” Instead, these groups were named after the technology that supported them and were called “newsgroups,” “listservs,” “mailing lists,” “bulletin board systems,” or “freenets.” In some ways, the online communities that are the focus of this chapter bear little resemblance to communities in the physical world. They own few tangible resources; they require no visible or tangible commitment from members (such as taxes, dues, or attendance at meetings); members may never see or meet one another face –to face. Yet, some online communities have resources that may be economically valuable: their domain name, the wisdom accumulated in their FAQs (frequently asked questions), or the intellectual property created by their members. Fantasy game characters and properties have yielded nontrivial sums for their creators on eBay auctions. The members of one voluntary online community collected enough money in member donations to buy a new server to host the community (Boczkowski, 1999). Nevertheless, calling any electronic site where people may gather an “online community” does not make it one. As in the physical world, the term carries positive connotations, and some who have used it are merely guilty of wishful thinking. This wishful thinking characterizes those who, in the late 1990s, aspired to create online communities for profit (e.g., Bressler & Grantham, 2000; Hagel & Armstrong, 1997).

Supporting Technologies

In addition to the packet-switching technology of networked communication, many online communities rely on message-based group communication applications to support member interaction. These applications generally support either asynchronous or synchronous discussion and interaction. In asynchronous interaction, people do not have to be logged on at the same time because messages are saved for later reading. In synchronous discussion, people must be logged on at the same time because messages are not stored. Asynchronous discussion is often supported via mailing lists or bulletin board applications. Mailing lists, a push technology, send group messages to a person’s e-mail inbox where they intermingle with the

person’s other e-mail and are saved until the recipient logs on to read them. With bulletin boards, a pull technology, a person reads group messages organized by topic in a file exclusively devoted to that group. (Some people establish filters to move all mailing list messages into separate folders, thereby making distribution lists function somewhat more like bulletin boards.) Synchronous discussion may be supported via talk programs such as IRC (Internet Relay Chat), Instant Messenger, or text-based virtual reality (VR) environments. MUDs (multiuser dungeon, domain, or dimension) and MOOs (MUD object oriented) began as text-based virtual reality games, computer-based versions of fantasy games such as *Dungeons and Dragons*. Today, some are still organized as fantasy games; others are organized for professional or social purposes. Their spatial metaphors and programmable objects and characters are the precursors of today’s graphically based fantasy games.

With the spread of the Web and graphical browsers in the late 1990s, online communities could support more varied forms of interaction on their Web sites. Some use real-time chat for discussions that are scheduled and announced in advance. Some use special file formats to share image, sound, or video files. Wikis support community discussion through collaborative authoring of Web pages. Blogs (Web logs) support community discussion through comments on blog pages. Online game communities are supported by more or less elaborate software that supports play in board games such as chess or supports character creation and interaction in fantasy worlds. Most discussion among members on online community Web sites still occurs in message-based discussions, however. Even the fantasy games have discussion boards.

General Attributes and Processes

In synchronous online communities, people can participate from any place that has the appropriate technology available. In asynchronous online communities, people can also participate at any time as well as from any place. Common interest and enabling technology become the only two requirements for community participation. The enabling technology for online community, which is largely a keyboard-supported message-based technology, leads to some general behavioral implications.

Social Psychology of Message-Based Communication

Electronic discussion communities are characterized by reduced social context cues relative to the social context cues available in face-to-face discussions. Weak social context cues mean that messages carry few explicit reminders of the size of the group or members’ physical appearance, social status, or nonverbal reactions as compared with face-to-face or telephone communication. (In virtual reality communities, people can create entirely new personas.) Social context cues help to regulate communication in face-to-face and telephonic interaction. They provide feedback as to whom is receiving communications and how those communications are being received and interpreted. People adjust the style and substance of their communications as a function of these cues. When those cues are attenuated, communication tends to be relatively frank and open (Kendall, 2002;

Reid, 1999; Sproull & Kiesler, 1991). Weak social context cues can lead to different effects, even for people within the same community. They can increase affiliation and commitment among members because objective differences among them are obscured and subjective similarities, based on their common interest, are magnified (Galegher, Sproull, & Kiesler, 1998; Mackenna & Bargh, 1998; Sproull & Faraj, 1995). Alternatively, they can increase disaffection and dropout because it may be more difficult to establish common ground or consensus and manage conflict (Carnevale & Probst, 1997; Cramton, 2001; Dibbell, 1998; Herring, 1994; Kollack & Smith, 1996). Asynchrony and weak social context cues condition communication in many online communities. They allow for a potentially greater geographic and social diversity of participants than many physical communities do. At the same time, they offer few cues to that social diversity in interaction, except those revealed through linguistic cues (e.g., Herring, 2001).

Microcontributions

Many of the tools for electronic community discussion are based on a relatively fine granularity of time and attention—the text message. Although messages can be any length, ones sent to asynchronous discussion communities typically range between 10 to 30 lines or one to two screens of text. For example, Winzelberg (1997) reported a mean of 131 words; Galegher et al. (1998) reported a mean of 8 to 20 lines of new text; Wasko and Faraj (1999) reported a mean of 25 to 30 lines of text; Sproull and Faraj (1995) reported a mean of 22 to 42 lines of new text. Individual contributions in a synchronous chat room or VR environment are usually even shorter. In asynchronous communities, people can read one or more messages and post or send one or more messages at their convenience. The message can be thought of as a microcontribution to the community. When people are online much of the day as a part of their work, voluntary microcontributions can be interspersed throughout the workday. Even in synchronous communities, some members report that they keep a community window open on their screen while they are working. Every once and a while they “check in” on the community (Kendall, 2002). Participation can also be interspersed with other activities at home in the evenings. Some people may devote hours a week to an online community, but they can do so in small units of time at their own convenience.

Communities based on microcontributions have relatively low barriers to entry. It is fairly easy to read enough microcontributions to know if a particular community is relevant or appropriate. If so, that same reading readily demonstrates the appropriate form that a newcomer's own microcontributions should take. The production and posting of initial microcontributions is relatively low effort. Then, if all goes well, the newcomer receives positive reinforcement in the form of (easy to produce) responding microcontributions from other community members. Whereas microcontributions create low barriers to entry, they may also create high barriers to commitment. It can be difficult to develop complex arguments or achieve nuanced understanding through microcontributions.

Communities that are easy to join are often just as easy to leave (Butler, 2001).

Aggregation Mechanisms

Although people can make ad hoc contributions to online communities at random, microcontributions must be organized into larger units for efficiency and social effectiveness. Both technical and social mechanisms are employed to organize the smallest unit of contribution into larger units that are useful to participants. Software for asynchronous discussion lets people indicate that their contribution is a response to a previous one. All contributions so designated can be aggregated by the software and displayed as “threads”—a seed message and all reactions to it. Forms of threads common from the earliest days of the Net include a question with replies and a proposal or statement with comments. Threads organize microcontributions so that everyone can see their constituent parts, making it easy for potential contributors and beneficiaries to see what has already been said. (Software also allows readers to mark threads they have already read or to display only unread messages.)

Asynchronous discussion communities may have tens or hundreds of threads active at the same time, necessitating a level of organization beyond the self-organizing thread. In these cases, a human designer may suggest or impose a topic map or architecture to group threads into more general topic categories. (In some older bulletin board systems, people would vote to create a new top-level topic, which would get its own separate bulletin board.) Web-based software can display these maps graphically so that users may click on a topic that interests them and see all threads related to that topic. The shared interest of a group usually suggests the type of topical map that may be created. For example, medical concern communities may have topics for symptoms, medications and their side effects, negotiating the health care system, and managing relationships with family and friends. Movie or television fan communities may have topics for major and minor characters, actors who play those characters, and past and future episodes. Communities that build software may have categories for different types of code, bug reports, patches, and documentation.

Threads and topic maps may be insufficient to structure extremely large numbers of messages. Another form of microcontribution, the rating message, adds a quality dimension to message structuring. Some Web sites now give members the opportunity to rate the contribution of others' messages. Software then aggregates and displays these ratings in an overall quality index for contributions (e.g., Slashdot) or contributors (e.g., MotleyFool). Overt ratings of contribution quality surely increase economic trust within an electronic market such as eBay buyer and seller ratings (Kollock, 1999). It is an open question whether they increase or inhibit emotional trust and cohesiveness within an electronic community setting.

Software for synchronous interaction may organize contributions in channels or use a spatial metaphor to organize contributions in “rooms.” Online communities associated with a geographic locality may organize contributions around civic functions such as the garden club or public library (e.g., Sproull & Patterson, 2004). As these

communities increase in size, the organizers or members themselves construct new rooms, buildings, and territories to organize interaction. Some also offer rating and review functions to rate characters, contestants, and properties.

Norms and Motivations

Some norms of community behavior, which were visible from the early days of the ARPAnet, prevail across many types of online communities. One is peer review of content (Benkler, 2002). In most electronic discussion communities and collaborative work communities, there are no "authorities" to certify the accuracy of message content. Instead, it is expected that members themselves will comment on the quality, accuracy, completeness, and so on of one another's contributions. Similarly, peer review of behavior is also expected: it is normative for members to chastise or complain about inappropriate behavior and praise helpful behavior. Most important is the norm of altruism. Online community members freely offer information, advice, and emotional support to one another with no expectation of direct reciprocity or financial reward.

The fundamental dynamic supporting discussion communities is that someone asks a question or makes a proposal or statement and other people provide answers or comments. Utilitarian self-interest may be all that motivates the askers—a personal need for information. However, pure self-interest does not explain the behavior of people who reply. By definition, volunteer members are not paid for their replies. Because they are unlikely to have a personal relationship with the person they help, neither friendship obligation nor the expectation of direct reciprocity is likely to impel their behavior. Indeed, an early influential paper (Thorn & Connolly, 1987) predicted that computer-based information exchange systems that relied on volunteers would be doomed to failure. The authors argued that people who could give the best replies would have no incentive to participate because they would receive few benefits for doing so. It was unlikely that anyone could answer their questions; their time would be unrewarded. (In social dilemmas, helping in these situations is known as the "sucker's choice.") Over time, therefore, the quality of help would decline until people no longer even bothered to ask questions. The fallacy in this argument is the assumption that rewards to people who reply must come in the same form as the help they give. Yet, motivations for helping behavior can be quite complex. In studies of volunteers in the physical world, motivations include commitment to the cause or interest associated with the community, the desire to help others, benefits from displaying expertise, and the personal satisfaction and self-esteem derived from helping others (e.g., Clary et al., 1998; Omoto & Snyder, 1995). Studies of electronic discussion communities document a similar combination of motivations for people who answer questions and otherwise support their online community (e.g., Butler et al., 2004; Kollock, 1998; Lakhani & von Hippel, 2003; Wasko & Faraj, 2000).

In virtual reality (VR) communities, the environment indexes participants' motives (Reid, 1999). In VR game communities, the motives are tied to the rules of the game:

amass property, kill enemies, design an award-winning room, and so on. In VR professional communities, the motives are tied to the profession: contribute to shared databases, review articles, participate in policy discussions, and so forth. In VR social communities, the motives are tied to exploring social worlds.

HISTORY OF ONLINE COMMUNITIES

Both the technical and social trajectories of electronic communities began with the design and early deployment of networked computing in the late 1960s and early 1970s. (See Table 1 for timeline.) Whereas computer networking was initially conceived as a way to share scarce computing resources located in one place with researchers at other places via remote access, it soon became a convenient way for people to gain remote access to other people as well as to computers (Licklider & Veza, 1978; Sproull & Kiesler, 1991). During the 1970s and 1980s, people created additional networks and wrote e-mail and bulletin board software, which represented technical innovations and improvements that made networked computing more useful for supporting human communication. During the 1990s, the technical innovations of the Web and the graphical browser supported the broad diffusion of electronic communication to millions of U.S. households and hundreds of millions of people worldwide.

The social trajectory of electronic discussion communities had its beginnings in the same technical community that invented the ARPAnet. By the mid-1970s, ARPA program officers and researchers around the country had begun using group e-mail to share results, discuss plans, and organize meetings. Some researchers also began using group e-mail for purposes unrelated to work: for example, to share opinions on cheap Chinese restaurants in Boston and Palo Alto, favorite science fiction books, inexpensive wine, and new movies. This research community invented both the technology (group communication tools) and the new form of social organization (the voluntary electronic group). They appropriated technologies that were created for utilitarian purposes to create self-organizing forums for the voluntary discussion of common interests. The social trajectory of VR communities began in 1979–1980 with an effort to program a game that would be like the fantasy game *Dungeons and Dragons* that was played in the physical world. The first multiplayer VR game was accessible on the ARPAnet in 1980.

By the 25th anniversary of the ARPAnet in 1994, electronic group communication had become a taken-for-granted process and voluntary electronic discussion communities had become a taken-for-granted organizational form in universities, technical communities and scientific disciplines, and some corporations (e.g., Finholt & Sproull, 1990; Kiesler & Sproull, 1987; Orlikowski & Yates, 1994; Walsh & Bayma, 1996). Multiplayer games were also becoming popular on university campuses. Despite their growth, at this point both discussion groups and games were still in large measure the province of young, technically adept men. The final years of the 20th century saw Net-based communication enter the mainstream of U.S. life because of a combination of technical and economic developments. The technical

Table 1 Timeline for Community-Oriented Group Communication on the Net

Date	Name	Technical Developments	Social Developments
1965–68	ARPA projects	Research on networking to share scarce computing resources	Networking research community forms across small number of laboratories
1969	ARPAnet	First four ARPA sites connected	
1972	RD	First ARPAnet e-mail management program	
1973			75% of ARPAnet traffic is e-mail
1975	MsgGroup	First ARPAnet mailing list	
1978	BBS	First bulletin board system	
1979	Usenet	Free software to share bulletin board discussions	
1979	MUD	First multiuser VR game	
1979	CompuServe	Began offering e-mail to customers	
1980	MUD	MUD first played over ARPAnet	
1981	Bitnet	Computer network for non-ARPAnet universities	University computer center directors band together to support this
1981	Sendmail	Free software to send mail across networks	
1984–85	Delphi, Prodigy, AOL	Commercial information services founded that offered e-mail	
1985	Listserv	Free software to manage e-mail lists	
1986	IETF		Volunteers focused on technical operation and evolution of Internet
1988			>1,000 public listservs
1990			>1,000 Usenet groups; >4,000 posts per day
1990	World Wide Web	Invented by Tim Berners-Lee	
1990	LambdaMOO	VR environment created at Xerox PARC	
1991	Linux	Free computer operating system	First message about Linux posted to Usenet group
1992	AOL	Connects to Internet	
1994	Netscape	Introduced graphical Web browser	
1994			>10,000 Usenet groups; >78,000 posts per day; estimated 3.8 million subscribers to commercial online services
2000			34 million AOL subscribers; 44 million U.S. households online
2001			90,000 Usenet groups; 54,000 public Listserv groups
2004			65% of U.S. citizens are online 600 million people worldwide are online

IETF = Internet Engineering Task Force; MUD = multiuser dungeon, domain, or dimension; VR = virtual reality.

developments were the Web and the graphical browser, which made it much easier for ordinary people to find and access information and groups on the Net. The economic developments were the commercialization of the Net and AOL's business model. Once the Net began to be commercialized, corporations began to see potential economic value in electronic communities and so endeavored to support them and, indeed, to "monetize" them (e.g., Hagel & Armstrong, 1997). The online game industry began to grow. AOL's business model emphasized e-mail and member discussion forums in contrast with other commercial services that were still emphasizing access to databases. By 2000, AOL had 34 million members—more than all the other commercial services combined—and many of them were participating in electronic forums and communities of interest. That year, 44 million U.S. households were on the Net. (In 2004, nearly two thirds of Americans were online [Fallows, 2004].) Despite the enormous influx of people very different from the ARPAnet pioneers, four themes evident from the earliest days of the ARPAnet continued to characterize electronic communication at the beginning of the 21st century: access to people as much as to databases, group communication as well as dyadic communication, personal interest topics as well as utilitarian ones, and self-organizing, voluntary electronic communities.

TYPES OF ONLINE COMMUNITIES

Until the early 1990s, most electronic communities used similar technology and their members had similar attributes. Highly educated, young, technically adept people congregated electronically with similar others who shared similar interests. These congregations were relatively homogeneous in structure, process, and membership. At the beginning of the 21st century, however, the diversity of Internet users and group goals and processes is so great that it is helpful to differentiate types of communities to understand their costs and benefits in more detail. This section categorizes and describes types of online communities based on the interest that members or sponsors have in common. (See Table 2 for examples.) It is neither an exhaustive nor a mutually exclusive characterization, but it does represent some prevalent types. Despite the differences across types of shared interest, all of these communities are characterized by anytime, anyplace communication with weak social context cues, aggregated microcontributions, and norms of interaction. The boundaries across types can be fuzzy; the descriptions indicate central tendencies within types.

Types by Member Interest

Consumer Communities: Brands and Fans

Consumer communities are composed of people who share a common interest in and are loyal to a particular brand, team, entertainer, or media property. Although people organized fan clubs prior to the Net, it was difficult for them to arrange activities on a large scale and frequent basis. Online customer communities have a much broader reach. People voluntarily share their information and passion with thousands or hundreds of thousands of

others who share their interests in a particular product, entertainer, or media property. AudiFans, for example, is composed of more than 1,000 Audi enthusiasts who exchange information about parts suppliers and mechanics, post photos of their cars, and share the joys and sorrows of Audi ownership. The Britney Spears portal contains pictures, MP3 files, news, and forums where thousands of people comment (positively or negatively) on all things having to do with Britney. For most members of consumer communities, the shared interest may be an intense one, but it typically represents a fairly small and often short-lived portion of members' lives.

(A)vocation Communities

Experts and enthusiasts form and join voluntary (a)vocation communities to increase their pleasure and proficiency in their hobbies or work. Whereas a particular product may be a means to advancing a common interest in an (a)vocation community, it is not the primary focus of attention as it is in a consumer community. From bicycling to computer programming, dog training to quilting, karate to the Civil War, there are online communities for people who share these interests. "How-to" information prevails in (a)vocation community discussions and people who share their expertise are greatly appreciated. Network and Internet security are topics for some (a)vocation communities. Usenet, for example, supports more than 25 groups on the topics of cracking, hacking, and network security where people discuss how to make or break secure systems. BikeForums, for example, has more than 3,500 members who discuss and debate bicycle commuting, mountain biking, tandem biking, racing, training, and so on. TappedIn is a professional VR community for K–12 educators whose 14,000 members discuss curriculum, share lesson plans, and so on. The Internet Chess Club has more than 25,000 members who play chess with other members, take lessons, play in tournaments, watch grandmaster competitions, and so on. Everquest and Ultima are large online communities for people who delight in fantasy games. The shared community interest in (a)vocation communities may represent a relatively enduring part of members' lives.

Place-Based Communities

These online communities are organized by and for people who live in a particular locale. Their genesis in the early 1980s had a political agenda—to give residents a (electronic) voice in the local political process (e.g., Schuler, 1996; Schuler & Day, 2004). More recent versions have had the broader goal of building social capital by increasing the density of electronic social connections among residents of physical communities (Hampton & Wellman, 1999; Kavanaugh, 2003; Sproull & Patterson, 2004). In principle, the shared interest should last at least as long as people reside in the community. (Recent developments like MeetUp.com let people use the Internet to find others in their geographic area who share a common interest for the purpose of scheduling face-to-face meetings. These applications are not included in this discussion because they focus primarily on arranging face-to-face meetings, not on sustaining broader electronic discussion without regard to geography.)

Common Condition Communities

In these communities, people share the experience and interest of a common condition. The condition may be based on a demographic characteristic such as race, age, or ethnic background; a medical or psychological condition such as arthritis or depression; or being an alumnus/a of a particular organization such as a college or branch of the military. People join condition communities to learn how others experience or are coping with their condition and to share their own experiences. Along with practical information and advice, a “you are not alone” sentiment prevails in many discussions. BeyondHearing, for example, has more than 1,000 members who have a hearing loss or who have a loved one with a hearing loss. Topics range from cochlear implants to the best audiologists to funny

stories about lip reading mistakes. Systers’ membership is more than 3,500 female computer scientists and engineers who discuss female-friendly graduate schools and employers, how to manage male subordinates in the workplace, and so on. The shared community interest is often a long-term or lifetime one for members.

Concern Communities

In these communities, members share an interest in a common political, social, or ideological concern. Because members often wish to influence the state of affairs in the physical world, these communities usually have multifaceted ties to that world. They may announce and comment on real-world events and organize letter-writing campaigns, rallies, fundraisers, and so forth. They

may use click-and-donate applications to raise money or pledges of volunteer time. MoveOn, for example, began as an online petition drive to censure, but not impeach, former U.S. President Bill Clinton and has grown to include many online advocacy groups that organize volunteer campaigns. The Howard Dean presidential candidacy used the Net for organizing in 2003–2004. More than 1,000 members of soc.religion.mormon discuss and debate Mormon doctrine and practices. The shared interest of concern communities is likely to be a deep and abiding one for their members.

Collaborative Work Communities

Unlike other community types whose primary output is talk or amusement, members of collaborative work communities use the Net to voluntarily produce real products, be they software, literary works, or other creations. Much open source software is produced in voluntary communities today despite the growing interest of the corporate sector (e.g., Raymond, 1999). Indeed, much of the design and engineering of the Internet itself is accomplished by a voluntary community that conducts much of its business electronically: the Internet Engineering Task Force (n.d.). Poets participate in writers' communities whose members thoroughly critique one another's work. A more pragmatic writing community is creating a new encyclopedia. The community project has produced more than 346,000 entries as of August 2004 (http://www.wikipedia.org/wiki/Main_Page). The distributed proofreaders' project has digitized, proofread, and posted more than 5,000 public domain books. The shared interest of collaborative work communities is likely to be deeply involving for members, although it need not be as enduring as the shared interest in concern communities.

Types by Sponsor Interest

Only within the past 10 years have online communities been sponsored or organized by anyone other than members themselves (with a few exceptions such as the Well and geographically based bulletin board systems called freenets). Many recent third-party sponsors or organizers have been motivated by the profit potential of online communities with revenue models based on either sales (of advertising, membership lists, products, etc.) or subscriptions. During the dot-com boom, third-party sponsors of some customer and demographic condition communities used sales-based revenue models. Profit-oriented community sites were created for L'eggs panty hose, Kraft food products, women (iVillage), Asian Americans (Asia Street), and African Americans (NetNoir), for example. Some third-party-sponsored communities based on subscriptions are relatively healthy; arguably a substantial (but unknown) fraction of AOL's customer base is a function of online community memberships. Within the game industry, subscription-based revenue models have been successful. Several multiplayer game communities have thousands or hundreds of thousands of members. Members of one game, EverQuest, report spending an average of more than 22 hours a week playing it (Yee, 2001).

Some corporations have avoided revenue-based models and instead have supported online communities to

build market share or increase customer satisfaction and loyalty. Sun Microsystems sponsors the Java Developer Connection, an (a)vocation community designed to support and expand the Java software developer community worldwide. The Lego Corporation supports several "adult-fans-of Lego" sites, in addition to sponsoring its own site, to support loyal customers. Various software companies support voluntary technical discussion and support communities in the interest of increasing high-quality, inexpensive tech support. Harley-Davidson uses H.O.G., its online members-only group, to reinforce the brand loyalty of Harley owners worldwide.

In the not-for-profit sector, foundations and service organizations have sponsored communities for their target populations with the goal of improving their welfare. Thus, for example, The Markle Foundation sponsored the creation of SeniorNet, a not-for-profit online community for people over age 50, which currently has 39,000 members. The National Science Foundation sponsored TappedIn, a not-for-profit online community for K–12 schoolteachers and curriculum developers, which currently has more than 14,000 members.

ONLINE COMMUNITY CONSEQUENCES

Positive Consequences

Benefits to Members

Not surprisingly, most studies of online community members report that information benefits are important to them (e.g., Baym, 1999; Lakhani & von Hippel, 2003; Wasko & Faraj, 2002). What is noteworthy is the form that the information takes. It is not the disembodied, depersonalized information that can be found in databases or official documents, which are themselves easily accessible on the Web. Instead, it is often profoundly *personalized* information. Its form and content are personal—personal experiences and thoughts. Likewise, its audience is personal. Questions or requests for comment do not look like database queries: They are framed for human understanding and response. (A discourse analysis of Usenet groups found that almost all questions included a specific reference to readers; the few that did not were much less likely to receive replies; Galegher et al., 1998.) Replies typically address the person or situation engendering the request and are based on the replier's own situation or experience. In consumer communities, personalized information can increase members' pleasure in using or experiencing the product or property. Personalized information can increase members' pleasure or competence in practicing their (a)vocation. It can also challenge one's assumptions and beliefs (e.g., Kendall, 2002).

Members derive more than information benefits from online communities, however. Some also derive the social benefits that can come from interacting with other people: getting to know them, building relationships, making friends, having fun (e.g., Baym, 1999; Butler et al., 2004; Cummings, Sproull, & Kiesler, 2002; Kendall, 2002; Quan y Hasse, Wellman, Witte, & Hampton, 2002; Rheingold, 2002). Occasionally these social benefits are strong enough that they lead some members to organize

ancillary face-to-face group activities, such as parties, rallies, show and tell, reunions, or meetings at conferences or shows.

Members of medical and emotional condition communities may derive actual health benefits from their participation in addition to information and social benefits. The evidentiary base for these benefits is small but comes from carefully designed studies that use either random assignment or statistical procedures to control for other factors that could influence health status. Benefits for active participants include shorter hospital stays (Gray et al., 2000), decrease in pain and disability (Lorig et al., 2002), greater support seeking (Mickelson, 1997), decrease in social isolation (Galegher, Sproull & Kiesler, 1998), increase in self-efficacy and psychological well-being (Cummings, Sproull & Kiesler, 2002; Mackenna & Bargh, 1998).

Membership benefits do not accrue equally to all members of online communities. Passive members, those who only read messages, as a class may benefit least. This speculation is consonant with research on groups and communities in the offline world that finds that the most active participants derive the most benefit and satisfaction from their participation (e.g., Callero, Howard, & Piliavin, 1987; Omoto & Snyder, 1995). Most studies of online communities investigate only active participants because they use the e-mail addresses of posters to identify their research population; they have no way of identifying or systematically studying people who never post but only read. Research that has studied passive members systematically finds that they report mostly information benefits; their total level of benefits is lower than that for more active participants; they are more likely to drop out (Butler, Kiesler, Kraut & Sproull, 2004; Cummings, Sproull, & Kiesler, 2002; Nonnecke & Preece, 2000).

Among active participants, people who participate more extensively report having a greater sense of online community (Kavanaugh, 2003; Quan y Hasse, Wellman, Witte, & Hampton, 2002). More frequent seekers of information report receiving more helpful replies than less frequent seekers (Lakhani & von Hippel, 2003). More frequent providers of information report greater social benefits, pleasure in helping others, and pleasure in advancing the cause of the community (Butler, Kiesler, Kraut, & Sproull, 2004).

Benefits to Third Parties

Many attempts to directly “monetize” online communities through sales revenue from advertising or commerce have been relatively disappointing (Cothrel, 2001; Figallo, 1998; Sacharow, 2000). Although the potential customer base could be quite large for brand or demographic communities, attracting and retaining customer/members is difficult. By contrast, subscription revenues—in the online game industry at least—have been relatively robust. Specific figures are hard to get from privately held companies. However, estimates are that revenues from online games were more than \$200 million in 2000 and will grow to more than \$1 billion in 2004 (Zito, quoted in Castronova, 2001).

In consumer communities and (a)vocation communities, substantial nonrevenue benefits may accrue to corporations through reinforcing customer brand loyalty and

increasing customer satisfaction. Voluntary personal testimonials about a product or experience in the context of giving help can be quite persuasive, both to the person who asked for help or comment and to others reading the exchange. Motivational theories of attitude formation (e.g., Festinger, Schachter, & Back, 1950) and information processing theories of decision making (e.g., Nisbett & Ross, 1980) both point to the influential nature of voluntary personal testimonials. The process can be so powerful that there have been unsubstantiated reports of paid skills masquerading as community members in consumer communities (Mayzlin, 2001).

Much of the help offered in consumer communities and (a)vocational communities is personalized customer support—and potentially quite high-quality support at that. In the software industry, online communities have been recognized as the Best Technical Support Organization of the Year for 1997 and 1999 (Foster, 1999). Information that solves customers’ problems or enhances their product experience is likely to increase their satisfaction and loyalty. When it is provided by self-organized volunteers, the corporate cost is minimal and the benefits are substantial.

Some online communities offer potential product development benefits. Most remarked are probably open source software communities that have generated product revenues for companies like Red Hat and product enhancements for companies like IBM and Sun Microsystems. Some game and hobby communities offer extensive product testing before widespread product release (e.g., Wallich, 2001). Some actively propose, design, and discuss new product features (von Hippel & Krogh, 2003).

The strategic question for corporations today centers on what type of corporate involvement in online communities is likely to bring the greatest benefit. With few, but important, exceptions, direct corporate ownership and control of online communities is unlikely to be the answer. (This is not to say that corporations will not benefit from Web-based sales and customer support; e-commerce can be profitable even if online community revenue models are not likely to be.) Forging positive and productive relationships with independent online communities can be challenging, however.

Benefits to Society

Rigorous empirical evidence is almost nonexistent for online community benefits to society. If members of condition communities achieve improved health status, the cost of their medical care to themselves and society could decrease. Alternatively, better-informed members may seek out additional tests or treatments, thereby increasing the cost of their care. If members of targeted populations such as K–12 schoolteachers or senior citizens derive cognitive, social, and emotional benefits from participating in online communities, then the larger society may benefit as well. Data from Blacksburg Electronic Village suggests that participation in online community activities can increase civic involvement (Kavanaugh, 1999). If members of online concern communities can more effectively mobilize, then the causes served by their advocacy are likely to benefit (e.g., Gurak, 1997; Quan y Hasse et al., 2002). Note, however, that online communities can advocate

for harmful causes just as easily as they can for helpful ones.

Negative Consequences

Although anecdotes are widespread, systematic evidence on the negative consequences of online communities is sparse. Members can be harmed by erroneous, malicious, or destructive information. The norm of peer review of content in discussion communities acts as a damper on this kind of harm but cannot prevent it entirely. More seriously but less likely, individual members can be harmed by unhealthy, dangerous relationships that can form via online communities. Unscrupulous or criminal intent can be masked by an online persona that inspires trust and friendship within the community context. If a relationship moves away from community scrutiny and into private e-mail, it can lead to emotional harm, economic damage, or even physical danger. This is a particular concern when predators use online communities to identify children. Within VR communities, there have been a small number of widely publicized "attacks" that caused emotional harm to their members (Dibbell, 1998; Schwartz, 2001). A group itself can harm its members: cults can exist in cyberspace as well as in the offline world. One such, Pro-Ana, extols the joys and personal freedom of anorexia. Its members share tips on how to hide weight loss from family and friends, discuss the importance of personal choice, and praise members' announcements of their weight loss.

Although participating in an online community may not be directly harmful to its members, involved members may withdraw from their relationships and responsibilities in the offline world. People who spend a great deal of time online must be spending less time doing something else. The research thus far has only examined the effects of aggregate number of hours spent online. One study found it was associated with a small decrease in social involvement and psychological well-being for a particular group of new users (Kraut et al., 1998), but that effect was erased with continued use (Kraut et al., 2002). Some studies have found it to be associated with an expanded social circle (Katz & Apsden, 1997; Quan y Hasse et al., 2002; Kraut et al., 2002).

Just as members may be harmed by erroneous or malicious information, so too may be corporations. Corporate security weaknesses may be described and disseminated through cracker communities. Network attacks may be organized in the same way. Companies may fear liability if advice promulgated in an online community leads to product failure or product-related damages. Customer complaints can be shared very rapidly with large numbers of people and can snowball into widespread mobilization. The Intel Corporation had to manage a wave of Internet protest, much of it organized through Usenet groups, as it learned about and took steps to correct a flaw in its Pentium processor. Ultimately, of course, fixing the error benefited Intel and its customers (Uzumeri & Snyder, 1996). In a different case, members of a number of Internet groups mobilized to protest the introduction of a new household database product created by the Lotus Development Corporation. That protest led to the withdrawal of the planned product (Culnan, 1991). Online communities are not the only means of mobilizing discontent on

the Net (e.g., Gurak, 1997), but because they are characterized by member commitment, they can be particularly potent.

Intellectual property infringement is another area of potential harm for corporations. Trademark infringement is easy to spot in many consumer communities. Copyright infringement can be particularly troublesome for media property companies. Fan community members create and discuss fan fiction, that is, new story lines or alternate plot endings for their favorite shows, movies, or characters. Corporations routinely issue cease and desist orders against these groups, fearing loss of copyright control (Jenkins, 2002; Silberman, 1996). As with mobilizing discontent, online communities are not the only mechanism on the Net for intellectual property infringement. Unauthorized media file sharing represents a larger area of intellectual property harm for media companies at the moment, but the social reinforcement that is generated when community members praise or critique one another's (arguably intellectual property infringing) creative work can be potent.

RESEARCH METHODS AND ISSUES

Two broad research traditions encompass much of the research on online communities. In caricature, these can be labeled "insider studies" and "outsider studies." Participant observation studies began with Howard Rheingold's (2000) description of the Well, a Northern California online community begun in 1983. Examples of scholarly ethnographies include those of a soap opera discussion community (Baym, 1999), a social MUD (Kendall, 2002), a lesbian café (Correll, 1995), and an IRC arts community (Danet, 2001). In each case, the writer/analyst was a member of the community for an extended period of time. The ethnography evokes the language, personalities, beliefs, interpretations, and daily lives of people inhabiting these worlds.

"Outsider studies" typically extract records of online behavior or attitudes for study outside the community context. Linguists may extract text records for linguistic analysis of online talk (e.g., Herring, 1996; Herring, 2001). Sociologists may analyze text records for norm development and strength (Sassenberg, 2002; Moon, 2004). Social psychologists may use questionnaires to survey community members about their social support systems in the online world and the offline world (e.g., Cummings et al., 2002; Mackenna & Bargh, 1998). Sociologists and political scientists may use questionnaires to survey members about their social and civic activities and attitudes (Kavanaugh, 1999; Wellman & Hayathornthwaite, in press).

Online communities are appealing subjects for researchers. New or newly visible social phenomena are intrinsically interesting to the social scientist. Moreover, online access to one's subjects of study offers beguiling efficiencies. Ethnographers can do ethnographic work without leaving the office. Survey researchers can administer questionnaires to multinational samples of respondents without buying a single postage stamp. Linguists have access to entire cultural corpora in digital form. The efficiencies are not problem-free, however. Ethnographers

have an incomplete picture of their community members' offline lives. Survey researchers often have no access to members who never post (e.g., Nonnecke & Preece, 2000). Linguists do not see private or back channel communication. Still, despite the drawbacks, the past 10 years have seen a substantial growth in social scientists and social science methods oriented toward understanding online communities.

Whereas general principles of ethical research are widely shared within the academic social science community (and are governed by federal regulation), procedures for implementing those principles in research on online communities are under debate. Consider just the principles of informed consent and subject anonymity. If a person's words in a community discussion are considered private, consent should be obtained before analyzing them. If they are considered public, consent should be obtained before quoting them (except for fair use). If a researcher plans a participant observation study, she or he should seek permission from community members before beginning the study. Because most communities are open, members who join after the study has begun do not have the same opportunity to give or revoke permission, however. When publishing results, the researcher must honor promises of anonymity by disguising participant identity. Yet powerful full-text search engines can use verbatim text, even with no identifier, to find the original (identified) source. Bruckman (2002) pointed out that norms in the humanities encourage attribution and reproduction. Several scholarly and professional associations are currently grappling with the ethics of online research (Frankel & Siang, 1996; Thomas, 1996).

CONCLUSION

The Internet has been a home for self-organizing voluntary groups since its inception. As the Net grew, so did the pace of people and technology mutually adapting to form and support new online communities of interest (e.g., Boczowski, 1999). Despite the large number of online communities and online community members today, the social form has been widespread for less than a decade. The nature of the Net means that experimentation and evolution into new variants of the social form can occur rapidly. The next 10 years should see more new community types, new ways of aggregating microcontributions, and new community processes.

The social form is also immature in terms of effect on members and on the offline world, but with a more differentiated view of community types, we should be able to better specify which types of online communities should or could have which kinds of effects on which types of members. Nevertheless, people also live in the offline world. The biggest online community design payoffs may come from supporting online extensions of the places where people live, work, send their kids to school, recreate, vote, and worship (e.g., Hampton, 2001). Television has had an enormous effect on family communication patterns, teen culture, political activity, and consumer behavior. Most of the decisions that led to those effects were made by an extremely small number of wealthy and influential individuals. In online communities, by contrast,

everyone has the opportunity to shape the processes that will make a difference.

GLOSSARY

- Dot-com** Internet sites or businesses designed to make money during the late 1990s.
- Internet Relay Chat (IRC)** A program for simultaneous text communication among two or more users.
- Listserv** A program for managing a distribution list of e-mail addresses.
- Multi-user Dungeon/Domain/Dimension (MUD)** A text-based virtual reality environment, initially used for fantasy games, now also used for social and professional purposes.
- MUD Object Oriented (MOO)** Text-based virtual reality environment in which users can program objects that have persistence.
- Seti@home** An activity organized over the Net in which people donate idle central processor unit (CPU) cycles to process data looking for radio signals.
- Usenet** A system of electronic bulletin boards.
- Virtual Reality (VR)** A text-based or graphics-based environment that evokes a self-contained world.
- Wiki** A specific type of editable, Web-based document collection.

INTRODUCTION

Groupware refers to computer- and network-based technologies that help people accomplish a group's objective. Some forms provide greater support for real-time collaboration (such as electronic meeting support systems, chat rooms, shared whiteboards, and real-time videoconferencing) than others, some can support the individual's work, as well as work that can only be accomplished collaboratively (collective writing, for example). Helping people who are in the same place at the same time (meetings, for example) is the forte of some types of groupware, whereas other forms excel at connecting group members who might be continents and time zones away (such as e-mail and shared database access). Some are geared to support specific group subtasks (e.g., shared calendaring and scheduling, e-mail), whereas some forms are designed for a wider array of integrated support functions (such as dispersed project management). To make this more complicated, the Internet has driven both the amazing popularity and adoption of these tools, but has also driven the creation of new classes of tools that are proving important (shared databases, for example). In this chapter, we first remark on the reason for groupware and then present some defining concepts and classifications for these myriad of tools. We then explore some generic and common functionalities of groupware tools, turn to detailed descriptions of some popular modern examples, and show how these examples map to our classifying scheme. We then adopt a management perspective and present a theory-based framework for mapping these functionalities to the varying circumstances of individual and group work. The final part of the chapter addresses issues of human productivity and groupware as well as issues surrounding the changes in organizational and

human processes that often accompany the proliferation of groupware-supported work.

WHY GROUPWARE?

There has been more than five centuries of research devoted to group and team processes in an effort to understand why the desired synergy of group work is often elusive and why the group work is instead often difficult and inefficient. Figure 1 lists the more common positive (+) and negative (–) influences on collaborative work.

Many things can go wrong with group work. Participants may fail to understand their goals, may lack focus, or may have hidden agendas. Some people may be afraid to speak up, whereas others may dominate the discussion. Misunderstandings occur through different interpretations of language, gesture, or expression. Besides being difficult, teamwork is expensive. A meeting of several managers or executives may cost several thousands of dollars per hour in salary costs alone. In *Fortune 500* companies, there are more than 12 million formal meetings per day in the United States. That is more than three billion meetings per year. American managers typically spend about 20% of their time in formal meetings and up to 85% of their time communicating. For all its difficulties, though, group work is still essential. People must still collaborate to solve tough problems. And, as business becomes more global in scope and computers become more ubiquitous in the workplace, the need for collaboration—and the means to achieve it—has surely continued to increase. Enter groupware, with functionalities that, when appropriately selected, applied, and managed, can bring users tremendous support for their group's tasks (Collaborative Strategies, 2002).

Figure 1: Influences on the quality of group work.

GROUPWARE AND SECURITY

Groupware systems, including group support systems (GSS), group decision support systems (GDSS), and electronic meeting systems (EMS), all have one thing in common. They use computer technology to facilitate the exchange of information and ideas between individuals and teams. Often, teams use these technologies to facilitate teamwork in distributed environments where the members are often separated by spatial distance and time.

Every organization in today's global, wired environment should be concerned about information systems security. Of particular importance should be the goal of keeping systems and data that are used by teams working in distributed environments secure from unauthorized access. However, as indicated by recent hacker attacks (e.g., "slammer worm"), companies are still experiencing problems keeping their information safe. Teams that work in distributed environments using groupware must be very careful about what kind of information they are exchanging and via what means. The security of the network and software is very important. The risk of exchanging valuable and proprietary information through insecure media can lead to considerable financial losses.

Slammer: The First Flash Attack Worm

On Saturday, January 25, 2002, at 05:30 UCT, a worm began to spread throughout the Internet. This worm was called by several names, including Sapphire and Slammer. The worm spread with astonishing speed. Slammer reached its peak packet-attack traffic in an amazing 3 min. Within 10 min, it had infested about 90% of all vulnerable hosts on the Internet. Although Slammer was brought under control within hours, it had achieved its aim of infesting nearly all vulnerable servers before the world even realized what was happening.

Many articles described Slammer as a minor attack that did not do widespread damage. However, although Slammer did not delete files or do other deliberate damage, it took many critical database servers out of service, resulting in extensive damage worldwide. Most of Bank of America's 13,000 automated teller machines (ATMs) became unavailable. Continental Airlines experienced some flight delays because of the need to revert to paper transaction handling. A Boston medical center experienced slow-downs for about 6 hr, during which the center had to revert to paper-based processing for patient orders and other

processes. Police and fire dispatchers outside Seattle also had to revert to slow paper processing at a 911 call center serving two suburban police departments and at least 14 fire departments. Other companies hit by the worm included Countrywide Financial Corporation, American Express, and several U.S. and Canadian banks (Panko, 2003).

Defining the Problem

A survey conducted by the CSI/FBI indicated that 75% of surveyed firms and agencies detected computer security breaches and acknowledged financial losses as a result of computer breaches (Power, 2002). Through the continual monitoring of hundreds of *Fortune 500* companies, Symantec found that general Internet attack trends are showing a 64% annual rate of growth (Anderson & Shane, 2002). Information systems are not necessarily risky. However, when humans interact with computer systems, it is the behavior of humans that is risky. Thus, the analysis of threats/risk in groupware should start with the analysis of the behavior of individuals, and technological improvements in system security should be based on an analysis of human behavior.

In a study investigating areas of risk in groupware (Gallegos, 1999), the authors indicated that one of the greatest risks is the possibility of information leaks that would permit outsiders to assess the present state and characteristics of an organization. Controls should be provided for the security of sensitive information wherever a user has contact with data. Methods should focus on controlling access to the organizational databases and controlling the use of data. Controls must also exist to detect and report possible security violations.

Beyond common sense, there are now "enhanced regulatory compliance" provisions from the federal government that affect the implementation and use of groupware systems in organizations. We will introduce here the HIPAA and Sarbanes-Oxley Act.

- **HIPAA.** HIPAA is an acronym for the Health Insurance Portability and Accountability Act of 1997. This is a federal law that protects the privacy of a patient's personal and health information and provides for electronic and physical security of personal and health information. It affects companies that store and transmit protected health information in electronic form, which includes health plans, health care clearinghouses, and health care providers. HIPAA is not legislation that sets standards for computer applications' functional capabilities. It sets standards of behavior and requires the use of best practice.

All health care organizations and related entities must implement complete and effective security solutions that will protect their valuable information assets. The portion of HIPAA that is security related can be found in Title II, which includes a section, known as "administrative simplification," that requires improved efficiency in healthcare delivery by standardizing electronic data interchange, protection of confidentiality, and security of health data through setting and enforcing standards.

Figure 2: Common network security target model.

At the time of this writing, there was no HIPAA compliant software, HIPAA providers, HIPAA firewall, or any other HIPAA security term for which you could put the characters “HIPAA” in front of. The issue is applying adequate security to your processes and treating patient data according to HIPAA privacy regulation. Two ways to ensure compliance are by (a) deploying digital signature technology and (b) using public key infrastructure (PKI) to protect information integrity (Artisoft, 2003).

- **Sarbanes—Oxley Act.** The Sarbanes—Oxley Act of 2002 includes provisions addressing audits, financial reporting and disclosure, conflicts of interest, and corporate governance at public companies. It holds executives personally liable for many operational aspects of a company, including computer security, by making them pledge that the company’s internal controls are adequate.

Under this legislation, the Securities and Exchange Commission holds executives accountable for reliable internal controls, record retention, and fraud detection. As a result, executives are looking to information systems (IS) and to IS auditors for help (Volonino, Gessner, & Kermis 2004). They state that

while the act stops short of mandating detailed security provisions, the requirements for companies to produce audit reports is driving a recognition that IT security policies and procedures are an essential part of the process. . . . ‘Enhanced Regulatory Compliance’ regulations, such as Gramm—Leach—Bliley, SARBOX, and HIPAA, require organizations to

ensure that unauthorized users cannot access systems that contain sensitive data.

Groupware Risks, Threats, and Vulnerabilities

Risks, threats, and vulnerabilities are constantly changing as the technologies used by different organizations change and new technologies are created, and as threats adapt and evolve with the technology. Figure 2 (Horton and Mugge, 2003) depicts a model that indicates different areas of an information system network that should be considered for protection. In the model, it identifies the key services and applications present, such as the organization’s firewall, users, contractors, and so forth. Next, the operating systems exposed should be inventoried and, finally back-end organization should be defined, keeping in mind reliance on people, process, and technology.

E-mail has traditionally been considered to be a separate application from groupware. In a true groupware implementation, for security reasons, there should be minimal or no content exchanged via e-mail. However, e-mail is increasingly being integrated with groupware (e.g., Lotus Notes, Groove, Kubi, and Microsoft Outlook). For example, Kubi Software’s groupware product “enables business users to collaborate spontaneously without having to leave Email—the application in which they ‘live’ for most of the business day” (Kubi Software, 2004). Today, we have access to increasingly rich graphic interfaces that provides workspaces in a familiar e-mail environment.

Many distributed teams communicate via e-mail because it is fast, very familiar to users, inexpensive, and convenient. However, it can also expose private messages to “snoopers” and “hackers” if not encrypted. Users of e-mail must be careful about messages that have files

attached that may be suspicious. These files can carry viruses, worms, or other malicious computer code. A virus can be damaging to distributed computer systems because it spreads by executing infected programs. Worms are self-propagating malicious pieces of computer codes that are highly automated.

Parasites refer to unsolicited commercial software that often gets installed on computers, unbeknown to the user. Antivirus software programs or firewalls often do not detect these programs. These programs can cause unwanted pop-up advertising, capture information about the user's activities on the Web, and sometimes alter browser settings.

Deception

The visual anonymity inherent in most computer-mediated communication (CMC) systems results in a lack of certainty regarding an individual's identity. This provides opportunities for users to engage in different types of deception practices. Deception is an area in computer-mediated communications that has only recently begun to receive attention. It is defined by Buller and Burgoon as "a message knowingly transmitted by a sender to foster a false belief or conclusion by the receiver" (Buller & Burgoon, 1994).

It should come as no surprise that information technology (IT) is being used to transmit deceptive information, given that deceptive communication is common during traditional face-to-face interactions and given that CMC is widely used in organizations and individual homes (e.g., instant messaging, e-mail, discussion groups, usernet, etc.). Some of the ways in which humans deceive others in CMC generally include identity play, impersonations, lies, fabrications, concealments, misdirection, bluffs, trolling, fakery, deflections, evasions, exaggerations, and the like. More specific and increasingly troublesome forms of deception are e-mail hoaxes, social engineering, and gender bending.

Examples of e-mail hoaxes include claims offering recipients money for forwarding messages to others and messages warning recipients to delete virus files on their computers that are really system files. Social engineering occurs when a person poses as someone else to obtain access to off-limits information or to persuade the deceived to comply with some other type of request. It has been described as "hacker-speak" for tricking a person into revealing a password. A classic social engineering trick is for a hacker to send e-mail claiming to be a system administrator. The hacker will claim to need your password for some important system administration work and ask you to e-mail it to him/her. Often the hacker will send this message to every user on a system, hoping that one or two users will fall for the trick. Similarly, "phishing" is an increasingly common practice where cyberthieves fish for information among thousands of potential victims, using cleverly disguised e-mails to trick recipients into volunteering personal and financial information. The e-mails claim to be from a legitimate source, such as a bank or government entity, and usually ask recipients to update their account or personal information.

Gender bending involves experimenting with gender identities in CMC. This phenomenon is more commonly

observed in multiple user dialogues (MUDs) and in chat rooms. It often involves men posing as women, women posing as men, or either posing as nongendered or "neutral" characters.

The problem is that people are not very good at detecting deception, especially in CMC, where there is often the absence of certain verbal and nonverbal cues. George and Marett suggest that one possible remedy for improving detection accuracy is to educate people about various indications of deception and then train them to spot these indicators when they are used in normal communication (George & Marett, 2004).

Denial of Service

DoS and DDoS (denial-of-service and distributed denial-of-service) attacks have been a growing concern as more and more businesses do business via the Internet. DoS attacks are deliberate attempts by intruders to prevent legitimate users from accessing and using a site or a particular service. In DDoS attacks, the Internet is often used to break into computers, thereby using the compromised computers to attack a network. As a result, several computers across the Internet can be used to attack other systems. Such attacks can be directed at an operating system or at the network. Routers can also be used as attack platforms. Some examples of DoS and DDoS attacks include

- attempts to "flood" a network, thereby preventing legitimate traffic;
- attempts to disrupt connections between two machines, thereby preventing access to a service;
- attempts to prevent a particular individual from accessing a service;
- attempts to disrupt service to a specific system or person; and
- consumption of scarce resources (Cert Coordination Center, 2001).

Bandwidth consumption is a kind of DoS attack where an intruder uses up all of the victim's bandwidth or uses all of a system's resources on a server. Intruders can also shut down a system by generating an excessive number of e-mail messages, thus flooding the network.

DoS Attack

In February 2000, a number of popular Web sites were slowed or shut down by distributed denial of service attacks. Amazon.com, buy.com, CNN.com, eBay, E*Trade, and ZDNet were all victims of these attacks. Analysts estimated that Yahoo! lost \$500,000 in e-commerce and advertising revenue when it was knocked offline for 3 hr (Dunne, 2001).

Solutions for Security Problems

Tackling the information security problem for individuals using groupware can be achieved in much the same way as with computer systems in general. This can be achieved by the organization's creation of a team responsible for evaluating the various internal and external risks

and their potential effects on the organization, and then developing and practicing a detailed, comprehensive, and easy-to-follow plan. The goal should be to avoid unauthorized access, prevent intrusion, and stop secret information disclosure.

Risk Analysis

An analysis of risk should include both internal and external risks. Internal risks include human error and physical computer security threats. External risks include the potential for unauthorized users to gain access to computer systems.

Cryptography software is used to protect companies from hackers. This software encrypts and decrypts messages. Encryption transforms (scrambles) data into unreadable forms, and decryption restores data to the original forms. Secure socket layer protocol (SSL) provides a method that encrypts information passed between a server and a browser (on the client machine) to prevent others from accessing user information.

Access Controls

To gain access to the system, users should be required to authenticate their identities via the use of password codes (e.g., personal identification numbers), magnetically coded badges, voice print analysis, or other biometric authentication devices. Procedures should exist to authenticate which users will have read-only, write-only, or read-and-write access.

Other measures include third-party certification, firewalls, and intrusion detection systems. Third-party certification refers to a neutral third party who has verified the authenticity of a Web site and has issued the owners of that Web site a unique certificate (e.g., VeriSign, Inc. is a certificate provider). Firewalls are software or hardware that is placed between the company's network and the Internet to provide ongoing protection by denying suspicious traffic. An intrusion detection system informs companies when they are under attack.

Horton and Mugge (Horton & Mugge, 2003) give the following as effective security defense measures:

- Protect user accounts.
- Protect administrative accounts and remote management interfaces.
- Protect against Trojan applications, viruses, and other malicious scripts.
- Protect against software architecture design flaws.
- Protect against system and application configuration errors.
- Protect against software programming errors.
- Protect against user naiveté, carelessness, or stupidity.
- Protect against eavesdropping (from network sniffing to shoulder surfing).
- Protect against user impersonation (electronically or by phone).
- Protect against physical theft (office, datacenter, traveling, and remote locations).
- Protect against inappropriate use of resources.

Symantec provides the following 10 steps to protect your enterprise from denial of service attacks (<http://enterprisesecurity.symantec.com>):

1. Adopt a security policy and educate, educate, educate.
2. Use multiple internet service providers (ISPs, i.e., use different providers who use different pipes).
3. Practice good load balancing. Distribute your site's load across multiple servers—even multiple sites, if possible.
4. Insure redundancy (or “fail over”) in all network devices, servers, and power sources.
Develop recovery plans covering each potential failure point for your site.
5. Protect your critical systems with a hardened firewall. Although any firewall can control access by using Internet protocol (IP) addresses and allowing “only port 80” to the Web server, be sure your firewall also can analyze the incoming Web access data stream to filter out sophisticated attacks embedded within the protocol and hypertext markup language (HTML).
6. Auto-check your Web site.
7. Keep the system simple. Minimize the number of services running on the systems by turning off the options you don't need.
8. Stay current on upgrades, updates, vendor advisories, and security bulletins.
9. Stay vigilant through testing and monitoring.
10. Be ready to respond.

DEFINING AND CLASSIFYING GROUPWARE IN THE INTERNET AGE

Groupware is technology—typically software and networks—designed to support people working in groups. Under this broad definition, any technology that is used to communicate, cooperate, coordinate, solve problems, compete, or negotiate is classified as groupware. This definition can apply to some of the newest forms such as informational Web pages and multiuser database applications, as well as to more established and familiar forms such as e-mail, newsgroups, videophones, or chat. The simplicity and breadth of this definition is intentional because definitions of groupware tend to evolve as rapidly as the technologies themselves, often becoming outdated because new technologies support group work in ways that were not represented. For example, an early definition for groupware was “intentional group processes plus software to support them.” At the time, this definition placed more emphasis on the activities of the group and much less on the technologies, which were quite limited. As we will see, although much of that early definition is valid, the reality that it does not address is that much group work contains a great deal of individual work. Many modern forms of groupware, as we explain, support not only the actual group work, but also much of the individual group members' work that may precede, be contemporaneous with, or follow that actual interactive group processes.

Table 1 Traditional Dimensions of Groupware

	Same time (synchronous)	Different time (asynchronous)
Same place (collocated)	GSS, GDSS, presentation support	shared workspaces
Different place (dispersed)	videophones, whiteboards, chat, virtual rooms	e-mail, threaded discussion, workflow

A later definition of groupware by Robert Johansen (1988) is “specialized computer aids that are designed for the use of collaborative work groups.” Again, this definition rightly focused on the actual group collaborative processes but does not mirror the current reality of how the tools extend to support the individual work processes that underpin group work. A major contribution by Johansen and others, however, was to provide a categorization scheme for groupware technologies that is still valuable today. As shown in Table 1, groupware technologies can largely be categorized along two primary dimensions:

1. whether users of the groupware are working together at the same time (real-time or synchronous groupware) or different times (asynchronous groupware), and
2. whether users are working together in the same place (collocated or face-to-face) or in different places (distributed or dispersed).

Another way to understand groupware is by the generic group processes that it supports: communication (pushing or pulling information), collaboration (sharing information and building shared understanding), and coordination (delegating task, group technique, sequential sign-offs, etc.). Some definitions of groupware call erroneously for the added dimension of a common goal. Although all systems require some agreement among participants (at minimum that they should agree to

participate in the process), groupware can readily support negotiation-type interactions. Management of conflict is often a crucial feature of a groupware system (a voting tool is a good example of this incorporated in groupware designed to support meetings). However, this classification scheme also does not pay much attention to individual work processes that can be supported by groupware and are a component of group work, and it does not emphasize geographic location or temporality.

To build on these earlier perspectives and integrate them with the realities of individual work processes, as well as to reflect the ubiquity of access afforded by the Internet (and, commonly, proprietary organizational networks and intranets), we offer a new model of groupware. Table 2 illustrates an emerging model for groupware as represented by a 3 × 3 matrix of the nine discrete yet interrelated software groups. From a user’s perspective, the horizontal axis represents a spectrum between synchronous and asynchronous functionality (in typical usage) but now includes “any time/any place” to connote the accessibility to information or functionality that the tool can provide. As we discuss, many modern forms of groupware, although primarily synchronous or asynchronous, have features that are accessible any time and any place if one has an Internet or intranet connection and a browser (Coleman, 1997). The vertical axis represents the group size targeted by the technology. In this representation, the “place” dimension of Table 1 has disappeared—networks have so increased in speed and computers have become so ubiquitous and powerful that geographical dispersion has

Table 2 Categorization of Groupware Systems by Time and Targeted User Audience

	Asynchronous groupware	Any time/Any place groupware	Synchronous groupware
Large	Database-oriented Portals Collaborative portals E-community Newsgroup/Usenet List servers	E-learning/virtual classrooms	Web real-time communication (RTC) Audio/video conferencing
Limited	Telework virtual workplaces Workflow systems Personal portals Group calendars	Distributed project management Collaborative writing Threaded discussion	Group decision support systems (GDSS) Meeting support Chat Shared whiteboard
Individual/dyad	Electronic mail	Mobile/wireless messaging	Collaborative customer relationship management (CRM)

lost its categorization power. For instance, any computer-supported meeting can be attended in face-to-face mode or by cyberspace connection.

GROUPWARE FUNCTIONALITIES IN THE INTERNET AGE

Common Groupware Functionalities

Although stand-alone groupware components such as e-mail can still be purchased separately, many modern products offer a number of common functionalities (e.g., e-mail) integrated in one suite. These common functionalities (or characteristics) might include the following:

- **Graphical user interfaces (GUIs).** Most groupware programs today can take advantage of the color graphics and sound capabilities of multimedia computers. They are often made available via the Internet as either a client/server application or an application that uses a common browser interface.
- **WYSIWIS.** This stands for What You See Is What I See. It is analogous to two people each at their own homes watching the same television show at the same time. Computer technology extends this concept in groupware products and allows users to interact and communicate in a WYSIWIS environment.
- **Integration.** Most groupware products integrate components of different applications into a standard interface so the product feels like a multifaceted tool.
- **Online communication.** Discussions can be held in real time, with active interaction between participants. Several products allow for textual and video exchanges in real time.
- **Replication/synchronization.** Replication is the process of duplicating and updating data in multiple computers on a network, some of which are permanently connected to the networks. Others, such as laptops, may only be connected at intermittent times. Synchronization is the goal of having all computers in a distributed network providing the same information at the same time. The replication/synchronization concept has two components: (a) everyone should have access to the same information in the database and be able to replicate the data locally; (b) several users can make changes to the same document, and somehow the system synchronizes all those changes into one master copy of the database. If the replication manager has multiple update requests to the same record, the system sends messages out asking for clarification as to what the correct entry should be. An example of this function is the use of a shared database of product inventory by a distributed sales force. When each person sells some units, the database would update itself so that there is an accurate count of inventory available to all users.
- **Remote access.** Using database replication/synchronization, remote users can access and update information held in a groupware database (see previous example).
- **Workflow.** Workflow is a typical groupware subsystem that manages a task through the steps required for its

completion. It results in the automation of standard procedures (such as records management in personnel operations) by imposing a set of agreed-upon business rules on the procedure. Each task (or set of tasks), when finished, automatically initiates the next step in the process, until the entire procedure is completed. Although some users implement self-contained work flow systems, the technology often appears in more recent groupware and image management systems. Lotus Notes for Domino, for example, provides work flow applications that can be customized to an organization's particular needs.

- **Time management.** These groupware products offer group calendar diaries and group project schedules to help managers and subordinates better coordinate their time. Microsoft Outlook, among other products, offers these and related functionalities.
- **Secretarial functions.** These are background processes that perform "clean up" or "overhead" services for users. For example, the secretary would manage the real-time messaging system to manage the receipt of messages by accepting high-priority interactions but blocking unnecessary interruptions and redirecting (and prioritizing) those less important messages to the users' electronic mail platform. These filtering functions are common in many e-mail groupware products.
- **Project management.** Groupware's increasing adoption is due to its ability to easily support project management endeavors. As personal computers and networks have become more powerful, they provide the necessary performance for today's groupware, imaging, and document management applications. These technologies, originally distinct, have become more integrated in many organizations with the aim of supporting project management. This type of system improves distributed project management through controlling management of documents, schedules, and personnel; and allowing project personnel to be geographically dispersed without regard to location or time; providing communication among project personnel through a variety of means, including e-mail and discussion forums. Because project personnel and project information are linked, project information remains current and accessible. The right information gets to the right people at the right time.

Cutting-Edge Groupware Functionalities

As we noted in previous sections, it is still useful to categorize groupware tools on the basis of whether they support synchronous or asynchronous work, although some modern groupware tools support processes that do not fit neatly into these two forms. For simplicity's sake, we divide our discussion of modern Internet-age groupware into these two categories and comment on how the technologies fit in our classification scheme (Table 2).

Asynchronous Groupware

Asynchronous groupware can take a variety of forms from the early and simple (but very useful and enduring), such as electronic mail, to the most modern and complex, such as Lotus Notes for Domino. Although some forms

such as e-mail have been free-standing organizational communication support systems often run on a firm's local area network, all of the forms we describe can and typically do run on the Internet (as well as on private portions of the Internet such as corporate intranets and extranets). Below are functional descriptions of some of these systems.

System Profile: Lotus Notes/Domino—A Database-Oriented Portal

Lotus Notes is a sophisticated asynchronous groupware system from the Lotus Corporation, a subsidiary of IBM. It enables users to quickly and easily build secure and reliable messaging, calendaring and scheduling, and collaborative application solutions. Notes provides traditional group support functions that are tightly integrated to provide a virtual "workspace," library, and secretary for its users. Group members are able to communicate via e-mail, store all digitized information related to a project in a dedicated and secure database, and the scheduling and calendaring support functions aid in project management. These functions let an organization and its workers interact so that users at different geographic locations can share information with each other; exchange comment publicly or privately; and keep track of project schedules, guidelines and procedures, plans, white papers, and so forth. Notes keeps track of changes and makes updates to replications of all databases in use at any site.

Notes runs on a special server called the Lotus Domino Server. The servers and workstations use a client/server processing model and replicated databases are updated using special programs called remote procedure call (RPC) requests. Notes can be coordinated with Web servers and applications on a company's intranets.

In addition, Notes has strong workflow structuring capabilities and provides the basis for a document management system that is well integrated with its database functions. Although it ships with these and a number of other customizable application "shells," Notes also provides simple facilities so that custom end-user applications can be developed. Given the product's inherent complexity, new users, as well as application developers, face a steep learning curve.

Some aspects of Notes (e.g., the database functions) can be used by individuals as well as small and large groups. The database, for example, also would fit into our "any time/any place" dimension by virtue of its Internet or intranet accessibility. Other aspects such as e-mail fit more neatly into our "asynchronous" dimension and our individual/dyad dimension, although the latter could extend to large groups when used to support list server functions.

It should be noted that Notes is not a relational database and that the organization of a Notes database is different from that of a relational database (Moignard, 2004). A relational database contains tables of same-type "records," or sets of fields, and is optimized for rapid access by table-oriented operations. In contrast, Notes has no schema, does not implement referential integrity, and keeps application code and data in the one database. Its database can contain any number of notes, and a note can contain any number and type of field.

- **Collaborative portals.** Found on the Internet or intranets, collaborative portals are a single point of useful, comprehensive, ubiquitous, and integrated access. There are corporate, community (e-community), and personal portals that cater to specific communities of interest by providing tailored content. Groupware has recently been developed to automate the technical aspects of deploying a Web-browser-based portal so that end users are freed from the rigid limitations of traditional portal technology (Web page development) and end users can conduct business by the terms of their own communities, interests, tasks, and job responsibilities. Portals are increasingly becoming collaborative tools: they can manage personal data, create spontaneous collaborative work spaces, have real-time chat capabilities, and increase communication effectiveness by keeping track of who is online within the community (with pertinent information about users, such as topics of interest and job functions). These tools are also "any time/any place" and can support small groups. They may be asynchronous, serving more as passive postings of information, or when enabled with the appropriate technology, support near-synchronous interaction (e.g., a chat room).

Blackboard 6—Community Portal System features a highly customizable community portal environment that unifies academics, commerce, communities, and administrative services online through one integrated interface. This advanced functionality is backed by a sophisticated product architecture that runs on relational databases and can be scaled to support tens of thousands of users utilizing a multiserver configuration.

First Class 8.0 is a highly scalable, feature-rich messaging and communications solution for enterprises, learning organizations, governments, and service providers. Their collaborative groupware provides users with the ability to build online communities and provide unified communications.

Microsoft 2003 Microsoft's newest office suite, focuses on getting users to work together faster and smarter. The program's expanded XML (extensible markup language) lets a company tie data from a back-end server database (e.g., SQL Server or Oracle) to the Microsoft Office documents its employees use day in and day out. Using XML in Office applications can give users who share documents more accurate data automatically.

Microsoft Office 2003's SharePoint Portal Server gives users quick access to business-critical information throughout an organization. It integrates basic document management functions such as check-in, check-out, document profiles, and document publishing with Microsoft Office products used every day. In addition, users can create SharePoint Portal Server workspaces that could improve a team's efficiency. Some examples of the team collaboration and team management features include the following:

- Share information with enhanced security and work together with employees and customers from any location.

- Document alerts—automatic e-mail notifications alert your team to content changes.
- Online discussions—document discussions, facilitate collaboration and team review.
- Assign users different levels of access using flexible, role-based security.
- Simple Web hosting and document file sharing.

• **Newsgroups/Usenet.** Usenet is a collection of user-submitted notes or messages on various subjects that are posted to servers on a worldwide network. Each subject collection of posted notes is known as a newsgroup. There are thousands of newsgroups and it is possible for users to form new ones. Newsgroups are similar in spirit to e-mail systems except that they are intended for messages among large groups of people instead of one-to-one communication. In practice, the main difference between newsgroups and mailing lists is that newsgroups only show messages to a user when they are explicitly requested, whereas mailing lists deliver messages as they become available. Most browsers, such as those from Netscape and Microsoft, provide Usenet support and access to any newsgroups that users select. On the Web, Google and other sites provide a subject-oriented directory as well as a search approach to newsgroups and help users register to participate in them. In addition, there are other newsgroup readers that run as separate programs. This technology is typically asynchronous with any time/any place access via the network and supports large and small groups.

• **Listserv.** Listserv is a small program that automatically redistributes electronic mail to names on a mailing list. Users can subscribe to a mailing list by sending an e-mail note to a mailing list they learn about; Listserv will automatically add the name and distribute future e-mail postings to every subscriber. (Requests to subscribe and unsubscribe are sent to a special address so that all subscribers do not see these requests.) This technology is typically asynchronous with any time/any place access via the network and supports large and small groups.

• **Work Flow Systems.** These allow digital versions of documents to be routed through organizations through a relatively fixed process. A simple example of a work flow application is an expense report in an organization: an employee enters an expense report and submits it; a copy is archived then routed to the employee's manager for approval; the manager receives the document, electronically approves it, and sends it on; and the expense is registered to the group's account and forwarded to the accounting department for payment. Work flow systems may provide features such as routing, development of forms, and support for differing roles and privileges.

Work flow systems can be described according to the type of process they are designed to deal with. Thus we define three types of work flow systems:

- *Image-based work flow systems* are designed to automate the flow of paper through an organization by transforming the paper into digital "images." These were the first work flow systems that gained wide acceptance. These systems are closely associated with "imaging" technology and emphasize the routing and

processing of digitized images. Lotus Notes, for example, supports both document management (via scanning or "imaging") and work flow by directing the digitized material via user-defined routes.

- *Form-based work flow systems* are designed to intelligently route forms throughout an organization. These forms, unlike images, are text based and consist of editable fields. Forms are automatically routed according to the information entered on the form. In addition, these form-based systems can notify or remind people when action is due. This can provide a higher level of capability than image-based workflow systems. Notes can also provide customizable forms (invoices, for example).

- *Coordination-based work flow systems* are designed to facilitate the completion of work by providing a framework for coordination of action. The framework is aimed to address the domain of human concerns (business processes), rather than the optimization of information or material processes. Such systems have the potential to improve organizational productivity by addressing the issues necessary for customer satisfaction, rather than automating procedures that are not closely related to customer satisfaction. Customer relationship management systems, for example, can be set up to route customer problems to specialists.

Work flow systems can support individual and dyadic functions but are typically used to support larger groups. They are typically asynchronous and may permit any time/any place access.

- **Group Calendars.** These allow scheduling, project management, and coordination among many people and may provide support for scheduling equipment as well. Typical features detect when schedules conflict or find meeting times that will work for everyone. Group calendars also help to locate people. Typical concerns are privacy (users may feel that certain activities are not public matters), completeness, and accuracy (users may feel that the time it takes to enter schedule information is not justified by the benefits of the calendar). Calendars are also typically asynchronous with any time/any place access.

- **E-Mail.** E-mail is by far the most common groupware application. Although the basic technology is designed to pass simple messages between two people, even relatively basic e-mail systems today typically include interesting features for forwarding messages, filing messages, creating mailing groups, and attaching files with a message. Other features that have been explored include automatic sorting and processing of messages, automatic routing, and structured communication (messages requiring certain information). E-mail, although typically asynchronous, can appear to become "near synchronous" with a fast-enough network.

- **Handheld Computers.** These are also referred to as palmtops and personal digital assistants (PDAs) and are changing the way people use and interact with information (e.g., PDAs featuring Palm OS and Windows CE). Because of their small size, users can take their most important information with them. The highest level of PDA use is in the area of teamwork and collaboration.

“Palmtop computers can be synchronized with programs such as Lotus Notes and Novell Groupwise for team scheduling and project management. Databases and documents can be shared to monitor organizational goals. Communications such as e-mail and Web-based discussions take on new meaning. Wireless networks allow instant messaging and communication anywhere in the network” (Pownell & Bailey, 2000). Microsoft Outlook is another program that can exchange information such as e-mail, schedules, and contacts with a variety of handheld devices.

Synchronous Groupware

Synchronous groupware systems are interactive computer-based environments (physical and virtual) that support individuals (collocated or dispersed) working together at the same time. This emerging generation of groupware is also incorporating new technologies, such as Internet telephony, videoconferencing, speech recognition, and simplified yet secure connections, with corporate databases. However, the key point of collaborative software remains connecting the “islands of knowledge” represented by each employee for the organization’s greater good.

Featured Systems: GroupSystems, Groove Virtual Office, and Kubi Client

GroupSystems is a meeting support system that offers a comprehensive suite of tools that can shorten the cycle time for business processes such as strategic planning, product development, and decision making. There are three main features that apply to all tools in the GroupSystems suite:

- **Simultaneous contribution**—everyone is “speaking” at once, which saves time and increases productivity.
- **Anonymity**—the identity of each contributor is unknown, so participants tend to feel freer to express their opinions, and ideas are evaluated more objectively.
- **Complete records**—at the end of a meeting, you can easily produce a complete and accurate report of all ideas, comments, and vote results, in .doc or .rtf format.

There are seven different tools in the GroupSystems suite. Each focuses on a specific aspect of a group effort, including idea generation, evaluation, organization, and exploration. For example, their electronic brainstorming module (EBS), a tool that supports simultaneous and anonymous idea sharing, is commonly used for team building, broad or focused brainstorming, and visioning or strategic planning sessions. Their group-voting module supports eight voting methods, including a customizable point scale, and makes the decision process efficient, flexible, and powerful. Organizations use the voting module to evaluate, make decisions, and build consensus.

Early forms of the GroupSystems tool set were designed to run on local area networks, often in dedicated meeting rooms with networked personal computers (PCs), electronic whiteboards, and audiovisual support. More recent forms are now Web-enabled and provide similar functionality to distributed meetings. In addition,

these systems are among the oldest and best researched types of groupware (e.g., Nunamaker, Briggs, Mittleman, Vogel, & Balthazard, 1997).

Groove Virtual Office 3.0 was designed to help users share documents, track issues, hold ad hoc meetings, and access legacy system data. Users can work securely over the Internet as if they and their team are in the same physical location. Beyond being able to share files, Groove’s work space includes a discussion board, work flow, a chat window, and common tasks such as setting alerts.

Kubi Client’s collaborative e-mail is a new class of collaboration software that tightly couples the power of collaborative functionality and ease of use of e-mail. Kubi makes it easy for e-mail users to spontaneously share documents, discussions, contacts, events, and tasks in organized team spaces without leaving e-mail. Team members can join Kubi Spaces, begin collaborating immediately, and share knowledge, documents, and ideas with others. It can be integrated to work with other software products such as Microsoft Outlook and Lotus Notes.

Typical synchronous groupware includes the following types.

- **Chat Systems.** They permit many people to write messages in real time in a public space. As each person submits a message, it appears at the bottom of a scrolling screen. Chat groups are usually formed by listing chat rooms in a directory by name, location, number of people, topic of discussion, and so forth. Chat systems, like their cousin e-mail, may be accessed any time/any place when hosted on an Internet server or may be available only at certain times or via certain connections if run on a proprietary intranet.
- **Shared Whiteboards.** An electronic whiteboard is one of several kinds of writeable presentation display systems that can be used in a classroom or videoconference. These whiteboards generally fall into one of three categories: standalone *copy boards*, where the content of the whiteboard can be scanned and printed out; *peripheral boards*, which transfer information in the form of digital files to an attached computer; and *interactive boards*, which are like large touchscreen monitors that can be synchronized to an attached computer (users can interact with the display, visit Web sites, and access databases directly from the board). Some peripheral boards can accommodate a projector that can be calibrated to the display, making them interactive. There are a number of add-on *whiteboard digitizer* products available that can also be used to make traditional dry-erase whiteboards interactive.

In cyberspace, a whiteboard is a space on the display screen in which one or more participants write or draw, using a mouse, keyboard, or other input device. It allows users to view and draw on a shared drawing surface even from different locations. This can be used, for instance, during a phone call, where each person can jot down notes (e.g., a name, phone number, or map) or to work collaboratively on a visual problem. Most shared whiteboards are designed for informal

conversation, but they may also serve structured communications or more sophisticated drawing tasks, such as collaborative graphic design, publishing, or engineering applications. Microsoft's NetMeeting allows collaborative real-time use of its PowerPoint application via the Web. Users can pass control of the cursor to each other while sharing a single view of a common screen, thus collaborating on the development of a slide or graphic. Although whiteboards themselves might be real physical devices or may be virtual representations, the information they capture can be accessed any time/any place when they are connected to a network.

- **Collaborative Customer Relationship Management (CRM) Systems.** Collaborative customer relationship management (CRM) systems are groupware that support the communication and coordination across the customer life cycle between channels and customer touch points. They are aimed at providing an enhanced understanding and management of the customer relationship—increasing knowledge of customer behavior, building switching costs, and increasing customer satisfaction and retention—especially relationship-centric, process-centric, and productivity-centric collaboration. Collaborative CRM addresses the problems of traditional CRM solutions that are inwardly focused on an enterprise, not on the customer. By understanding the heterogeneous environment of most enterprise application portfolios, collaborative CRM provides a framework where sales, service, marketing, and product development organizations can work together but still maintain their unique way of doing business. Some CRM functions are very similar to work flow and are asynchronous, but other functions support the synchronous interaction that organizational teams utilize to provide customer support.

- **Videoconferencing.** A videoconference is a live connection between people in separate locations for the purpose of communication, usually involving audio and often text as well as video. At its simplest, videoconferencing provides transmission of static images and text between two locations. At its most sophisticated, it provides transmission of full-motion video images and high-quality audio between multiple locations.

Videoconferencing software is quickly becoming standard computer equipment. For example, Microsoft's NetMeeting is included in Windows 2000 and is also available for free download from the NetMeeting homepage. For personal use, free or inexpensive videoconferencing software and a digital camera afford the user easy and inexpensive live connections to distant friends and family. Although the audio and video quality of such a minimal setup is not high, the combined benefits of a video link and long-distance savings may be quite persuasive.

The tangible benefits for businesses using videoconferencing include lower travel costs and profits gained from offering videoconferencing as an aspect of customer service. The intangible benefits include the facilitation of group work among geographically distant teammates and a stronger sense of community among business contacts, both within and between companies.

In terms of group work, users can chat, transfer files, share programs, send and receive graphic data, and operate computers from remote locations. On a more personal level, the face-to-face connection adds nonverbal communication to the exchange and allows participants to develop a stronger sense of familiarity with individuals they may never actually meet in the same place.

A videoconference can be thought of as a phone call with pictures—Microsoft refers to that aspect of its NetMeeting package as a “Web phone”—and indications suggest that videoconferencing will some day become the primary mode of distance communication. Web-enabled videoconferencing is accessible any time/any place, although bandwidth considerations can limit the quality of transmission and reception.

- **Audio/Video Communications (RTC).** Real-time communication (RTC) systems allow two-way or multiway calling with live video, which is essentially a telephone system with an additional visual component. Cost and compatibility issues limited early use of video systems to scheduled videoconference meeting rooms. Video is advantageous when visual information is being discussed but may not provide substantial benefit in most cases where conventional audio telephones are adequate. In addition to supporting conversations, video may also be used in less direct collaborative situations, such as by providing a view of activities at a remote location.

Many RTC systems allow for rooms with controlled access or with moderators to lead the discussions, but most of the topics of interest to researchers involve issues related to unmoderated, real-time communication, including anonymity, following the stream of conversation, scalability with number of users, and abusive users. Although chat-like systems are possible using nontext media, the text version of chat allows a direct transcript of the conversation, which not only has long-term value but also allows for backward reference during conversation, which makes it easier for people to drop into a conversation and still pick up on the ongoing discussion.

- **Threaded-Discussion Systems.** Threaded-discussions systems are systems where messages can be posted for public display. The groupware tool allows participants to communicate with each other asynchronously. Communication takes place by having participants create a continuous chain of posted messages on a single topic. This chain is known as a “thread” or a “threaded discussion.” Several parallel threads can make up a full conversation. The threads can then be used to build a hierarchy with the content. In some instances, a threaded discussion may also be called a bulletin board or a forum. A discussion can be used to discuss general issues, discuss the specifics of an issue, or organize related content. With a threaded-discussion tool, users can read posted messages, compose new messages, attach documents to posted messages, and search and compile posted messages. Similar to its relatives, e-mail and its variants, these systems are any-time/any-place accessible with the right connection and hardware.

- **Rich Internet Applications.** Rich Internet applications (RIAs) are new technologies that offer the benefits of distributed, server-based Internet applications with the rich

interface and interaction capabilities of desktop applications. RIAs possess the functionality to interact with and manipulate data rather than simply visualize or present it.

This technology was developed as a response to the limitations inherent in HTML-based applications. Although the cost of HTML deployment is low, and it is easy to learn, certain applications are not a good fit with HTML. Some complex applications may require several page redraws to complete a transaction, resulting in unacceptable slow interaction. In contrast, RIAs utilize relatively robust client-side rendering engines that can present very dense, responsive, and graphically rich user interfaces. Also, data can be cached in the client, which allows a significantly more responsive user interface.

- **Decision Support Systems.** Decision support systems (DSSs) are designed to facilitate decision-making. They provide tools for brainstorming, critiquing ideas, putting weights and probabilities on events and alternatives, and voting. Such systems enable presumably more rational and even-handed decisions. Primarily designed to facilitate meetings, they encourage equal participation by, for instance, providing anonymity or enforcing process structure (such as a nominal group technique or a Delphi technique). Although in the past some forms were primarily designed for same-place/same-time situations, many individual tools can be installed on a network for any-time/any-place access. Some integrated suites such as GroupSystems (profiled previously) are now Web-enabled.
- **Virtual Workplace.** The virtual workplace concept seeks to create an electronic facsimile of an office workplace where coworkers would meet and work. This is typically manifest as a Web site that has pictures of team members, links to instant messaging, a link to asynchronous discussion boards, and access to all the documents and database links needed. The goal is to enhance also the sense of being on a team by giving dispersed team members a “place” to go, where they can all “meet” (i.e., communicate textually and possibly telephonically and/or visually in real time). Lotus Notes/Domino features a number of functionalities that support this goal.
- **Collaborative Writing Systems.** These may provide both real-time support and offline support. Word processors may provide asynchronous support by showing authorship and by allowing users to track changes and make annotations to documents. Authors collaborating on a document may also be given tools to help plan and coordinate the authoring process, such as methods for locking parts of the document or linking separately authored documents. Synchronous support allows authors

to see each other’s changes as they make them and usually needs to provide an additional communication channel to the authors as they work (via video-phones or chat). Microsoft’s NetMeeting provides this synchronous functionality with their Word application, and similar functionality with their spreadsheet (Excel), database (Access), and graphics programs (PowerPoint, as noted previously).

- **Mobile/Wireless Messaging.** Messaging is the ability to easily see whether a chosen friend or coworker is connected to a network and, if they are, to exchange relatively short messages with them. Messaging differs from electronic mail in the immediacy of the message exchange and also makes a continued exchange simpler than sending e-mail back and forth. Most exchanges are text only. However, some services now allow voice and attachments.

For messaging to work, the sender and receiver must both subscribe to a network service and be online at the same time, and the intended recipient must be willing to accept instant messages. Under most conditions, messaging is truly “instant.” Even during peak Internet usage periods, the delay is rarely more than a second or two. It is possible for two people to have a real-time online “conversation” by messaging each other back and forth.

Mapping Groupware Functionality to Work Processes

The broad (and expanding) range of modern groupware functionality means that those who adopt the technology would benefit from some guidance. To this end, the “groupware grid” (Figure 3) can serve as a theory-based, heuristic model for mapping the functionalities of groupware technology to organizational work. The groupware grid is useful for managers to understand the dimensions of individual and group work that can be supported by the different general functionalities. It is consistent with our technology-oriented classification scheme presented earlier but places its emphasis on the type of work that would be supported.

Team Theory and the Groupware Grid

The horizontal axis of the groupware grid derives from the team theory of group productivity (adapted from Briggs, 1994). *Webster’s Dictionary* defines a team as a collection of people working together for some specific purpose. Team theory is a causal model for the productivity of a team. It asserts that team members divide their limited attention resources among three cognitive

	Communications support	Deliberation support	Information access support
Concerted work level			
Coordinated work level			
Individual work level			

Figure 3: Groupware grid.

processes: communication, deliberation, and information access. Team theory posits that these processes interfere with one another, which limits group productivity.

Team theory's communication construct posits that people devote attention to choosing words, behaviors, images, and artifacts and presenting them through a medium to other team members. Team theory's deliberation construct asserts that people devote cognitive effort to forming intentions toward accomplishing the goal-solving activities: Make sense of the problem, develop and evaluate alternatives, select and plan a course of action, monitor results, and so on. The information-access construct addresses the attention demands of finding, storing, processing, and retrieving the information the group members need to support their deliberation. Team theory posits that a key function of information is to increase the likelihood that the outcome one expects will be obtained by choosing one course of action over another. Information has value to the extent that it is available when a choice must be made, to the extent that it is accurate and to the extent that it is complete. However, the value of information is offset by the cost of acquiring, storing, processing, and retrieving it.

Team theory also posits that the cognitive effort required for communication, deliberation, and information access is motivated by goal congruence—the degree to which the vested interests of individual team members are compatible with the group goal. Team members whose interests are aligned with those of the group will exert more effort to achieve the goal than those whose interests are not served by the group goal. The groupware grid does not address goal congruence because goal congruence may have more to do with the way a team wields the technology than with the technology's inherent nature. Therefore, the horizontal axis of the grid addresses the potential for technology to reduce the cognitive costs of joint effort. Groups may become less productive if the attention demands for communication, deliberation, or information access become too high. Groupware may improve productivity to the degree that it reduces the attention costs of these three processes.

Three Levels of Group Work and the Groupware Grid

The vertical axis of the groupware grid consists of three levels of group effort (Figure 4). Sometimes a team may

Figure 4: Three levels of group work.

operate at the individual work level, with members making individual efforts that require no coordination. At other times, team members may interact at the coordinated work level. At this level, as with a technical sales team, the work requires careful coordination between otherwise independent individual efforts. Sometimes a team may operate at the concerted work level. That is, several parts of an organization must support the sales team to ensure future results. Teams working at this level must make a continuous concerted effort beyond short-lived coordination. For example, the sales department of an industrial manufacturer must routinely interact with its engineering department to help determine customer specifications on a new product. Today, there are even interorganizational cross-functional teams that provide concerted efforts to support increasingly complex value chains for products and services.

The demands placed on the team vary depending on the level of work in which they are engaged. There is groupware technology to support teams working at all three levels. The groupware grid can thus be used to map the contributions of a single groupware tool or an entire groupware environment (Figure 5). A given technology will probably provide support in more than one cell. The potential for groups' productivity in different environments can be compared by examining their respective grids. For example, the shared database aspect of a product such as Lotus Notes is often used asynchronously and offers little support at the concerted work level but offers strong support for communication and information access at the coordination level. Furthermore, a team database offers only indirect support for deliberations at the coordination level, but a project management and work flow automation system offers strong support for deliberations at that level.

Synchronous groupware that supports meetings, for instance, offers a great deal of support for communication, deliberation, and information access at the concerted work level. For example, the parallel input and anonymous interventions can improve communication during a concerted effort. Other groupware tools affect deliberation in different ways. For instance, a brainstorming tool prevents a group from thinking deeply while encouraging them to diverge from familiar thinking patterns. An idea organizer, on the other hand, encourages a divergent group to focus quickly on a narrow set of key issues. With ubiquitous access to the Internet and client/server access to corporate databases, emerging synchronous groupware tools can support information access at the concerted work level by providing rapid access to the information in the minds of teammates, by providing permanent transcripts of past electronic interactions, or by providing an information search engine.

GROUPWARE MANAGEMENT ISSUES: PRODUCTIVITY AND ORGANIZATIONAL EFFECTS

Perhaps the most important management issues surrounding Web-based collaboration tools are how to use them to enhance productivity and how to manage their

	Communications support	Deliberation support	Information access support
Concerted work level	Anonymity	Structured processes	Database access
	Parallel contributions	Distributed participation	Online search engines
	Virtual presence	Alternative analysis	Organizational memory
	Synchronous communication	Process focus	Concept classification
Coordinated work level	Asynchronous communication	Distributed project management	Shared data
	Sequential contributions	Scheduling	Coordinated filtering
		Automated workflow	
Individual work level	Message preparation	Modeling support	Individual data
	Communication structure	Simulation support	Filtering
		Hypothesis testing	Categorizing
		Logic analysis	

Figure 5: Potential contributions of groupware to support productivity processes, as viewed in the groupware grid.

organizational effects. Not all organizations that adopt groupware reap the potential benefits, and this is often due to the same factors that can plague the adoption of any information technology. Companies may try to implement a product that is not designed for its intended use, companies may not think through exactly what benefits they wish to accrue with the technology, companies may not invest sufficient efforts in training and support, and companies may not understand that some of its processes are amenable to team and group work (technologically supported or not) but others are not. Adoption of Web-based collaboration support systems is often tantamount to a large and often ill-defined management initiative such as TQM or business process reengineering. That is, success or failure of the adoption is often difficult to measure, benefits will emerge at different and often unpredictable rates, and human issues such as culture, politics, power,

incentive, and personality either facilitate success or bring the project to its knees. We cannot pursue systems planning and development here but instead devote some discussion first to groupware issues that derive from individual users and their interaction with groupware-supported team members and second to issues that derive from an organization's larger culture.

Groupware and Productivity

Organizations may not realize that some group or team members may not have the personality, motivation, or teamwork and communication skills to be effective in their roles. These issues are now beginning to receive attention from researchers examining the performance of groupware-supported workers and teams (e.g., Potter & Balthazard, 2002). Findings suggest that first, people

collaborating via groupware do not leave their personalities at the virtual door simply because their new communication mode is textual and possibly asynchronous (e.g., Hiltz & Turoff, 1993). People's personalities drive how they interact with one another in both the face-to-face world and the virtual world, and in both modes, people are similarly affected by each other's individual style of interacting. These effects can determine whether a group enjoys enhanced or diminished information sharing, enhanced or diminished task performance (e.g., decision making), and positive or negative sentiments such as buy in to the team's solution or product, satisfaction with the team's processes, and the team's cohesion. The important implication is that groupware means group work, and not all people are equally skilled in group communication and work processes or otherwise predisposed to work best in a team situation. Interventions such as training are needed to help some groupware-supported people adopt more appropriate interaction skills before they tackle a task. Alternatively, future groupware could incorporate interfaces, communication aids, protocols, and intelligent agents designed to promote participation, constructive interaction, and team building, for example.

Organizational Effects of Groupware

For several years, researchers have compiled evidence that information technology such as groupware or other forms of computer-mediated communication can alter a number of relationships and processes in the workplace (e.g., DeSanctis & Fulk, 2002). An organizational hierarchy that has traditionally exhibited mostly top-down dispersion of information may find that the communication support capacities of a collaborative information system create new lateral and bottom-up flows of information. In more radical manifestations, command-and-control structures in the organization can be circumvented as employees reinvent information-intensive processes based on expertise, interest, and resources, rather than restrictive operating procedures, protocols, or customs. Some researchers suggest that once in place, collaborative systems become the vehicle for organizational redesign, and as such, their more profound effects are largely emergent. In many cases, not all purposes or uses of the systems can be identified beforehand. As such, their management should reflect a "wait and see" attitude and accept that they may give rise to a number of benefits that were not anticipated (e.g., Orlikowski, 1992).

Another common finding is the spontaneous creation of online communities of interest and/or professional practice. These can be the gateways into larger organizational strategic concerns such as knowledge management. Effectively managed collaborative technologies can and often do provide the venue for knowledge sharing—an important input into the knowledge management process, particularly when derived from communities of professional practice or interest (Pickering & King, 1999; Constant, Sproull, & Kiesler, 1999).

The national cultures of groupware users can also become a management issue for transnational organizations. Different traditions, social mores, and internal and national political realities can drive preferences for

certain technologies and interaction modes (e.g., text, video, threaded discussion, and e-mail) (Potter & Balthazard, 1999). In addition, preference of various groupware technologies can also differ by gender (Potter, Balthazard, & Elder, 2000).

This more expansive "sociological" view of the management of these systems is informed by knowing the politics and culture of the organization, on one level, and the personalities of system users, on another level. These—as much as the technology's functionality—will ultimately drive the use and potential benefits of the system. As noted previously, some suspension of "standard operating procedure" or organizational status quo is a very common result of these systems, and leaders often have to deal with relatively rapid changes in how things are done and, perhaps more important, how they are thought of in their organization. Many aspects of an organization's culture are "genies in a bottle" that are released when a new communication and collaboration system allows transcendence of predetermined, traditional communication paths. The good news is that installing the collaborative communication technology found in many groupware products into healthy organizations will likely spur new organizational knowledge, improved practices, and synergistic relationships to emerge.

CONCLUSION

Modern Internet-based groupware offers a plethora of useful functionality that is driving sizeable gains in organizational productivity by streamlining collaborative work that was traditionally encumbered by distance and time. It is also driving the reinvention of business processes, spontaneously altering the nature and connection of communication-driven relationships and enabling an unprecedented growth in organizational and professional knowledge. At the same time, these effects can represent important management challenges that need to receive increased attention from managers and researchers alike as the proliferation of Internet-based groupware continues. Thoughtful assessment of groupware functionalities matched with a true understanding of the human side as well as the work process side of the organizational context will ensure the creative and effective adoption of these revolutionary technologies in the foreseeable future.

GLOSSARY

Any Time/Any Where Groupware components and resources such as databases and threaded discussions that can be accessed via the Internet from any location at any time.

Asynchronous Groupware Groupware that does not allow users to interact in real time.

Groupware Technology—typically software and networks—designed to support people working in groups.

Groupware Grid A theory-based, heuristic model for mapping the functionalities of groupware technology to organizational work.

Organizational Effects Effects on work processes, social and authority hierarchies, and communication

pathways and processes that can occur with groupware adoption.

Synchronous Groupware Groupware designed to allow two or more users to interact in real time.

Team Theory A causal model for the productivity of a team developed by Briggs (1994). It asserts that team members divide their limited attention resources among three cognitive processes: communication, deliberation, and information access.

INTRODUCTION

Serious discussion of security for any system must confront two central issues: what is at risk and defenses that can reduce risk. Understanding the value of a thing to an attacker is necessary to understanding the risk. Risk never can be eliminated but, when the degree of risk is understood, risk can be managed by a balanced defense against attacks. The key is to prevent a ruinous failure, often by providing multiple layers of defense and risk management. Willie Sutton, though wrongly attributed the quote on robbing banks “Because that’s where the money is,” understood the reason to attack a bank (Sutton and Linn, 1976). Banks knowingly create risk by accumulating large amounts of cash in one location both for customer convenience and to manage risk economically through several defensive layers such as safes, guards, and the legal threat of incarceration. Despite these defenses, robbers still launch successful attacks, but banks still remain open and operate at a profit. Banks and bank robbers will be with us as long as banks hold the money and banks continue to manage the risk of attack economically.

Entities such as banks, or other well-known focal points for things of value, invite attack. Security measures attempt to discourage the predictable attacks but are typically designed as defense against past successful attacks; such security measures obviously cannot completely prevent the unexpected attack. If complete security against attack is not possible, security failure must be expected and managed. Complete trust in the security of a system such as the Web, exposed to attacks from the entire planet, is naive at best. Since security can fail, determining the risk and the cost of failure is critical. Retailers understand that it makes no sense to expend more to secure something than the something is worth; risk reduction usually comes at some cost. Stores suffer shoplifting and would be made more secure by frisking customers before they leave the store. However, storeowners have found it more cost-effective to hire guards and buy security technology to manage the risk and raise prices to cover added costs;

owners know that lost sales due to unhappy customers represent a greater risk to their existence than shoplifting costs.

Is search risky? In the connected Web, the common, apparently free, and seemingly anonymous act of search exposes risks to security and privacy. Anything of value is at risk and Web search has great value. Consider the Web without search; with no means to navigate, there could be no Web as we know it. Web search is relatively new, valuable, primarily shaped by private industry and individual effort, with few enforceable standards of behavior, mostly unregulated and little enforcement; something as America’s Wild West must have been.

This chapter examines some of the most egregious risks surrounding Web search and suggests a number of defenses. The chapter organizes search risks along the lines of the three main parties involved: the searcher, the search engine, and the sites searched to provide focus for those readers whose interest lies primarily with one or more of the three. There are inherent problems with this approach. Because the purpose of search technology is to interconnect the three parties of search, the chapter must often fail in a complete separation of the security and privacy issues of one party from that of another. A further complication is that, although all parties need and naturally benefit from the others, one party can, and often does, overtly attempt to place another at some risk to their own advantage. The chapter ends with a limited examination of ethical issues surrounding search as it intersects with the three parties.

The technologies that make Web search possible are discussed along the way to reveal the technical sources of risk and some insight into reasonable defenses by each of the parties. However, the full details of the underlying technology are well beyond the scope of this chapter, which gives only the rudimentary level necessary to recognize the security threats and the worth of defenses. Readings from other chapters of this text will be especially valuable for a more detailed understanding of the related technologies and threats referenced within the chapter.

Why Search

Why is searching the Web necessary and worth doing for even a small amount of risk? A simple answer is that the Web is too large and unorganized to find much useful information. Search engines represent a single point where the information of the Web is concentrated, organized, and can be scrutinized as a whole. The original Web design purpose was simply to interconnect bits and pieces of scattered information with no plan to find information other than by a searcher manually moving from one piece of information to another by following hyperlinks connecting one page to another. In some sense, the search engine merely automates the process, following a vast number of hyperlinks while collecting information along the way for later retrieval. Although any published number about the Web immediately falls short of current counts, some sense of scale is suggested by the announcement that the Google search engine surpassed 6 billion items indexed by February 17, 2004 (Google press release, 2004).

Search engines play a key role in the discovery of information on the Web. One analysis (OCLC, 2002) indicated that college students use search engines 96% of the time when seeking information for assignments. Much of the information sought is for profit in some way; search engines are the top way consumers find new Web sites online, used by over 73% of those surveyed (Van Boskirk, Li, Parr, & Gerson, 2001). Commerce drives Web growth, shopping for everything from individuals buying shoes to businesses searching for a community in which to locate a new factory.

Risk

Security implies safety; privacy implies secrecy; search creates risk for both. Search has value, and things of value are nearly always at some risk. Who is at risk, what are the threats surrounding search, and what are reasonable defenses against those threats? Before those questions can be considered in detail, one needs a foundation for discussing risk in the context of Web search based upon some knowledge of how the tools of search, the search engine and browser, operate and of the Web infrastructure that makes search possible yet vulnerable.

Web search has risk in part because the Internet encourages communication at a distance, allowing us to do things at a faraway place without the physical journey. Although the communicating parties can be distant, we still need and expect at least the relative level of security provided through face-to-face communication, regardless of the communication form. The Internet carries Web communication, and by design depends upon many cooperating intermediaries for passing communication between any two parties. In search, not only are all three of the communicating parties separated by distance, only one, at most, is human.

For our discussion of search engine security and risk, the definitions of three, interdependent security services, authentication, encryption, and verification, will be useful:

- *Authentication* is the proof of one's identity. We need to know that the search engine claiming to be www.search.com actually is www.search.com. Gener-

ally, we require some trusted third-party authority that can not only authenticate an identity but also ensure that the authentication is trustworthy.

- *Encryption* transforms an easily read message into a form that, without knowledge of the transformation details, is much more difficult to read. Decryption transforms the encrypted message back to a readable form. Ideally, only the authenticated sender can encrypt the message and only the intended receiver can decrypt and read the message, keeping the message contents secret and private from all others.
- *Verification* determines whether the message received was the message sent; no tampering has occurred.

Each of these services depends upon the others; proof of the sender's identity is of reduced value if the message sent cannot be verified or an encrypted message from an unauthenticated sender could be a replay of an earlier message. A failure of any one of these services can precipitate the failure of the others. Any communication, whether electronic or not, using these services correctly can greatly reduce the degree of risk to the communicating parties.

Security and privacy are issues that most affect the searcher. Since we generally agree security and privacy to be important, the reader should now reasonably expect a discussion on using the Web for secure search engine communications based on authentication, encryption, and verification. Unfortunately, the discussion must focus on managing risk due to the lack of security and privacy as there is little or no attempt to provide either for search. As necessary background for our discussion, the following sections provide a brief overview of the Internet, browser, and search engine operation useful in understanding the specific threats and defenses detailed in the later sections on the searcher, search engine, and searched Web site.

Internet Fundamentals

The Internet infrastructure carries the communications and consists of a large and growing conglomeration of machines, communication channels, and software that abide by an interdependent assortment of communication protocols. The fundamental element of the Internet is the routable protocol, which defines the datagram passed from one point of the Internet to another, also known as the Internet protocol (IP); the current predominant version is Internet protocol version 4 (IPv4). Other protocols, such as the transport control protocol (TCP) used by Web servers and browsers, depend upon IP for routing messages across the Internet so a weakness in IP affects virtually all Internet communications. Developed before security was a concern, IPv4 protocol does not address authentication, verification, or encryption, obviously a serious security vulnerability for all communications built upon the protocol. Figure 1 provides details of interest for security concerns of the IPv4 format.

Web search not only explicitly involves three parties: the searcher, search engine, and Web site searched, but also requires extensive use of the Internet infrastructure and protocols for the three to communicate. A simplified network configuration necessary for search or other

Figure 1: The header fields defined within an IPv4 datagram that are the most important to security and privacy.

1. *Version* defines the protocol version used for the header; important for the eventual transition to the more secure IPv6.
2. *Protocol* defines the protocol specification for the *Data* field; commonly used protocols are TCP by Web services such as search engines and UDP by the domain name system.
3. *Checksum* is the computed header checksum used for transmission error checking.
4. *Source address* specifies the four-octet IP address belonging to the data sender. The dotted decimal notation address, 123.45.67.89 for example, is the common representation. IPv4 provides no authentication of this field, allowing use of a bogus address or a different source address to replace the original sender's address undetected by the protocol. Without authentication, the true sender cannot be determined and one sender can masquerade as another.
5. *Destination address* specifies the four-octet IP address of the intended data receiver. Intermediate routers examine the address to determine where to deliver the data; by changing the address, one changes the data delivery location.
6. *Data* contains the message carried within the datagram. When the *Protocol* field specifies TCP, the *Data* field content is treated as a TCP message. Without strong encryption implemented outside of IP, the data can be read easily; without verification, the data can be changed undetected.

Web use (Figure 2) consists of the searcher machine that connects to the Internet through an Internet service provider (ISP) and includes a domain name system (DNS) server. The ISP is the usual searcher's connection point to the Internet; all datagrams between the Internet and the searcher must pass through the ISP. The ISP is one point at which the real identity of an individual is known for billing purposes or can be traced back to an individual machine. The DNS server is necessary to translate site names such as *www.search.com* used in Web pages into the IP addresses used by Internet routers. When given a name a DNS server returns the corresponding address; for example, given *www.search.com* the DNS server responds with the corresponding 167.89.12.34 address.

Although the interaction between parties and use of the Internet infrastructure necessary for search or other Web application is too extensive and detailed for all but a superficial scrutiny, a coarse observation is useful to our later examination of risk to security and privacy. The following lists the basic steps necessary for a searcher to receive the search engine's home page:

1. Searcher enters *www.search.com* in browser address.
2. Browser requests DNS server (145.89.67.23) to translate *www.search.com* into an IP address.
3. DNS server responds to browser with 167.89.12.34 address.

4. Browser requests that 167.89.12.34 send its default page.
5. *www.search.com* responds to browser with the search engine's default page.
6. Browser displays search engine's default page; searcher can now enter query, sending a search request that would repeat the process again.

The searcher may query the search engine a number of times; each time the above steps repeat; each time the datagrams between the searcher and *www.search.com* pass over the Internet and through the ISP. Eventually the searcher might find something of interest and follow a link to *www.BigU.edu*, where the basic steps listed above remain essentially the same. Given the number of cooperating machines, software, and communication complexity, the reliability of the Internet is remarkable.

However, the lack of intrinsic Internet security using IPv4 becomes an issue when communication passes openly across a public network. Recall that each datagram must contain a destination address for Internet router delivery and a source address to identify where to send a response, the data field that holds the actual message. With no security, as the datagram traverses the Internet from source to destination, these and other fields are open for reading and writing along the path where communication can be monitored, stolen, or changed.

Figure 2: A typical network for Web search. The Internet cloud holds the communication channels and routers for passing datagrams between sending and receiving points of the network.

```

```

Figure 3: Browser communication sending query “babble” to www.google.com search engine.

Browser Fundamentals

The browser and search engine communicate via the hypertext transfer protocol (HTTP), a standard that specifies valid interactions between a client such as a browser and a server such as a search engine (RFC 2616). HTTP is a stateless protocol, meaning that each connection is independent of previous ones; there is no state information contained within the protocol. In search practice, this means that each query appears independent to the search engine, providing some measure of privacy. An example browser message presented in Figure 3 sent the query “babble” to the Google search engine. The browser sends instructions that include the query string “babble” and automatically volunteers useful data to the search engine server such as the type of images the browser might render. The search engine prefaces its reply by instructions to the browser, followed by search results written in hypertext markup language (HTML) for rendering by the browser.

Of special interest to privacy is the cookie, data stored on the searcher’s machine, sent by the browser with the query to the search engine. The search engine server placed the cookie on the searcher’s computer during a previous query, the browser returns the cookie automatically whenever contacting a server whose host domain name and cookie match. The browser can be set to accept or reject cookies: if accepted the cookie contents are under the control of the server; otherwise, rejecting cookies often comes at the cost of reduced service to the user. A common use of cookies is to identify each browser machine uniquely to track visits, something generally not possible with a stateless protocol. The ID field of this cookie would presumably give information to the search engine for associating this browser’s current actions with past and future queries, allowing search personalization and possibly sharpening the future search results. Although normally there is no browser information that explicitly identifies an individual, giving personal information such as an e-mail address would allow cookie, queries, and an identity to be directly connected.

Cookies obviously then present some risk to privacy, and several defensive options exist. The most obvious is to recognize that manually disabling cookies

does not seriously affect results on major search engines. Another option is to locate the cookie directory and delete the file holding the cookie; Internet Explorer stores cookies in the directory “C:\Documents and Settings\username\Cookies”, and the Google cookie would be under the filename “username@google[1].txt”.

The search engine reply in Figure 4 to the query in Figure 3 begins with a HTTP header followed by the text in HTML listing the search results. The search engine has sent another cookie; if accepted the browser will return the cookie data on the next visit to the search engine. Notice that the cookie contains what appears to be encoded data (i.e. S=X60DAR7nmCtEjlx) retrievable on the next visit to the search engine. Cookies have expiration dates after which the browser will discard; this cookie expires in 2038, allowing tracking of the browser activity on the search engine for a long time.

In addition to the obvious risk to privacy, using cookies for authentication, such as logging in to a banking account, presents a security risk. The risk is primarily due to the lack of any consideration for security in the cookie design; with no standards, any cookie security must be implemented by individual Web sites (Sit & Fu, 2001), producing uneven results. Many sites do encrypt cookies. Still, attackers can obtain a cookie by masquerading as the original site that stored the cookie; the browser automatically gives up the cookie if contacted by what it believes to be the owner of the cookie. In addition, an eavesdropper can capture the cookie during transmission between the browser and server. Once captured, merely storing the cookie file on another computer and contacting the same server could replay the login automatically.

Search Engine Fundamentals

Although Web search is commonplace, much of the chapter’s discussion depends upon a rudimentary knowledge of the interplay between search engines, the searcher, and Web site searched. The following brief section is intended for those readers who may appreciate such a basic explanation; those with some knowledge of search engines can safely skip this section.

```

HTTP/1.1 200 OK

```

Figure 4: Preface of the reply to query “babble” from www.google.com search engine.

Figure 5: An overview of a search engine and its relation to Web sites and information searchers. The basic steps to Web search are as follows: a search engine spider visits a Web site to retrieve and index pages for later searches; the searcher sends queries to the search engine and receives a list of page locations; the searcher selects and retrieves pages from the Web site.

Search engines are merely specialized Web servers; the obvious work of a search engine is communicating with the searcher's browser, either receiving or answering queries; less obvious is the mostly unnoticed but protracted work of gathering information from Web sites. Figure 5 illustrates the characteristic interaction between the three partners in search: 1) the searcher, 2) the search engine, and 3) the Web site searched. The first key step occurs when a Web site creates pages with information and sends the main Web site page location to a search engine. Next, in the typical search engine architecture (Arasu, Cho, Garcia-Molina, Paepcke, & Raghavan, 2001), one search engine component called a spider (or crawler, robot, etc.) visits the Web site to retrieve pages linked from the main page much as a person using a browser would follow links to new pages. The spider follows links, indexing meaningful words of the retrieved pages to be stored along with the page's Web site location in a specialized database on the search engine for later searches and retrievals. As the searcher sends queries to the search engine, the engine consults the database for pages containing similar words and phrases. After ranking the pages for relevancy to the query, the engine returns the ranked list of Web site page locations. The searcher selects location entries from the list and retrieves pages directly from the Web site. Closing the information gap between the searcher and sought-after Web site pages is the primary purpose of the search engine.

The remainder of the chapter, forming its core, focuses on the threats and defensive measures for the three parties to search. The first section considers how the act of searching exposes one to threats. The second section examines the search engine in more detail, how search engines operate and their known vulnerabilities. The third section examines how search exposes the Web site to threat and how sites attempt to manipulate search engines and searchers to their own benefit.

SEARCHER

The searcher is the reason search engines exist. Does search have risk? First, we must determine what is of value to determine what is at risk. The user of a search engine is

searching for information, which the search engine gives freely. As the information is free, it would seem there is nothing of value, so nothing is at risk. However, most of us value our privacy and expect our communication to be private and free from surveillance. We also place value on the results we receive from a search engine and assume the results are from an honest attempt by the search engine to respond to our query.

As we will see, the searcher has little guarantee of privacy and high likelihood of exposure to varying degrees of pretense, particularly by Web sites. Unfortunately, there are many places and methods for attacking privacy or conducting fraud against the searcher. To maintain a focus on the searcher, this section deals primarily with privacy and fraud attacks waged directly against an individual searcher by an agent other than the search engine or a searched Web site; specific sections will cover those issues.

Privacy

Privacy implies secrecy. To ensure secret communication the message transfer must occur privately, through no intermediaries or pass through intermediaries who are unable to either read the message or determine who is communicating. Is search communication secret? Internet communication, passing between the searcher and search engine through many public intermediaries, is not private. Search engine messages fail secrecy in at least two ways. Messages are generally in plaintext, readable by anyone able to intercept the message, and Internet messages list in the plaintext source who is communicating and destination addresses. Search communication is not currently secret. Although useful measures exist, such as encrypting messages between the searcher and engine, the search engine site must implement those measures and most do not.

Nevertheless, even with secret communication between the searcher and search engine, search has privacy risks. Search seems anonymous and free, and there is usually no authentication required for search. Search engines can and commonly do collect privileged data that can connect the searcher's real identity with search behavior. The cookie placed by the search engine on your computer

Figure 6a: All communications physically pass through one machine, such as a firewall, allowing that machine to read, change, or delete any communication.

uniquely identifies the searcher, making it a simple matter for the engine to store the search details in a database. In theory, future searches can factor in those past and produce results tailored to your search behavior; no personal data required. Connecting the cookie with an e-mail address or other personal information, the same search data can produce such minor intrusions as targeted marketing to serious invasions of privacy such as monitoring your Web site preferences. No perfect solution exists although measures discussed earlier on deleting cookie files, avoiding the use of personal identification, and using a public computer for sensitive searches can help.

Eavesdropping

Eavesdropping or secret monitoring of the conversation between the searcher and search engine is an attack on privacy. The search conversation consists of sending query terms to the search engine from a browser and receiving a list of ranked results in return. The searcher's first vulnerability is due to the transmitting of the query and response in plaintext. To make matters worse, the browser generates and transmits information that can identify the searcher. Sending communication in plaintext is the standard for the HTTP protocol used for communication between the browser and search engine. The open conversation between the searcher and search engine can be covertly monitored at many points on the communication path, allowing a third party to easily determine the search terms and at least the host machine, if not the identity, of the searcher.

Surveillance

Eavesdropping differs from surveillance only by being conducted in secret. Many employers regularly monitor Internet communication to limit employee access to presumably non-work-related sites. Surveillance is relatively easy for the network administration given the unlimited access to traffic at communication concentration points, see Figure 6a, such as firewalls, content filters, gateways, and routers. For the searcher, the risk to privacy continues to exist wherever communication is in plaintext. The institution that operates the network represents a more formidable risk to privacy than the average eavesdropper primarily due to superior opportunity, resources, and incentive to monitor Web use in general. The surveillance software needed is widely available, often marketed explicitly to track or limit employees' use of the Web. The software is tunable to capture all communication between the host of a specific searcher and a particular search engine, making it possible to capture the complete search session.

Monitoring communication between the searcher and search engine occurs in many ways; the two discussed here are merely among the most widely accessible. Casual eavesdropping is particularly a problem on broadcast networks such as Ethernet where there is no native security and any host computer physically connected to the same network wire can generally read all messages transmitted over the network. Using widely available packet sniffing software such as Ethereal or Dsniff (<http://www.monkey.org/~dugsong/dsniff>), the technically unsophisticated eavesdropper can listen in from the comfort of their office down the hall. Figure 6b illustrates how communication over a hub between searcher and gateway to the Internet automatically broadcasts to the eavesdropper on the same hub. When communication between the browser and search engine transmits as plaintext, the eavesdropper can easily read each bit passed through the hub. Wireless base stations (802.11b) can extend the network range several hundred meters beyond the end of the Ethernet wire or your home cable modem, which is great for eavesdropping attacks by someone in a car parked down the street. Although enforcing restrictions on joining a wireless network are relatively simple, many networks automatically configure to operate with no restrictions, opening the wireless network to the same eavesdropping attacks possible through Ethernet hubs.

Law enforcement and security agencies in many countries have extended their surveillance to the Internet. The FBI developed a packet-sniffing system named DCS1000 (previously named Carnivore) that passively captures and records specified packets from network traffic. Within the United States, the Electronics Communications Privacy Act restricts domestic surveillance by law enforcement agencies. Under authorization by a federal district court judge, the statute allows the capture of all communication, such as content between a searcher and a search engine, and obliges the cooperation of service providers (Graham, 2004). Strongly encrypted communications

Figure 6b: A hub broadcasts all communications to others on a local area network; eavesdropping is easy.

that are easily copied cannot necessarily be read; however, individuals can be compelled by law to provide the decryption key. For U.S. citizens, intelligence agencies are required by the Foreign Intelligence Surveillance Act (FISA) to obtain a court order from the Foreign Intelligence Surveillance Court to conduct domestic surveillance. Order (E.O.) 12333 requires approval by the attorney general for surveillance of citizens in foreign countries (Legal Standards for the Intelligence Community in Conducting Electronic Surveillance report required by FY 2000 Intelligence Authorization Act, 2004).

However, the September 11, 2001, terrorist attacks raised significantly the tolerance for domestic surveillance, precipitating the rapid passage of the USA PATRIOT Act (Uniting and Strengthening America by Providing Appropriate Tools Required to Intercept and Obstruct Terrorism, USAPA), H.R. 3162, on October 26, 2001 (U.S. 107th Congress, 2001). Although the act contained many provisions not related to privacy, the act generally widened government authority to conduct surveillance while weakening judicial oversight. Although many of the act's provisions expire December 31, 2005, additional legislation of the "Domestic Security Enhancement Act of 2003," also known as "PATRIOT Act II," includes further and permanent changes to domestic surveillance. According to the American Civil Liberties Union, much of the act is aimed at providing greater government access to electronic communication such as the Internet (Edgar, 2003).

Considerable confusion and debate surrounds details on the interpretation and application of current law and in particular on the effectiveness of privacy safeguards. However, the broad purpose of the USAPA was to remove a number of restrictions from the CIA and FBI on monitoring individuals, including domestic electronic communications. Previously, law enforcement could obtain a "trap and trace" order, which allowed access to numbers dialed and received by a specific telephone; under USAPA the scope of accessible information has been extended to "dialing, routing, and signaling." Routing refers specifically to Internet use and recording source and destination address. Although the PATRIOT Act states that trap and trace orders may not be used to obtain communication "contents," the term is not defined. In addition, the routing and contents of Internet communication are parts of a single message and not easily separated for capture. The order giving access to routing also gives access to content, entrusting government agents to view only the routing information. Technologies used to gather routing information, such as Carnivore, must be trusted not to gather information about coincidental users of the same ISP or law enforcement agencies must be trusted to filter out information on other users. This raises privacy issues for not only legitimate targets of investigation but also those who happen to be customers of the same ISP.

Privacy and Security

Privacy and security are under threat from many directions, inside and outside the ISP, legal and illegal. Eliminating all threats is not practical but defensive actions can manage most threats. In the United States, a common defense against burglary is the security alarm system and the security company sign in front of the house; other

countries use high walls topped with broken glass to discourage attacks. The purpose is the same: to present a more difficult target for attack than others; to send the less-than-determined attacker somewhere else.

Search Computer

Search depends upon connection to the Internet, automatically exposing your computer and communication to outside attack. Attacks against networked personal computers are too numerous and varied to even begin a limited enumeration; but reasonable defenses do exist. Basic protection includes disabling any services, protocols, and ports not necessary, operating a firewall to restrict access to those that are necessary, and installing security patches regularly.

Local Infrastructure

Certain threats are beyond the control of the average searcher, sometimes occurring far out on the Internet infrastructure. For example, your ISP has, by necessity, extraordinary access to network equipment and communications and is the sole agent who can maintain certain defenses on your behalf. Nevertheless, the ISP presents a serious threat for actively monitoring communications and passively by failing to secure the network infrastructure from attack. The following describes the more common threats when an attacker has access to the local infrastructure and suggests some defense, none of which is foolproof.

As discussed earlier, communication surveillance is easier when one has physical access to the communication infrastructure; perhaps as simple as running free packet-sniffing software on your local area network (LAN). The majority of LANs use the Ethernet protocol, which broadcasts all communications over the wire to all stations connected by hubs. All stations connected to the network can monitor each other's full communications. A simple defense that requires more work of an attacker uses switches rather than hubs as connection points to the network, isolating each station's communication from others connected to that switch. In Figure 6c, communication between the searcher and gateway is isolated from a casual eavesdropper, requiring at least some effort to conduct a monitoring attack.

However, a more determined attacker with access to a connected station can trick the switch to gain control

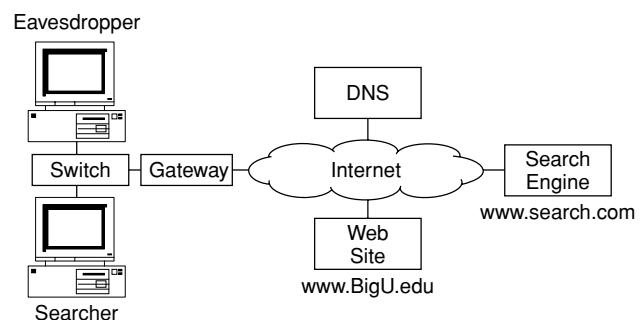

Figure 6c: A switch separates communications from others on a local area network; eavesdropping is more difficult. All communication between Internet and LAN must pass through the gateway.

of communications. A medium access control (MAC) address on a LAN such as Ethernet uniquely identifies each station network connection. A switch stores source MAC addresses when a station sends a message; by storing the source address of the message the switch knows on which port to send later messages destined for that station. To trick the switch, the attacker sends a message with the source MAC address of the searcher's station; the switch will then send messages destined to the searcher instead to the attacker. LANs connect to the Internet through a gateway that has a MAC address on the LAN side of the network. By tricking the switch to store the attacker's port for both the searcher and gateway addresses, the attacker can in theory capture communications destined for both. This is not the perfect or simple attack for several reasons. Ideally, for the attacker, they monitor and change communications in both directions, placing themselves in the middle of the searcher and the gateway to the Internet search engine. However, when the searcher sends messages, the switch updates the source address to the searcher's port connection; the attacker is now in a race to change the switch back to the attacker address. The same is true for the gateway. One defense is to define the MAC addresses and connections stored by the switch statically and not allow them to change; attempting to do so could also signal a warning that an attack was in progress. The downside to this defense, as with many others, is the inconvenience of updating the switch each time a computer physically changes its connected port on the switch.

With physical access to a LAN connection, a moderately determined attacker can attempt another, potentially more successful attack: address resolution protocol (ARP) spoofing. ARP spoofing tricks the searcher's machine into treating the attacker as the gateway to the search engine, placing the attacker between the searcher and the gateway, able to not only monitor but also change communications. The purpose of ARP is to bind IP addresses used by the Internet to MAC addresses used on a LAN such as Ethernet. As noted earlier, computers on the LAN communicate to the Internet through a gateway attached to the LAN and Internet. Normally, when the searcher's machine first contacts the search engine, it knows the IP address of the gateway needed for Internet connections but not the gateway MAC address needed for communicating over Ethernet. To discover the gateway's MAC address, the searcher's computer broadcasts the IP address of the gateway and receives a reply matching the gateway IP with its MAC addresses. Spoofing subverts ARP by the attacker sending a reply to the searcher's machine that instead matches the gateway IP with the attacker's MAC address. Believing the attacker to be the gateway, the searcher now sends all communication to the attacker who can examine and change the communications before forwarding to the real gateway. The gateway returns any search engine replies back to the attacker who again can examine and change the message before returning it to the searcher. The attacker has effectively placed herself between the searcher and search engine; ARP spoofing is another of the man-in-the-middle attacks. The problem for the attacker is that, because the searcher broadcasts an ARP request for the gateway, the gateway will also respond; the attack is not reliable. A related, more reliable

attack known as cache poisoning, sends the targeted station directly the bogus ARP request using the target's MAC address; the target now matches the gateway IP with the attacker's MAC address in a cache of addresses without any conflicting response from the gateway. By directly sending the gateway the searcher's IP and the attacker's MAC address, the attack is complete, all that remains is to monitor the communications.

Wireless LANs are open to most of the same threats as wired LANs with the added problem that a physical connection is not necessary, only in reasonably close proximity of a few hundred meters to a wireless access point. In an attempt to make wireless installation simple, the default mode of the wireless network often is to broadcast in clear text; anyone within range can then easily connect and attack the network. The IEEE 802.11 standard describes a wired equivalent privacy (WEP) for encrypting communication in which each station shares a key with the wireless base station. Although WEP is far from perfect, having several known flaws such as community keys for stations and access points, enabling WEP can make an attacker's work somewhat more difficult. One reasonable defense is to require individual authentication for each station to connect, such as afforded by using a virtual private network (VPN) (Miller, 2001).

Message Encryption

As noted earlier, a key source of privacy risk in search is search engines that use HTTP for plaintext communication over the Internet. Encrypting the end-to-end communication between the searcher and search engine using a protocol such as HTTPS (Secure HTTP) makes eavesdropping, surveillance, and man-in-the-middle attacks considerably more difficult. HTTPS is HTTP in conjunction with SSL (secure sockets layer) and is widely used for securing financial transactions over the Internet. SSL acts as a new protocol layer between HTTP and transport control protocol responsible for data encryption and compression. The browser vendor Netscape Communication Corporation introduced SSL in 1995; since then most browsers and servers have incorporated SSL.

The basic purpose of HTTPS is to secure communication between the two communicating ends; it requires both the searcher's browser and the search engine to use HTTPS. Where normally HTTP relies upon TCP to carry plaintext between client and server Web applications, HTTPS uses SSL to determine a common key and encrypt plaintext messages before passing to TCP for delivery. Unfortunately, although SSL is widely available on browsers and servers, none of the major search engines supports HTTPS (i.e., SSL) so most search communications remain in plaintext.

The searcher is generally interested in ensuring they are communicating with the authentic search engine, the communication is private, and communication is unaltered. HTTPS using SSL attempts to accomplish these by the following means:

1. Two-party negotiation of parameters to agree upon SSL version, cryptographic algorithms, key size, compression, and other options. The searcher's browser sends preferences and a random number for later encryption use to the search engine. The search engine responds

- with preferences, a random number, and an authentication certificate containing its public key.
2. Authentication through certificates issued by trusted certification authorities (CAs) allows the browser to confirm the search engine's identity. The CA certifies proof of identity and digitally signs a publicly available certificate that contains the search engine's public key. Browsers are preloaded with a list of well-known, trusted CAs, allowing the browser to authenticate the search engine's certificate and public key. Normally the browser end has no need to be authenticated.
 3. SSL uses public-key cryptography for secret communication to determine a common session key. After authenticating the search engine certificate, the browser responds with a random premaster key encrypted using the search engine's public key, allowing decryption of the premaster key only by using the search engine's private key. The common session key used for encryption can only be computed from the premaster key and the random numbers exchanged between the search engine and the browser. At this point, we have two important results. The searcher can be confident that all subsequent communications will be with the search engine and not some other site masquerading as the search engine. Secondly, all communications can now be encrypted using the common session key, allowing only the searcher and search engine to write and read subsequent messages. Some other site masquerading as the search engine could attempt but, without the common session key to write or read messages, would be unsuccessful. Without the common session key, an eavesdropper would be unable to read messages.
 4. Data integrity protection ensures that messages have not been altered during transit. Each message and the session key is hashed using an agreed upon algorithm such as MD5; the resulting hash is appended to the message, encrypted using the session key and transmitted. The receiving end decrypts the message and recomputes the hash to verify the message integrity. The need of the session key to decrypt the message thwarts attacks that intercept and modify messages between the searcher and search engine. Because constructing a different message with the same hash value is computationally unfeasible, verifying the hash ensures that the message is genuine.

Although the majority of e-commerce applications use SSL to secure financial transactions SSL is not used more generally to protect privacy and ensure no one has

tampered with communications. The major search engines do not use SSL but communicate in plaintext. One reason is the added burden and delay placed on the search engine to negotiate a SSL connection; rather than sending a single message with search results back to the searcher, several are required. There is also the overhead to perform the necessary encryption, decryption, compression, and hash computations on messages. However, the major reason is that search engines and most other Web servers operate as stateless applications, meaning they keep no memory of the searcher's visits from one to the next, other than by a cookie. Being stateless allows the search engine implementation to be much simpler, makes it possible to distribute new queries among a group of search engines independent of previous queries, generally requiring less resources of a search engine when responding (we will see later that search engines do log query information but typically not for answering queries). Because each query is independent of those made previously, the search engine response only depends upon the current query. For large search engine sites consisting of multiple identically functioning systems, the independence of queries implies that any system can answer any query, a critical point for load balancing. From the search engine's point of view, there is little benefit to remembering the history of each searcher, only to answer their immediate query. For a major search engine with millions of daily searches, the additional time required for SSL is significant.

Proxies and Anonymous Search

Anonymity on the Internet results in privacy, anonymization proxies attempt to cloak one's identity by acting as intermediaries between the searcher and search engine. In their simplest form, a proxy merely passes data between the searcher and search engine. Proxies are useful to searcher privacy in two important ways: one is to maintain searcher anonymity with the search engine; the other is to provide the searcher encryption of communication. Placing an internal proxy (see Figure 7) physically between the searcher and the Internet gateway gives the proxy complete control of all communication; the proxy is able to examine and modify messages, such as changing addresses. A proxy may also be located on the Internet, handling only communication the searcher explicitly routes through it. In either case, using proxies improves the possibility but, unfortunately, does not guarantee privacy.

In theory, the searcher can remain anonymous by relaying communications through an intermediate proxy connection to the search engine or other Web sites, hiding the searcher's identity, at least from the search engine

Figure 7: Two types of proxies: the internal proxy passes all Internet communication through it whereas the external proxy passes only communication explicitly routed through it by the searcher.

Figure 8: Two forms of the man-in-the-middle attack. The conceptually simpler internal network attack depicted requires physically arranging communications to pass directly through the attacker, giving the attacker access to all communication regardless of the destination address. The more technically sophisticated external attack requires tricking the searcher into addressing communication to the attacker rather than the search engine.

if not the proxy. The proxy performs the anonymization service by receiving a searcher's request and forwarding it with the proxy's identification IP source address. The proxy then receives and returns the search engine results to the searcher (Berghel & Womack, 2003). In practice, simple measures taken against the searcher's browser by search engine or other Web site can render anonymization services ineffective. A browser allowed to execute JavaScript can return identifying data that the proxy leaves intact, although some anonymization services filter or at least comment out all JavaScript destined to the browser. The browser can quietly be redirected by HTML tags (such as the meta-tag REFRESH property) on the page received from an external proxy to another location, bypassing the proxy and exposing the identification of the searcher. Filtering page redirections out is possible but is not necessarily an attempt to bypass proxies, for example, as it is often innocently used on Web sites that have moved to a different location.

As noted, search engines generally communicate only in plaintext, rendering the searcher open to unsophisticated eavesdropping, particularly on a LAN. For encrypted communication, the searcher establishes a SSL connection with the proxy that in turn communicates in plaintext with the search engine; the proxy serves to encrypt and decrypt communication between the searcher and search engine. Although communication between the searcher and proxy over a SSL connection is secure, the proxy can still be bypassed using many of the same methods already discussed.

The anonymization service itself may present the greatest danger to privacy. Enlisted as a trusted intermediary, the service occupies the coveted man-in-the-middle position with access to communications between the searcher, the search engine, and other Web sites. The service may also require a registration based on your real identity, now directly associated to any communications.

Fraud

Fraud is defined as deceit, trickery, or cheating. Whereas listening to communications is a passive attack on privacy, fraud is an active and more nefarious attack. For our discussion, fraud results in the searcher receiving false or misleading information from an agent other than the search engine, such as being directed to a bogus Web site. Fraud is the usual purpose of the man-in-the-middle attack, where all communication between the searcher and the search engine is intercepted, giving the attacker total control over the communication between the searcher and

search engine. Privacy is lost if the attacker can decipher the communication and fraud can be conducted if the communication is changed and forwarded clandestinely. There are two essentially different approaches to implementing this attack, depending upon whether the attack is physical to the searcher's own internal network or external through the Internet infrastructure.

Internal

Physically attacking the local network, although effective, requires the attacker to be present and places the attacker in some personal danger; it is not the method of choice when remote attacks are possible. However, the physical model is useful for understanding remote attacks. In both cases, the attacker seeks to be in a position where all communication passes through the attacker. Figure 8 illustrates a physical but unrealistic case of man-in-the-middle; the attacker needs two network connections, one to the searcher network and the other leading eventually to the search engine. All communication between the searcher and search engine then physically flows through the attacker. The attack is unrealistic because the effort needed to get access to the network is unnecessary when much easier and safer methods are available. As discussed earlier, ARP spoofing places the attacker where needed without rearranging network cabling.

After establishing the man-in-the-middle attack, all communication between the searcher and search engine is completely open to attack. With HTTP using plaintext communication, the attacker can easily modify any part of the communication in either direction or covertly act as the searcher or the search engine. For example, the attacker can read the search engine result, make changes, and forward on to the searcher to whom the changes are opaque. Using HTTPS to encrypt the communication can still allow the attacker to read and change the communication after exchanging keys with both the searcher and the search engine. The attack depends upon the searcher accepting a certificate not signed by a trusted certification authority when warned by the browser. After the searcher accepts the certificate, the attacker completes the SSL setup with the searcher's browser and completes a separate SSL setup with the search engine. The attacker can now decrypt communication in any direction, make changes to the plaintext, and encrypt and forward without detection.

External

The external attack requires more sophistication to implement because the attacking agent must be in control

Figure 9a: Normal DNS operation.

1. Searcher's browser contacts DNS server for IP of www.search.com.
2. DNS server replies with IP 148.13.23.4 of www.search.com.
3. Browser sends search query to search engine at IP 148.13.23.4.
4. Search engine returns results.

of the communication without being physically near the searcher, but now the attack can come from anywhere on the Internet. The basic approach again deceives the searcher into addressing packets directly to the attacker rather than the search engine; the attack is similar to the ARP spoofing but using an Internet protocol rather than a LAN protocol. With the searcher fooled, the attack can then proceed much as before as the attacker places their own address as the source and forwards messages to the search engine; the search engine addresses replies to the attacker who places the searcher address as the destination and forwards to the searcher. Again, with plaintext HTTP the attacker can easily monitor or modify any part of the communication in either direction.

Tricking the searcher into addressing packets to the attacker rather than the search engine is itself the key trick. One deception is through DNS spoofing (Tannenbaum, 2002). Normally DNS servers supply IP addresses that correspond to some search engine name on the Internet; the searcher client machine sends the name such as www.search.com to a DNS server and receives back the IP address as in Figure 9a. The client then caches the IP address for a limited time for future references to the search engine name. DNS servers are organized into a hierarchy of servers where each has authority for resolving names to IP addresses for a specific domain. When a client requests a name unknown to the DNS server, that server requests another designated server in the hierarchy to resolve the name; the process of passing the request to other servers in the hierarchy continues until the name is resolved or not. Iterative queries pass the response directly to the client from the resolving DNS server while recursive queries pass the response back to the local DNS server to respond to the client. The distinction is important as recursive queries have the advantage of informing the local DNS server of the IP address for resolving the name again later but also open the door for DNS spoofing.

DNS spoofing is possible in a number of ways but each with the result of the searcher using an attacker's IP address instead of that of the search engine. The goal of DNS spoofing is again to place the attacker in the middle of communications between the searcher and search engine

site name such as www.search.com. DNS servers maintain a database of paired (DNS name, IP address) from which they answer requests for DNS name with IP address. When the DNS server cannot answer a request from the searcher, the request is sent to a higher authority server. DNS servers can request that the higher authority return the response directly to the searcher, an iterative request, or return the response to itself, a recursive request, caching the response in the database and returning to the searcher. Configuring DNS servers for recursive requests assumes future requests can be answered from the cache without the overhead and delay of contacting a higher authority. The fundamental trick of the spoof places the record (www.search.com, attacker IP address) on the DNS server used by the searcher; DNS servers configured for recursive requests are open to attack because the cached record is not permanent. In Figure 9b, the attacker first sends a request to the searcher's DNS server for the IP address of www.search.com counting on that DNS server to consult a higher DNS server to locate the IP address. The attacker then follows the request with a forged response from a higher authority DNS server that contains the attacker's IP address. The searcher's DNS server now caches the forgery pair (www.search.com, attacker IP address) in its database. In Figure 9c, when our searcher tries to contact www.search.com they receive the attacker IP address instead and the man-in-the-middle attack can begin.

DNS spoofing is amenable to brute force attacks where the attacker requests the victim DNS server to resolve a search engine name requiring a higher authority (Sacramento, 2002) and fakes multiple higher authority responses until one is accepted. Responses are discarded by the DNS server when the transaction identification (TID), used to connect a response with a request, received does not agree with the TID expected. The attack blindly sends many responses until the DNS server eventually

Figure 9b: Attacker masquerading as a search engine.

1. Attacker contacts DNS server for IP of www.search.com.
2. DNS server requests IP of www.search.com from higher authority DNS server.
3. DNS server receives attacker's IP 147.17.32.6 response to www.search.com.
4. Searcher's browser contacts DNS server for IP of www.search.com.
5. DNS server replies with attacker's IP 147.17.32.6 of www.search.com.
6. Browser sends search query to attacker at IP 147.17.32.6.
7. Attacker returns results.

Figure 9c: Attacker intercepting communication between searcher and search engine.

1. Attacker contacts DNS server for IP of www.search.com.
2. DNS server requests IP of www.search.com from higher authority DNS server.
3. DNS server receives attacker's IP 147.17.32.6 response to www.search.com.
4. Searcher's browser contacts DNS server for IP of www.search.com.
5. DNS server replies with attacker's IP 147.17.32.6 of www.search.com.
6. Browser sends search query to attacker at IP 147.17.32.6.
7. Attacker forwards query to search engine.
8. Search engine sends response to attacker.
9. Attacker forwards response to searcher.

accepts one, which can easily be determined when the victim DNS server responds with the attacker's IP number for the search engine name. On older DNS servers, the TID is incremented for each request allowing the attack to be more efficient by discovering a recent TID used in the victim DNS server request and sending higher numbered responses. Launching the attack begins by sending the victim DNS server a request that requires contacting a valid DNS server under the control of the attacker. The TID of the request is noted, a new request for the search engine IP is then sent to the victim DNS server, followed by multiple fake higher-authority responses with the attacker IP and incremented TIDs to ensure acceptance by the victim DNS server.

Fraud Defense

Whether message interception is local or by spoofing the result is the same: the attacker can completely monitor and control communication. Defense is often beyond the control of the average searcher who must rely upon network administrators to secure the network infrastructure.

DNS spoofing is fundamentally a problem of the DNS protocol (Schuba, 1993). An attack is more difficult by using random TIDs but analysis (<http://www.kb.cert.org/vuls/id/457875>) has shown DNS is still susceptible to spoofing. Among the best protections is for DNS administrators to upgrade BIND, the Berkeley Internet Name Domain software used by nearly all DNS servers on the Internet, which addresses problems with the TID random number generator, and to limit forwarding to only one of multiple requests for the same name to a higher authority.

The best personal defense is to practice safe computing: keep antivirus and operating system software updated and signatures current. Always confirm SSL certificates when making secure online transactions and never accept a certificate not signed by a trusted authority. If you suspect spoofing, contact the ARIN WHOIS records at <http://www.ARIN.net/whois> to determine whether an IP address pairs with an assigned name. Eventually DNSSec, secure DNS, will allow domain servers to have cryptographically signed records, but it is not widely implemented at this time.

SEARCH ENGINE

Search engines have value to the searcher due to the access it gives to an otherwise opaque Web, to the site searched through the wide public exposure, and to the search engine owners through advertising revenue. As with anything of value, Web search engines are under threat of attack, a curious circumstance as the product, access to the accumulated public data of the Web, is freely available and willingly yielded upon request. Unlike traditional targets of theft such as cash or property, search engine attacks are frequently subtle, often through manipulation by the very Web sites that search benefits. Major search engines are high-profile sites and prime targets for malicious attack, such as denial of service, which if successful serves to advertise the attacker's power and the vulnerability of the technology. Search engines can also assist attackers by providing a source of information on Web sites or individuals and for methods of attack. This section examines how search engines work, common threats, and some of the standard defenses.

Although search engines are careful to distinguish themselves by the algorithmic details of how they determine responses to queries, they share general operational principles with major search engines that search the Web and local engines that search a single Web site, the key difference being the scale of information searched. To a searcher, a search engine purpose is to match their query words with words on Web pages and list those pages containing the matching words. Entering the query word "zucchini" returns a list of pages containing the word "zucchini." In practice, Web search engines examine vast numbers of pages to calculate the page ranking to reduce quantity and improve relevance or quality of the information. Accurately determining page rank based on a few query words is challenging and can produce completely irrelevant results. Entering the single word "zucchini" will find any page mentioning "zucchini," from gardening to cooking to diet; which "zucchini" page is important is ultimately in the mind of the searcher. Determining how to rank one document against thousands of others is a key point of competition between search engines, the identical search on any two will often produce different results; searchers may need to consult several to have confidence in the results. Meta-search engines automate searching on multiple sites by sending the search query to a number of search engines and creating a fusion of the results.

Web search engines have two main tasks: placing keywords from each page into a searchable index and answering search queries from that index. Web-based search

engines are only recent versions of traditional full-text systems, such as the SMART and SIRE systems (Salton & McGill, 1983). Rather than employing human editors to manually extract and index subject information from pages, such systems perform automatic indexing of complete pages into a database, creating lists of words and the page locations that contain each word. Answering queries from the index compares query words to page words, retrieving those pages that have some high, calculated relationship value to the query.

Indexing

A Web site creates pages with information and a search engine spider (or crawler, robot, etc.) visits the Web site to retrieve pages for indexing. The spider begins at a root page on the site and follows links to other pages on the site, indexing meaningful words of the retrieved pages along with the page's Web site location on the search engine for later searches and retrievals. The automatic indexing of a page first removes most common or stop words such as "a," "the," and "it"; because almost all pages contain those words they are nearly useless in discriminating between pages. Each remaining word then has a weight factor calculated based in part on word frequency. Weight measures also may give greater or lesser importance to words in different parts of the page; for example, title words generally receive more weight than regular text words. A word that occurs in few pages also has a higher weight, based on the proportion of times that the word occurs in a single page relative to all other pages indexed. A word that occurs on only one page would then have relatively high weight whereas a word occurring on all pages would have low weight, the rationale being that a rare word is more useful in finding a page than a word common to many pages. The same rationale applies to the removal of stop words. Conceptually, the resulting index contains all words from all pages, excluding stop words. Included with each word is a list of all the pages that contain the word; for each page in the list, the frequency the word occurs in the page is stored for weight calculation along with the location of the page for retrieval.

Web search engines differ significantly from traditional search engines in that pages are scattered across many thousands of Web sites and each page can have connections to many other pages. To find pages and build the index, the indexing spider program must then visit Web sites as one would with a browser, starting at a page, visiting connected pages on the site, indexing each page as it goes.

Because spiders visit Web sites and pages much as someone browsing the Web, they are subject to many of the same attacks (e.g., man-in-the-middle). More common are Web sites that play bait-and-switch on a spider by hosting two different sets of pages, one for normal visitors, and special pages presented to visiting spiders. Spiders follow specific rules when indexing a Web site; the rules define which pages on the site are indexed, which parts and how much of the page is selected, and how links to other pages are treated. Visiting spiders are shown the bait pages designed specifically for the spider's indexing rules; a searcher visit is switched to the real page. Not

only can the site content be switched on the spider, the Web site can also manipulate the spider through the indexing rules; exactly how is examined in the section "What Search Engines Search."

Retrieval

The traditional retrieval process produces a ranking of all pages that contain one or more query words entered by the searcher. The retrieval operation consists of converting the query words to the same representation as the pages, calculating a similarity measure between the query and each page in the collection, and retrieving pages from the collection ranked in order of high to low similarity.

A common similarity measure is the cosine of the angle between the words of the query and the words from individual pages. Determining the cosine similarity measure requires representing the words of the query and pages as vectors in a multidimensional word space where each axis corresponds to a different word drawn from the indexed pages. Roughly described, if a page matches the query, the angle between the query and the page vector is zero; having fewer words in common produce a greater angle or smaller similarity. Figure 10 illustrates the indexing of pages p1 and p2 containing the words "weight" and "diet loss," respectively, where each axis corresponds to one of the three words. Representing the pages and query as vectors in three-dimensional space, the query vector for "diet" has a smaller angle with respect to the "diet loss" page p2 than with respect to the "weight" page p1. Intuitively, the "diet" query is somewhat similar to the "diet loss" page and not similar to the "weight" page. Based strictly on similarity to the query "diet," the search engine would return a high ranking for the p2 page and a low ranking for the p1 page.

Retrieval, particularly the calculation of page rank from the search query words, is vulnerable to manipulation, creating a service industry devoted to increasing the rank of a client's Web site pages. The purpose of manipulating search engine rank is to promote traffic to the Web site holding that page. The manipulation depends upon constructing pages that exploit known characteristics of

Figure 10: Two pages indexed on the words "weight," "loss," and "diet," where page p1 contains the word "weight" and p2 contains the words "loss" and "diet." Measuring similarity is as the cosine of the angle between a page and query vectors; the smaller angle corresponds to greater similarity. A query of "diet" would have some similarity to page p2 but no similarity to the "weight" page p1.

the spider and the ranking algorithm to produce a higher rank for specific queries. For example, a search engine might use a similarity measure that ranks pages highest that contain the greatest number of matches with query words. Pages can achieve a higher ranking for a given query by adding gratuitous but frequently used query words, a practice known in the trade as “spamdexing” where pages contain hidden words from a list of those most commonly used in actual queries. Standard candidates include “thong,” “jobs,” and “maps,” with “santa” making the list near Christmas. Such words may have nothing to do with the Web page’s apparent purpose and seldom appear when viewing the page in a browser. Other, crude manipulations include repeating the same word many times to increase the page rank; more manipulation details are in the following sections.

People continue to search because they trust search engine results to some degree; although the results may not always be useful, we expect a best effort on the part of the search engine. Manipulation places that trust of a search engine in jeopardy; as a defense, manipulation attempts generally deemed excessive can lead to the banning of a Web site by a search engine. Manipulation must exist to some degree, as Web pages are, of course, designed to attract an audience. The problem is the degree of manipulation; deciding between excessive and reasonable attempts at manipulation is up to the search engine site. Indexing and retrieval algorithms follow predictable patterns that attempt to produce highly relevant search results. A Web site aids the search engine and itself with pages crafted to match those characteristics, that is, manipulation; the ethical dividing line lies somewhere between truthful content with no attempt at manipulation and overt manipulation practices such as “spamdexing.”

Web search engines attempt to exploit the special features of Web pages to improve retrieval quality beyond those possible using traditional text retrieval methods alone. Assigning specific elements of a page, such as title words or links to other pages, special weight can improve the results over a strict similarity measure ranking. Page popularity and importance measures utilize the natural links between Web pages to refine rank calculated on word matches alone. Popularity assigns a higher rank to pages having more references from other pages under the assumption that a frequently referenced page is more relevant than a page with fewer references. Figure 11 illustrates the popularity of page A to be greater than that of either B or C, as more links or references are to A than to either B or C.

Figure 11: The number of links to a page measures its popularity. Two links confer on page A the greatest popularity, B the next, and C the least popularity. The ranking based on popularity would be ABC.

However, a popular page is not automatically important. One definition of page importance is in terms of the number of links to the page and the importance of the linking sites. For example, a link from an Internal Revenue Service page to a page on taxes is intuitively more important and adds greater rank than a link from a random individual to the same page. This global ranking scheme is the basis of PageRank (Page, Brin, Motwani, & Winograd, 1998), used by the search engine Google.

Although a discussion of the full PageRank algorithm is beyond the scope of this chapter, the basic concepts (Arasu et al., 2001) are relatively clear when limited to a Web where every page is reachable by every other page. For that assumption, let $1, 2, 3, \dots, m$ be pages on the Web; let $N(i)$ be the number of links from page i ; let $B(i)$ be the set of pages linking to page i . Then $r(i)$, the simple PageRank of page i , is

$$r(i) = \sum_{j \in B(i)} \frac{r(j)}{N(j)}.$$

Note that dividing by $N(j)$, the number of pages linked from a page, reduces the ranking contribution of a page as the number of pages linked to increases. This fits one’s intuition that a page with links to many, possibly loosely related pages should not contribute as much rank as a page that links to only a few, likely more closely related pages.

In practice, the algorithm ranks a page higher than an otherwise identical one if a large enough set of pages link to that same page. This characteristic of the algorithm has proven sensitive to manipulation by a relatively few cooperating Web sites. Called “Google bombing,” pages on multiple Web sites are constructed to hold essentially the same phrase and links to the target page. As more Web sites add the manipulation page, the rank of the target page increases to the point where a matching search query returns a high ranking of the target page. After a successful bombing, the algorithm ranks the targeted page higher than the referring pages that contain the actual query words. A manipulation page could consist of only the HTML tag `bomb phrase`; after indexing enough sites containing the bomb page, Google will respond to the query “bomb phrase” by returning a highly ranked link to the target site `www.bomb.com`. This particular manipulation method appears to have been first recognized by an individual (Mathes, 2001) when searching for “internet rockstar” using Google.

WEB SITE

Web sites provide the fodder, the reason to search; though the site is dependent on search to attract visitors, the exposure naturally places the site at greater risk to external attack. Web sites are also threats to the other parties of search, having the most to gain by deceiving and manipulating the search engine and by intrusion upon the searcher’s privacy; some manipulation practices can result in banishment from a search engine or legal action. Web sites are also vulnerable; attacks against searchers (discussed in the section “Searcher”) can redirect them

to bogus Web sites and search can expose sensitive data, threatening privacy and security. This section examines only the special facets of Web site security, privacy, and threats that are most directly a result of search while necessarily ignoring the important but more general issues surrounding Web server and site security.

Web Site Discovery

Most Web sites have the goal of attracting visitors who most often find a new site via a search engine; building an easily found and searchable site is critical. A study of search success (*Users Don't Learn to Search Better*, 2001) illustrates the difficulties and necessity of designing a Web site for search. After watching 30 searchers search different sites for content that was on the sites, the study concluded, "The more times the users searched, the less likely they were to find what they wanted." Single searches found the content 55% of the time, those searching twice found the content only 38% of the time, and those searching more than twice never found the content. Nearly 23% of the searchers received a "no results" response on their first searches, causing most to give up immediately. For those who continued to search, results only grew worse. Further compounding search problems is the prevalence of invalid links to pages no longer accessible; one study (Lawrence et al., 2000) gives the percentage of invalid links ranging from 23% of 1999 pages to 53% of 1993 pages.

How does a search engine discover a Web site? Given that any search engine indexes only a small fraction of the Web (Lawrence & Giles, 1999), the answer is of critical importance to the Web site designer hoping to attract visitors. Most search engines accept free submissions for indexing all or part of the Web site and paid submission to multiple search engines is available through service companies. Complementary links with other sites will also widen visibility and speed the discovery of a Web site; sites with few links have a lower probability of indexing. The most certain and direct approach is to purchase key words on a search engine; a query with a site's key word is guaranteed to return the site, though normally distinguished from those listed by the merit of rank. Once a Web site is discovered by search engines, the methods to influence automated search become important, though often the best strategy is to develop and maintain high-quality content to attract and cultivate loyal visitors. Where content quality or time is in shorter supply than money, the paid listing can guarantee that a site is highly ranked for specific query words.

What Search Engines Search

Since Web sites compete against one another for a high page rank and search engines sell placement at the top, the searcher has reason to question the accuracy and veracity of the ranking results. Driving the competition for visitors are searchers who are more likely to visit the higher ranked sites first; given that search engines bring in the majority of first-time visitors, high placement in the ranking means money to the commercial Web site. The search engine positioning industry has sprung up to evaluate and manipulate search engine bias in order to raise the

ranking of their client's Web site. Pages can be crafted to match the spider indexing and search engine ranking algorithms in an attempt to indirectly manipulate the query results. Indexing and ranking algorithm rules are often sensible but sometimes appear fickle. Some rules are based on apparently common sense approaches such as assigning the page title a higher weight than other text; other rules look for patterns considered abusive that when discovered can theoretically lead to banning of the site. Arbitrarily changing the rules as defense against too successful manipulations such as the "Google bomb" noted earlier is common among search engines. The following Content and Tag Sections details those parts of the Web page most commonly used for indexing and ranking.

Web pages can be richer sources of search and ranking information than traditional documents such as books and journals due to the natural connections formed to related pages and the characteristics of the HTML used for writing Web pages. Web search engines generally seek to improve upon traditional retrieval systems by extracting added information from the title, description, and key word HTML tags and by analyzing the connecting links to and from a page.

Recognizing the parts of a Web page that attract the attention of indexing spiders is critical to Web site designers attempting to raise the visibility of the Web site. Ideally, a Web site designer could give instructions to visiting spiders on precisely how best to index the page to produce high-quality search results. Unfortunately, self-promoting Web sites generally have a history of hijacking spider indexing rules for their own benefit. In response to blatant self-promotion, few spiders observe a published protocol as to which page to index or which parts of the page are considered important. However, most observe published guidelines to Web site promotion (Sonnenreich & Macinta, 1998).

Risks of Search

Web sites by nature expect global exposure and increased risk over operating in a closed environment; search tends to exacerbate any existing risks to privacy and security. Public exposure of personal information, either accidental or purposely, is a serious risk to individual privacy. For example, many individuals place personal e-mail addresses on pages for specific reasons; an instructor might include their e-mail address on a course syllabus for students. Privacy can suffer by using public information for unintended purposes, such as when e-mail spammers automate address collection by seining for pages containing the "mailto" tag.

There are some privacy defenses for personal information exposed on the Web. The most common and effective protection places sensitive information, such as an e-mail address, in an image. Spiders do not index images, only text, foiling direct harvesting through a search engine; requiring a human to read the information, a prohibitive inconvenience and expense for e-mail spammers. A different approach effectively hides the mailing information in JavaScript code since spiders generally do not index JavaScript source or execute the source and examine the results; the browser can execute the JavaScript to display the address for normal use. The simple JavaScript

```

<script language="JavaScript">
  document.write('<a href="mailto:Me@">');
  document.write('mail.com">');
  document.write('Me@');
  document.write('mail.com</a>');
</script>

```

Figure 12: Hiding sensitive information in program code from spiders.

in Figure 12 displays clickable text and “mailto” attribute of Me@mail.com in a browser but forces the spider to execute JavaScript for indexing. Camouflaging, such as in JavaScript or images, makes visible to humans information that should be hidden from spiders.

A form of piracy, copying images, content, pages, or even the entire site, is made easy and potentially undetected; stealing from a top-ranked site is one way to mimic their success. In most cases, the HTML, script, and images of pages viewed in the browser can also be saved and published in a few seconds on another Web site; robots that copy each page while traversing each site link can automate stealing the entire site. One defense makes public only encrypted pages that the browser can automatically decrypt for viewing. The page is encrypted and delivered with a program script to decrypt the page; the browser must execute the script in order to render the page for viewing. Although copying the page is still possible, the encrypted portion cannot easily be decrypted into plaintext without executing the script outside the browser; probably more effort than the page is worth to the average pirate. However, encrypting the page makes it unreadable to nondecrypting spiders also and therefore not searchable.

Content

The end result of search leads to a Web site and some page content that the searcher sees and reads. The readable text, as displayed by a browser in Figure 13, provides the bulk of the words indexed by the spider. As noted in the section on search engine implementation, the spider ignores stop words, which are worthless in distinguishing one page from another. Less common words increase the page rank but are valuable only if a searcher uses that word in a query. Using many different words in a page improves search breadth but the words again must be used by the searcher. Including important key words in the title, increasing the frequency of a key word in the text, and placing key words near the beginning of the page content can improve page rank on most search engines. Be aware that repeating a key word multiple times in the title may gain a higher ranking but many search engines ban blatantly bogus attempts at manipulation and may reject the page or site entirely. The challenge to the page author is to find the right key words rare enough to stand out, descriptive of the content subject and familiar to the

searcher. Bear in mind that most indexing spiders only examine the first few hundred words of content so it is important to provide descriptive key words early in the content text.

Web sites that present deceptive content threaten the trust of searchers and, by implication; the search engine reputation is jeopardized. But Web site authors intentionally follow practices in writing page content with the purpose of achieving a higher ranking by search engines, much as any author attempts to attract readers. However, most search engines consider manipulating content to achieve an artificially high rank abusive and, in theory, can result in banning of the site by the search engine. This raises some important questions—where is the line drawn between good writing to attract searchers and abusive practices? Who decides when the line is crossed? What is appropriate punishment? For a commercial Web site, banishment from a major search engine can be devastating to attracting new business. Search engines, due to lack of any formal regulations, are for now the de facto Web police, with the motivation and power to control at least some aspects of site content and promotion.

Search engines also face a conundrum. The search engine manipulation policy, if enforced and a site is banished, has potentially serious consequences that could affect the conscientious Web site; but if Web sites face no serious threat to their abuse, search engines face a race to the bottom in deceptive practices to achieve a higher ranking. At least one search engine (Ask Jeeves, 2004) posted a policy outlining abusive practices as part of the agreement for submitting a Web site. The policy is concise but leaves considerable room for interpretation by the search engine and Web site writer. The policy defines abuse in terms of spamming techniques designed to return a result unrelated to a user’s query or that is ranked artificially high. Examples given of manipulation include Web pages that contain:

1. deceptive text
2. intentionally misleading links
3. deceptive self linking referencing patterns among others in a group
4. off-topic or excessive keywords
5. duplicate content
6. different content than the spidered pages
7. material designed to lead users to other web pages
8. metadata that do not accurately describe the content of a Web page

Crafting the metrics of such a policy is obviously difficult, given that simply stating some fixed number of keywords above which is excessive, is arbitrary and invites other abuse. The approach apparently taken by search

Automated Search Engines
Automated Web search engines have two main tasks; one of indexing the Web information, the second of answering search queries from the index. First, an indexing program visits a Web site much as you would with a browser, normally starting at the default home page, visiting connected pages, and indexing the site information (see Figure 14).

Figure 13: How the HTML of Figure 14 would appear in a browser.

```

engines has been to offer threats more strongly than action in specific cases and to modify indexing and ranking parameters as a more general response to disruptive practices.

Tags

HTML tags are not generally visible to the reader but do contain information important to the spider and are one source of abuse cited by search engine policies. Along with content key words, spiders also extract the page location and may examine HTML tags when indexing a page. The Web site designer can influence the page rank and provide more descriptive search results through the tags. Figure 14 gives the source for a HTML page to illustrate the page content and use the following tags.

Key word: The HTML key word meta-tag contains human-defined key words to augment the automated indexing of the page content. One use of the tag is to provide alternative words or phrases for those in the content, for example, using “PDA” in the content and “personal digital assistant” as key words. Unfortunately, promoters have so often abused the key word tag that Web search engines probably ignore it. As noted in the Ask Jeeves (2004) spam policy, the search engine policy forbids excessive key words, indicating that the key word tag will be spidered but not what number constitutes “excessive.”

Description: The description meta-tag provides a short content summary for display when the search engine

```

http://www.insearchof.org/how.htm

```

Figure 15: An example of how a search engine might respond to a query. The word “indexing” is part of the key word meta-tag and embedded in the text content. The title is “How Search Engines Work” and the description meta-tag is “Human lists and automated search engines.” The document URL “http://www.insearchof.org/how.htm” and the title provide links to the complete document.

retrieves the page. Figure 15 illustrates how a search engine would display the description tag with other page information.

Title: Indexing the title tag independently allows explicit searches on the title; the search engine can also display the title as part of the page information, as in Figure 15. As previously mentioned, key words placed in the title are intended to define the page purpose and improve page rank.

Heading: The large print of headings catches the attention of the reader and is important to an indexing spider. The influence of headings on rank generally follows the scale of the heading number, so that weight of the words of a level 1 heading is greater than the weight of the words of a level 2 heading.

Links: The spider follows link connections to other documents through the attribute and hypertext reference tag; for example, “” directs the spider to follow the link to the index page “Figure15.html.” The popularity ranking method would generally rank a page with many links from other pages relatively high. A cross-listing agreement with other sites serves to increase the rank of each site involved. One could, of course, take the low road and maintain a number of complementary linked sites specifically to manipulate search engine ratings. Despite the apparent advantage to a site connected by links from others, legal challenges have been mounted to stop what is known as “deep linking” (Rosencrance, 2000). The complaint is that unauthorized direct links to deep pages rather than the home page take control of the visitor experience away from the site owners, allowing different visitors to visit different pages, possibly avoiding revenue-generating advertising. Because search engines are effective precisely because they find and link directly to pages, such litigation could have a chilling effect on search.

What Search Engines Ignore

Most spiders purposely ignore or cannot see large parts of a page that human readers might see and use, effectively

hiding that part from search engines. Page designers normally expect the spider to index the full page and follow links to other pages but some sensitive material should be excluded from search. By accident or design, spiders can be excluded from indexing some or all pages of a Web site.

Frames: Visibly dividing a browser screen into several parts is the purpose of frames, but unfortunately, frames can stop an indexing spider and create confusion for visitors arriving from a search engine. Frames require at least three separate pages: a hidden frameset page that defines the frames and links visible pages into the frames, a second page for visible content, and a third often for navigation. A spider normally arrives at the hidden frameset page but must understand how to handle frames in order to follow links to the other, visible pages. Spiders that do not understand frames simply stop and never index further. For those spiders and browsers that do not understand frames, the remaining site pages are unreachable unless alternative links exist.

HTTPS: Spiders generally use only HTTP for communications with Web servers and do not normally index a server requiring HTTPS.

Scripts: Most spiders ignore script programs written in JavaScript or other scripting languages; others simply index the script program text. Spiders ignore scripts for two main reasons: the spider must be able to execute the script, which requires an interpreter for the script language; and the spider must simulate any required human interactions such as button clicks. Both are doable but currently not considered worth the effort by spider developers. As a result, scripts can hide sensitive information; see Figure 12 for an example.

Java applets and plug-ins: To a spider, a Java applet, plug-in, or other browser-executed program is invisible since no text is given, other than that needed to execute the program. Unless the spider is willing and able to execute the program, there is nothing to index; if executed by the spider, the program output is likely to be graphical and unreadable by the spider.

Server-generated pages: Spiders may ignore any unusual link references, such as ones that do not end in “HTM” or “HTML.” For example, a spider will follow the connecting link “” but may not follow the link to the Web server program of “” due to the ending “ASP.” Generating the Web site main page with a server program can mean that some spiders ignore the complete site.

Forms: Collecting visitor information is one of the most important functions of many Web sites, but spiders do not know how to fill out forms. Spiders that do index the content and links of the page containing the form create potential problems by leading visitors directly to the form page from a search engine rather than through the pages intended to precede the form.

Robot exclusion: Forms represent one good reason to exclude spiders from indexing certain pages; sensitive

information is another. Two standards exist that instruct well-behaved spiders on excluding specified pages. The recognized standard is the “robots.txt” file that lists acceptable and unacceptable directories, pages, and robots (i.e., spiders). A single robot.txt file exists for the entire Web site, which only the site administrator can access, creating a maintenance bottleneck as multiple designers make changes to the site. A distributed but less accepted solution defines a special “robots” meta-tag to specify how to index each individual page. Options are that every spider or no spider should index the page, the page should be indexed or not, or the page links should be followed or not. Neither of the standards prevents a badly behaved spider, such as an e-mail address harvester, from ignoring the exclusion instructions.

Images: Spiders may index the image location, image title, and alternate text but that is probably all due to the effort required to analyze an image.

Meta-tags: The purpose of meta-tags is to provide specific information, such as the character set to browsers or key words to spiders. Most spiders now ignore meta-tags due to past attempts by Web sites to manipulate rank.

Deeply linked pages: Most spiders index only small sites completely, generally indexing only a limited number of pages on each site. Spiders limit indexing to several connecting deep links, ignoring pages linked beyond that depth.

Measuring Success and Tracking Visits

A site can determine whether efforts to attract search engine attention have been a success; the site can also determine information about visitors and their point of arrival. Search engines offer one of the most obvious and direct means for checking whether and to what extent a specific search engine has indexed a site by limiting search to that Web site. These same controls used by searchers can also provide feedback to point out search problems with the Web site. Although tests with individual search engines will determine whether and how a Web site has been indexed, it will not tell if, why, or how anyone visits.

A site can perform visitor tracking by logging and analyzing the details of each visit. Logging by itself is useful for the site administrator to locate problems but also to track a searcher’s behavior and discover elements of their identity. The site server holds visitor information in the server access log file with details about every attempted or successful visit. Table 1 lists the information retained in the Web server access log following the Common Logfile Format. Free and commercial analysis software can produce detailed summaries and graphs of the log; the most telling information about search success is contained in the following three fields:

Client request line: This field contains the page on the server the visitor requested. For visitors arriving from a search engine, this contains the link to the page indexed by the spider.

Table 1 Server Access Log Fields in Common Logfile Format

Access Log Field	Example
Client IP address	24.10.2.3
Client identity—unreliable	—
Authenticated client userid	—
Time request completed	[01/May/2002:17:57:03 -0400]
Client request line	"GET/mainpage.htm HTTP/1.1"
Server status code	404
Referring site	"http://www.food.com/ search.html"
Client browser	"Mozilla/4.08 [en] (WinNT; I;Nav) "

Server status code: Status codes starting with a 2 indicate success; those starting with 4 indicate that the visitor probably encountered a mistake. In Table 1, the “mainpage.htm” page does not exist, earning the visitor a “404 Not Found” response from the Web site.

Referring site: Search engines respond to queries by supplying pages that link or refer back to the original page found by the spider. When the browser follows a link from the search engine page, it reports the search engine address that supplied the page or referred them. In Table 1, the visitor arrived via a reference to “mainpage.htm” made by the “www.food.com” search engine.

The log has many legitimate functions in maintaining the Web site but also represents risks to the privacy of visitors. The client IP address and request line alone are sufficient to track visitor behavior on the site, providing information on who (the IP) and what pages (the request line) were visited. Simple analysis of behavior is possible; merely sorting each IP address by the time field yields the page order visited by each client. The search engine used can be determined from the referrer field, which contains the referrer link the visitor followed to the site. Deeper analysis requires additional data; to determine what search brought the visitor to the site requires the query from the search engine; to determine the real identity of the visitor requires connecting the client address to personal data. Such connections intrude upon one’s privacy but such inferences are possible by combining cookies or other sources of personal data with the data in the site log.

The log’s main utility goes beyond tracking visitors. Examination of the log entries can point out the Web site errors and successes. Counting the number of visitor requests (i.e., client request line) to each page immediately grades pages on success in attracting visitors and, by their absence, identifies those pages that failed. Investigating the referrer list will show how visitors arrive at a Web site; search engines missing from the list have not indexed the Web site or rank its pages below others. A table of visitor page requests with the referring site will clearly show which search engines successfully found specific pages and can flag pages that create indexing problems for particular search engines. As discussed earlier, some spiders are stopped by frames, only index the first few content lines, or crawl a limited number of links on each site. Pages never accessed can indicate indexing problems for

the spider or navigation problems for the visitor. Examining the access log file is a good starting point for finding these and other potential search engine and link problems.

Self-Search

Many sites maintain their own local search engine but why does a site need its own search? Are there any special benefits or risks involved in operating a search engine? One can easily provide visitors with search by placing a link on site pages to a Web search engine. Spiders are far from perfect at indexing Web sites, ignoring some pages that are important, and Web search results focus not on the one site alone but must compete with results from other sites. Moreover, spiders ignore changes to sites because of long periods between their visits; Web search would be unsatisfactory for a news site. Web search engines, which bring most new visitors to a Web site, are poorly suited for searching a site exclusively. However visitors arrive, one authority (Nielsen, 2000) has found that many visitors immediately use search on arrival as the preferred means of locating information and ignore site navigation aides; those visitors need a search engine tailored to the Web site.

Operating the search engine and the Web site allows deeper analysis of search behavior and possibly to connect that behavior with personal information. The Web server site log contains visitor IP address, pages viewed, and referrer page data; the search engine can log searcher IP address and query; combined with cookies to track multiple visits, the site can build a profile of an individual. Shopping sites make use of these techniques in determining purchasing patterns to suggest purchases similar to those others have made. One can imagine the site monitoring failed searches to determine new stock to carry, a smart business strategy. One can also imagine abuse of the same information.

What should a site designer look for in a search engine? A search engine for a site is comparable in function to a Web search engine but can limit search to the given site. Beyond the raw power required to index a complete Web site, a key capability is to create and search specified branches of the Web site. Indexing every word of the entire site is easy to do but ignores the different reasons visitors search the site and the principle that search works best when the information searched is narrow and homogeneous. For example, search of a university Web site should give visitors the choice of whether to search the business and science separately or all school categories combined.

Separating business from science capitalizes upon natural and recognized differences to create a narrower, homogenous, and recognizable information area to search. Another issue is the sophistication and flexibility of the search engine. Does it support automatic or manual word stemming, common misspellings, indexing of the HTML tags, synonyms, inclusion and exclusion query operators, and phrase and proximity search?

Two basic options exist for search dedicated to a site: site operated or retained by an off-site search service. Having someone else handle search is the easier solution but does not necessarily match the owner's needs; handling search oneself can be more flexible but involves more work and expense.

Search Service

Search service companies will index a few pages or an entire Web site, will operate the search engine on their computer, and are in some cases free. The free services generally index a limited number of pages; in return the service places advertising on each search result page. A good service should index pages located on any Web site, index with reasonable promptness whenever the owner chooses, and provide regular summaries of search activity for the site. The main advantage is that someone else maintains the search engine and bears the responsibility for security.

Operational concerns of a search service are the continued cost, the possible limit on pages indexed, scheduling the occasional reindexing, the lack of control over the search results or the result page appearance, and the advertising banners that may not impress your site visitors. Analysis of search behavior may not be possible since access to the search engine log may not be allowed. However, the most serious problem occurs should the service company drastically change policies or technology or go out of business, forcing the Web site search to change.

Security issues include those normal to Web search engines such as denial of service attacks combined with the additional concern over the impact of a search service failure; search is critical to certain site operations such as an automobile parts business. Susceptibility of the search service to attacks and overall security management can be difficult to determine.

Privacy concerns are similar to those for Web search, an issue for both searchers and the site. Searchers are at risk because the search engine service can use cookies or other means and the search query log to track search behavior of an individual. The search engine is in a position to gather detailed search data on a complete site, data that would be useful for refining the site for search and to other competitive sites for the same purpose. Privacy policies of search services vary widely; not to sell spammers your e-mail address is the only stated policy of at least one search engine.

Reasons for a Private Search Engine

The only compelling reason to operate a private search engine is to benefit site visitors, at least under the theory that what is good for the visitors is good for the site. For private search, operating a basic search engine can be relatively easy and many Web server systems include

a search engine. Commercially packaged Linux systems come with the ht://Dig engine installed and ready to index the entire server; the owner need only type the `“./rundig”` command and add a search form link to the site pages.

The main advantages of a private search engine are control of parameters such as indexing depth and access to the information of the logs produced by the search engine during indexing and visitor queries. The obvious disadvantages relate to maintaining the infrastructure necessary to support search, likely an additional computer and software for searching, and the exposure to additional security risks. In addition to the usual concerns of operating a Web server, most search engine software has proven open to attack in some way; ht://Dig has been reported vulnerable to a denial of service attack (SecurityFocus, 2001).

The following examines common search engine parameters that provide some control over search and much of the motivation to operate a search engine:

Excerpts: Search results can include text excerpted from a page to help place query key words in context. Because the excerpting generally takes place during indexing, the searcher needs a little luck for the excerpt to include at least some of his or her query terms. Controlling the size of the excerpt improves the likelihood that the excerpt will contain some query key words or possibly an entire page.

Indexing: It is important to control the number of words indexed and how often indexing of the site occurs. Although most pages contain fewer than 2000 words or about 7 pages of typed text, indexing spiders with the word limit too low can routinely miss indexing important parts of large pages. Also important to sites with news, pricing, and other frequently updated information is how often indexing occurs and whether it occurs whenever information changes.

Stop Words: Stop words often include numbers and common words such as “the,” “computer,” “system,” and “HTML” and should not be indexed. Words that occur often on many Web site pages should also be included in the stop word list. For example, on a bread Web site, the word “baking” would possess little value in discriminating one page from another.

Measuring Success: Successful searches mean that the visitor follows or “clicks through” to a suggested page. The Web server access log will list the page the visitor follows but only the search engine can log the query words entered to find the page; connecting the query words with the referred page measures the effectiveness of search on a Web site. Other measures of search success are whether visitors actually sought the information they received or immediately searched again, and whether they followed the referred page further to accomplish some task such as buying a car or registering for a class. Failed queries are also valuable for determining words to add to pages as indicated by the key words searchers used, expecting to find information, but failing.

Measuring Failure: Failed searches are valuable in identifying what visitors actually want and expect to find

on the site. Visitors are sending a clear message if a Web site for programmers sells nothing except Java programming tools but 75% of the searches are for FORTRAN. Search engines that log failed searches give insight into possible improvements. For example, queries containing predictable misspellings of FORTRAN can succeed after adding misspellings such as FOTRAN to the engine's synonym list.

SEARCH ETHICS

On the surface, particularly to the average user, search appears safe, anonymous, free, and very useful; an unusual bargain. Why is a discussion of ethical issues relevant to search? As we have seen, search has value and poses hazards to security and privacy; and, on many issues that matter is unregulated. While such a discussion will not by itself reduce potential danger or damage, it can play a role in the process of marking the boundaries of acceptable behavior. There are some actions that are clearly improper, such as reading another's communications, and have been examined in previous sections from a technical perspective; actions of an individual will be examined in this section from an ethical perspective.

Ethical behavior by an individual conforms to the standards of right and wrong for their member group. Web search intersects the behavior of at least three groups, the searcher, search engine, and Web site, in addition to deliberate attackers. While not to discount the reasoned ethics of attackers, the discussion focus will continue on members of the first three groups. Membership in the search engine and the Web site group is sharply defined, by nature being public knowledge and exposure, reasonably long term presence, and each having a financial investment in search. Membership in the searcher group is transitory and usually anonymous, with individuals having no knowledge of other searchers, nothing obviously in common other than search, and essentially no financial investment in search. Laws and the threat and cost of exposure provide some of the motivation for ethical behavior, particularly on the part of search engines and Web sites. Search engines are motivated to follow ethical practices to maintain public trust. Web sites may be guided by legal codes or professional organizations, such as the Web site promotion industry, which publish a code to their membership on the ethical issues of the profession and appropriate behavior. Individual searchers bring with them their own ethical standards.

What are the ethical issues in Web search?

Search engines have an interest in maintaining a public appearance of ethical behavior given that the public trust in search results form the foundation of their continued existence. Two key ethical issues for which search engines are directly responsible are bias in site indexing and ranking of search results. Bias in site indexing is spider behavior idiosyncrasies that result in ignoring some legitimate pages and sites, or through deliberate policy decisions by the search engine owners. Spider bias is in part a practical requirement that limits what and how much of a page or site the spider indexes due to technical limitations such as the search engine storage capacity, communication demands, and the relationship of indexing to the

retrieval algorithm performance. In theory, bias is then a result of technical decisions to improve search results. In practice, search engines also apply policies that restrict search to approved parts of the Web. The stated target of these policies is spammers, those Web sites who use tactics the search engine finds abusive. Search engines publish spamming policies but do not publish indexing rules and occasionally change those rules as Web site promoters (termed search engine optimization or SEO) eventually infer enough indexing patterns to increase a site's ranking artificially. Such behavior is a defense against attempts at Web site manipulation by SEOs but can reduce traffic and income of conscientious sites when indexing rules seemingly arbitrarily change; a number of search engines warn against specific manipulation practices (Google, 2004). Related to intentional manipulation attempts by a Web site to improve search ranking is the selling of rank placement by search engines. Web sites can pay to have their site prominently displayed on the search response to specific query words; responsible search engines clearly identify these sponsored links as essentially paid advertising.

There is obvious competition between the search engine and an SEO in the selling of visibility to Web sites and a financial interest in each manipulating search to their advantage. The search engine holds the key levers of control; it owns the search service, controls the indexing and ranking rules, sets and enforces the spamming policy, and can decide to make changes to any of these arbitrarily. The search engine by default plays a shadow role of enforcing standards on Web sites, at least those submitting agreements to be searched. One concern here is that financial issues rather than technical performance may influence decisions directly affecting the search engine behavior and the ultimate ranking of a Web site.

Should search engines prevent search of objectionable sites? Spamming policies are evidence that search engines possess at least some technical means to enforce standards by restricting the sites searched and therefore what is generally visible on the Web. Given the cost of operating a large search engine, only a handful exists, creating one of the few central points where access to the Web can be influenced. Currently search is restricted only to those sites deemed abusive for purposes of the search engine.

Should search engines prevent objectionable searches? The automated search engine indexes words from across the Web and responds to queries that contain a subset of those words, generally with no recognition of the semantic value of the search or the intent of the searcher. A search for "build a nuclear weapon" is currently handled the same as a search for "build a swing set" with no attempt or real ability to understand either search. The "build a nuclear weapon" search returns sites on constructing the weapon but also news of efforts to restrict nuclear weapon proliferation; current search engines do not understand the search query beyond simply matching words and calculating a corresponding rank. Network attackers use search engines to locate victims, by marketers trolling for e-mail addresses to harvest, by shoppers hoping to spend less money, and by young children who stumble upon adult material. Most would agree that the attacker, shopper, and child occupy starkly different poles of the ethical spectrum covering search engine use and

shades of ethical behavior exist somewhere in between. By the apparent absence of legal implication of search engines in criminal or civil cases, one can infer that current standards have not yet connected responsibility for the use by the searcher of search engine results back to the search engine.

What harm can a search engine cause an individual? Search engines certainly make locating any personal data that happen to be published on the Web much easier. One can reasonably argue that is not the fault or concern of the search engine but the Web site to avoid exposing sensitive data to search. The Web search engine service is usually free to the searcher. The search engine only has access to information posted on a public Web page. The information is freely, if not always consciously or intentionally, available and exposed to the world. What are the standards for use of the search engine and retrieved information? Does placing your e-mail address on a Web page imply an invitation for e-mail spamming? Most would agree that spammers violate no U.S. law, as of yet, but also consider spam an annoyance at best and occasionally causing harm. Although spammers use their own engines to automate e-mail address harvesting, search engines make it possible for individuals to locate personal information from Web pages. Obviously the difference is in how the information is used, whether to contact an old friend or to send thousands of e-mails.

However, search engines often store cookies on the client machine for holding information, perhaps of a personal nature, used in tracking individual behavior if not an individual. A searcher can choose to disable cookies on their browser. Whereas sites that require authentication generally require enabled cookies, major search engines have no authentication and no required need, so cookie use is up to the individual. However, cookies allow the search engine to construct a history of searches identified by a specific machine if not the individual. The search engine generally does not monitor the sites visited or pages viewed through the search, although with site cooperation, that can be performed also. Given that a site may have data that connect to an individual's identity, such cooperation can connect identity to search behavior. Such possible exposure is not expected by most searchers. Collecting data imparts responsibility for its safeguarding and proper use, requiring technical competency to secure the data and motives to protect the individual from harm.

What are the Web site concerns? Web sites far outnumber search engines and span a broader range of behavior; unlike search engines that need long-term trust of the public, Web sites can benefit from disingenuous behavior. Web sites that attempt to gain ranking and traffic by presenting one site to a spider and another to a browser misrepresents the site, seemingly a clear violation of ethics; one that harms the accuracy of the search engine and misleads the searcher. Because spider and search engine manipulation ranges over a continuum, one usually measured by degrees rather than discrete events, objectively categorizing actions is difficult. However, the business of a SEO involves methods that benefit their client's Web site; though the methods are not necessarily manipulative, they do target known search engine behavior to gain some advantage for their client. Whereas the SEO

industry is not unethical, the methods often employed characterize the excesses of some Web sites; hence a natural tension exists between search engines and SEOs. It is instructive to examine some of the industries' own ethical standards; one company's ethical code (Search Engine Ethics, 2002) states that "Any SEO should not use any methodology which may result in having a client removed from a search engine index or directories, or rendered inoperative." It goes on to say that published search engine rules should not be violated, copyrights must be respected, and confidential information is not to be disclosed; a concise statement of ethical behavior. Web sites as a group have no representative body and no published standards of conduct other than that enforced by search engines and regulatory agencies such as the Federal Trade Commission. The global nature of the Web search brings into question the standards applicable to a Web site.

Are the interests of society being served? What behavior serves the long-term interests of the search community and the larger interests of society? Are new laws and regulations needed to protect and promote the future development of the Web and search? Search engines have democratized information retrieval much as the Web has democratized authorship; it is now easy for a large number of the privileged people in the world, from students to hobbyists, to publish and be discovered electronically. Society benefits from the wide and rapid exchange of ideas, Web search occupies a potentially historic position in the communication of knowledge. Does placing work on the Web place the work in the public domain? Most would agree that the act of publishing does not yield one's rights to benefit from the work. However, a work published on the Web often garners different treatment than one published and printed in the traditional manner. The sharpest distinction is on cost; traditional publishing is financially risky, in large part due to the inventory and distribution of the physical product. Publishing electronically, requiring no inventory, has a much lower risk, being able to generate the product on demand for each sale.

Society gains when ideas are exchanged. The printing industry gains from copyright laws that serve to protect the financial investment in producing the means of expression. Society trades gains in the sharing of ideas for some restrictions by offering protection through these same laws. However, some argue that on the Web, plagiarism matters more than copyright piracy to society (Snapper, 1999). Copyright piracy causes harm to the copyright owner; plagiarism fails to give due credit. For example, including copyrighted work without permission in a published collection may deprive the copyright owner the opportunity of future sales. Failure to credit the creator of the work is plagiarism. Society has laws against copyright piracy but not against plagiarism, implying that protection of the means of expression is important to society but not credit for the idea. Failure to credit the author is not a punishable offense, except for good reasons, among academics. Injury to society results because plagiarism breaks the intellectual trail established by citations, when prior work is not cited the trail is broken.

Plagiarism is an old problem encouraged by the modern Web and search engine technologies. By definition, a plagiarist passes off another's ideas as his or her own.

One can define degrees of plagiarism that ranges from the modest, perhaps unintentional, parroting of a well-turned phrase to the lifting of complete passages or programs to the blatant copying of complete Web sites. The search engine technology only locates and exposes the Web page to the searcher; the searcher must intentionally copy the page to their computer. Although the same ethical issues of recognizing ownership apply to Web pages as to traditional work, search has made locating intellectual property and the Web has made copying almost effortless.

Society's interest lies at the new intersection between piracy and plagiarism formed by Web search. Can copying a published Web page be any more or less ethical than copying from a published book? Is society better served by a loosening of copyright laws and a strengthening of plagiarism prohibition on the Web? The dynamics of the Web are different from traditional printed publications. Whereas printed work cannot easily be revised after publication, Web published works can be changed without evidence of the revision. Whereas there are many printed copies distributed after publication, Web published works may exist as a single copy. The conundrum of the Web is that citations may reference a work that has changed, moved or no longer exists; breaking the intellectual trail valuable to future work. Where in the past, citing a work was sufficient to establish the trail; certainty of the work's existence in the form cited can only be ensured by archival of the work. This practice is already common among academic journals but not on the Web generally. Loosening copyright protection to allow archival copying by individuals and strengthening prohibitions on plagiarism may benefit the future development and growth of Web-based work.

One small irony; the search engine both promotes and exposes plagiarism of Web page information as many student authors of term papers have discovered. Surprisingly, many fail to recognize that phrases copied from a Web page originally found by a search engine serve as the perfect query to produce an unambiguous target back to the source. Evidence of copying entire pages is clear from many queries that return identical pages from several different sites that fail to credit the author. Sadly, pages on computer ethics have appeared nearly verbatim on other Web sites with no acknowledgements.

CONCLUSION

Web search is critical to navigating the Web but is still in its infancy, with many remaining details to sort out; accuracy will improve as efforts to make Web content more searchable progress and the new models needed for sharing and maintaining legacy information will develop. The chapter paints a somewhat gloomy picture of the current security and privacy when searching the Web, a Web that depends upon an infrastructure designed and implemented with little thought for risk management. Although there are measures that individuals, ISPs, and Web sites can take to manage risk, all require extra effort and continued diligence. Technology exists and efforts are underway that eventually will result in Internet communications and Web search designed with security in mind, so the future

does hold out the promise that successful attacks will become technically more difficult. However, many non-technical issues affecting privacy, such as identification and monitoring of search behavior by search engines, government agencies, and employers will remain and almost certainly grow with the importance of Web search as a source of information.

GLOSSARY

- ARP (Address Resolution Protocol)** A protocol for associating IP addresses to local area network addresses.
- Common Logfile Format** A standard format for logging and analyzing Web server messages.
- Cookie** Information stored and retrieved through the browser on the client computer.
- DNS (Domain Name System)** The Internet service that translates mnemonic site names to IP site addresses.
- HTTP (Hypertext Transfer Protocol)** Protocol used by Web servers and browsers for communications.
- Index** List of words extracted from pages and the location of each page where the word was extracted, used for matching query words and locating the pages containing the matches.
- Meta-search** The fusion of the results from multiple search engines simultaneously searching on the same query.
- Page** A Web document containing plaintext and hypertext markup language for formatting and linking to other pages.
- PageRank** A system of ranking Web pages where a link from page A to page B increases the rank of page B.
- Phrase search** A search for documents containing an exact sentence or phrase specified by a user.
- Precision** The degree to which a search engine matches pages with a query; when all pages are relevant to the query, precision is 100%.
- Query** Words given to search engine in order to locate pages containing the same words.
- Recall** The degree in which a search engine matches relevant pages; when all relevant pages are matched, recall is 100%.
- Relevancy** The degree to which a page provides the desired information, as measured by the searcher.
- Search engine** The software that searches an index of page words for query words and returns matches.
- SEO (Search Engine Optimizer)** A business that attempts to match a client's Web site design with those features likely to produce a high ranking by a search engine.
- Spider** The software that locates pages for indexing by following links from one page to another.
- SSL (Secure Socket Layer)** A communications software layer for secure end-to-end communications between two parties.
- Web site** A Web location holding and providing access to pages via the World Wide Web.

INTRODUCTION

There were two predominant trends in computing over the past decade—(i) a movement from monolithic software to objects and distributed components and (ii) an increasing focus on software for the Internet. Web services (or e-services) are a result of these two trends.

Web services are described as distributed services that are identified by URI's, whose interfaces and binding can be defined, described, and discovered by XML artifacts, and that support direct XML message-based interactions with other software applications via Internet-based protocols. Web services that perform useful tasks would often exhibit the following properties:

- *Discoverable*: One of the foremost requirements for a Web-service to be useful in a commercial scenario is that it can be discovered by consumers (humans or other Web services).
- *Communicable*: Web services follow a message-driven operational model exchanging messages in XML syntax. The operational model is thus also referred to as document object model. Various communication patterns are used between Web services: synchronous, and asynchronous as well as transactional communication.
- *Conversational*: Sending a document or invoking a method and getting a reply are the basic communication primitives. However, complex interactions between Web services involve multiple steps of communication that are related to each other.
- *Secure and manageable*: Properties such as security, manageability, availability, and fault tolerance, as well as transactions, quality of service, and reliability, are critical for a commercial Web-service.

A gradual paradigm shift from object-oriented (monolithic) software to software available as a service via the Internet is taking place.

THE GENESIS OF WEB SERVICES

Contrary to public perception, the development of Web services has followed a rather modest evolutionary path. The underpinning technologies of Web services borrow heavily from object-based distributed computing and the development of the World Wide Web (Berners-Lee, 1996). In this chapter, we review related technologies that help shape the notion of Web services.

Tightly Coupled Distributed Software Architecture

The study of various aspects of distributed computing can be dated back as early as the invention of time-shared multiprocessing. Despite the early start, distributed computing remained impractical until the introduction of object management group (OMG) common object request broker architecture (CORBA) and Microsoft's distributed component object model (DCOM), a distributed extension to component object model (COM). Both CORBA and DCOM create an illusion of a single machine over a network of (heterogeneous) computers and allow objects to invoke remote objects as if they are on the same machine, thereby vastly simplifying object sharing among applications. They do so by building their abstractions on more or less OS- and platform-independent middleware layers. In these software architectures, objects define a number of interfaces and advertise their services by registering the interfaces. Discovery of interfaces and objects implementing them is done by using unique identifiers assigned to

them when they are created. In addition, CORBA supports discovery of objects using descriptions of the services they provide. Sun Microsystems' Java remote method invocation (RMI) provides a similar functionality, where a network of platform-neutral Java virtual machines provides the illusion of a single machine. Java RMI is a language-dependent solution though Java native interface (JNI) provides language independence to some extent.

The software architectures supported by CORBA and DCOM are said to be tightly coupled because they define their own binary message encoding and thus objects are interoperable only with objects defined in the same software architecture; for example, CORBA objects cannot invoke methods on DCOM objects. Also, it is worth noting that security was a secondary concern, although some form of access control is highly desirable, partly because method-level/object-level access control is too fine-grained and incurs too much overhead, and partly because these software architectures were developed for use within the boundary of a single administrative control, typically a small local area network.

Loosely Coupled Distributed Software Architectures

As computing becomes more pervasive, more intelligent and autonomous devices with powerful computing capabilities have sprung up in the market. The fundamental changes in computing landscape make it rather microscopic to reason about utilization of these devices in terms of object invocation. For instance, viewing document printing as a printing service provided by a printer is more intuitive than viewing it as a method invocation on a proxy object of a printer. Thus, the notion of a service-centric view of computing has emerged.

These services tend to be dispersed over a wider area, often crossing administrative boundaries for better resource utilization through load balancing and exploitation of locality. Such physical distribution has called for more loosely coupled software architectures where scalable advertising and discovery are a must and low-latency, high-bandwidth interprocessor communication is highly desired. Specifying and enforcing security policies as well as protecting data themselves at every corner of a system can no longer be put off.

A slew of service-centric middleware developments has come to light. We note three distinctive systems from the computer industry's research laboratories, namely, HP's client utility, Sun Microsystems' Jini, and IBM's TSpaces (here listed in the alphabetic order). These have been implemented in Java for platform independence.

Client Utility Systems

HP's client utility is a somewhat underpublicized system that became the launching pad for HP's e-Speak. Its architecture represents one of the earlier forms of the peer-to-peer system suitable for Web service registration, discovery, and invocation (Kim, Graupner, & Sahai, 2002). The fundamental idea is to abstract every element in computing as a uniform representation called "service" (or "resource"). Using the abstraction as a building

block, it provides three facilities, namely, advertising and discovery service, dynamic service composition, and fine-grain capability-based security. What distinguishes client utility from the other systems is the fact that it makes advertisement and discovery visible to clients. Clients can describe their services using vocabularies and can state specifically what services they want to discover.

Jini

Jini technology at Sun Microsystems is a set of protocol specifications that allows services to announce their presence and discover other services in their vicinity. It prevails a network-centric view of computing. However, it relies on the availability of multicast capability, practically limiting its applicability to services/devices connected with a local area network (such as a home network). Jini's Unicast overcomes this limitation by providing a discovery mechanism in which a service user can find services that reside beyond the local network. Jini exploits Java's code mobility and allows a service to export stub code, implementing a communication protocol using Java RMI. Joining, advertisement, and discovery are done transparently from other services. It has been developed mainly for collaboration within a small, trusted workgroup and offers limited security and scalability supports.

TSpaces

IBM's TSpaces (TSpaces, 1999) is network middleware that aims to enable communication between applications and devices in a network of heterogeneous computers and operating systems. It is a network communication buffer with database capabilities, which extends Linda's Tuple space communication model with asynchrony. TSpaces supports hierarchical access control on the Tuple space level. Advertisement and discovery are implicit in TSpaces and provided indirectly through shared Tuple spaces.

Convergence of the Two Trends

Web services are defined at the cross point of the evolutionary paths of service-centric computing and the World Wide Web, where the idea is to provide service-centric computing via the Internet. Services are delivered over the Internet (or intranet), whereas the World Wide Web has strived to become a distributed, decentralized, all-pervasive infrastructure where information is put out for other users to retrieve. It is this distributed, decentralized paradigm of information dissemination that upon meeting the concept of service-centric computing has led to the germination of the concept of Web services.

The Web services paradigm has caught the fancy of the research and development community. A large number of efforts in industry and universities are actively defining standards, platforms, and concepts that will determine how Web services are created, deployed, registered, discovered, and composed as well as how Web services will interact with each other.

WEB SERVICES TODAY

Web services are appearing on the Internet in the form of e-business and portal sites. For example, Priceline.com

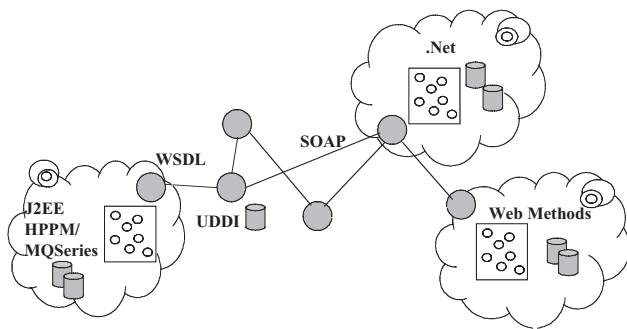

Figure 1: Web services.

and Expedia.com act as the broker for airline, hotel, and rental car bookings. They are statically composed Web services that have a prenegotiated understanding with certain airlines and hotels and broker their services through their portal sites. These are mostly a business-to-consumer (B2C) kind of Web services. A large number of technologies and platforms are emerging and are being standardized so as to enable the paradigm of Web services for satisfying business-to-business (B2B) and B2C scenarios alike in a uniform manner. These standards and platforms enable creation and deployment, description, discovery, and communication amongst them. Web services description language (WSDL) is used to describe service interfaces and to publish them together with the services' access points (i.e., bindings) and supported interfaces, both of which are described in an extensible markup language (XML)-based description language (see Figure 1). The universal description, discovery, and integration (UDDI) technology is used to discover described and registered Web services. After having discovered its partners, Web-services use the document model to exchange documents, and simple object access protocol (SOAP) to invoke service (which is an incarnation of remote procedure call (RPC) in XML) over hypertext transfer protocol (HTTP). Most services are implemented using platform-independent languages such as Java and C# on platforms such as J2EE and .Net. The primary means for enforcing security are digital signature and strong encryption with public/private key pairs. Standards such as SAML, XKMS, and XACML are appearing in this area. A large number of payment mechanisms are being defined, too.

Web Services Description

In traditional software development environment, software component interfaces are defined through interface definition languages (IDL). The interfaces describe the operations the software component supports, their inputs, and the expected outputs. This enables the interfaces to be decoupled from the actual implementation. As Web services are envisaged as software available on the Web that other services or users will use, they need to be described so that other components can easily use them without coupling the interfaces with the implementations. Web services description language is thus an attempt to describe the interfaces.

WSDL enables creation of flexible and generic interaction models for Web services, and enables description of the services irrespective of the message formats and

network protocols used. For example, in WSDL a service is described through a set of end points. An end point is in turn a set of operations. An operation is defined in terms of messages received or sent out by the Web service:

- Binding: a concrete protocol and data format specification for a particular port type.
- Message: an abstract definition of data being communicated consisting of message parts.
- Operation: an abstract definition of an action supported by the service. Operations are of the following types, namely, one way, request-response, solicit-response, notification.
- Port: a single end point defined as a combination of a binding and a network address.
- Port type: an abstract set of operations supported by one or more end points.
- Service: a collection of related end-points.

As the implementation of the service changes or evolves in time, the WSDL definitions must be continually updated, and versioning of the descriptions must be tracked.

Web Services Discovery

When the Web is browsed for information, search-engines are used to find relevant Web sites based on key words. However, this leads to a lot of unnecessary links that need to be sifted through, before the relevant sites can be found. Similarly, before Web services can interact to undertake business, they need to discover whether they are compatible with each other. The registration and discovery of Web services necessitates other entities to act as intermediaries, such as universal description discovery integration. UDDI is supported by IBM, Microsoft, and HP, and is a group of Web-based registries (operator sites) maintained by these organizations to expose information about a business and its technical interfaces and APIs. The core component of UDDI is its business registration, an XML file used to define businesses and the Web services they provide. There are three parts to the business registration, namely, *white pages* for name, address, contact, and other identifiers; *yellow pages* for classification of business under standardized taxonomies; and *green pages* for technical information about the Web services that are exposed. It also exposes a set of APIs for inquiry and publication of information related to Web services. The inquiry APIs enable browsing of the information in the repository site (e.g., `find_business`) and also drilling down (e.g., `get_businessDetail`). The publication APIs enable publishers to place their information on these repositories.

Marketplaces have been proposed as virtual meeting places managed by an intermediary to supply a series of benefits to participating Web services in addition to the basic registration and discovery functionality, namely:

- Enabling inter-Web service interaction with or without the direct participation of the e-marketplace in the actual interaction after the discovery;
- Enabling supply-and-demand mechanisms like traditional catalogue purchasing, RFP, or the more dynamic auctions and exchanges;

Figure 2: Intra- and inter-Web service modeling and interaction.

- Providing value-added services, such as rating, secured payment, financial handling, and certification and notification services; and
- Managing supply chains through collaborative planning and inventory handling.

Marketplaces could thus be developed as entities that use UDDI operator sites and provide value-added services on top of the basic functionality of registration and discovery. Vertical and horizontal marketplaces have been steadily coming up. VerticalNet, GlobalNetXchange, and Retailers Market Exchange are examples of the former targeting a specific section of the industry with key players performing B2B transactions. Other examples, such as Chemdex, E-Steel, and DirectAg.com, have been successful in their respective industries. Horizontal exchanges in turn are directed at a broad range of players, such as e-Bay targeting a wide range of clients and businesses.

Web Services Orchestration

Web services usually expose a subset of enterprise business processes and activities to the external world through a set of operations defined in their WSDL. The enterprise business processes must be defined, and some of their activities must be linked to the WSDL operations. This requires modeling of the Web service's back-end business processes, which necessitates intra-Web service modeling and interaction (see Figure 2). In addition, Web services need to interact with other Web services, which happens through a sequence of message exchanges, termed a *conversation*. The conversations can be described independently of the internal flows of the Web services and can be described simply by sequencing the exposed operations and messages of the Web services (as mentioned in their WSDLs). However, such an inter-Web service interaction automatically leads to coupling of the internal processes of the Web services to form what is called a *global process*. The participating Web services may or may not be aware of the whole global process, depending on their understanding with each other and the internal information they are willing to expose.

Intra-Web Service Modeling and Interaction

Modeling of processes is usually done through languages like XLANG/WSFL. The Web services flow language (WSFL) introduces the notion of activities and flows, which are useful for describing both local business process flows and the global flow of messages between multiple Web services. XLANG is another standard, from Microsoft, that provides a mechanism for process definition and global flow coordination.

WSFL (Leymann, 2001) models business processes as a set of activities and links. An activity is a unit of useful work. The links could be control links where decisions are made to follow one activity or another, or data links where data are fed into one activity from another. These activities could be exposed through one or more operations grouped through end points (as defined in WSDL). A service is composed of a set of end points, and a service provider can provide multiple services. Just like internal flows, global flows can be defined, specifically as consisting of plug links that link up operations of two service providers, which helps in the creation of complex services that can be recursively defined.

XLANG defines services by extending WSDL. The extension elements describe the behavioral aspects. A behavior spans multiple operations, and has a header and a body. An action is an atomic component of a behavior, and could be an *operation*, a *delay* element, or a *raise* element. A delay element could be of types delayFor and delayUntil. The delayFor and delayUntil introduce delays in the execution of the process either to wait for something to happen (for example, a time-out) or to wait till an absolute date-time has been reached, respectively. Exceptions are flagged through raise constructs. A raise element handles the exceptions by calling the handlers registered with the raise definition. Processes combine actions in useful ways, and could be a sequence, switch, while, All, Pick, Context, Compensate, or Empty.

Inter-Web Service Modeling and Interaction

Web service to Web service interactions need to follow certain business protocols to actually undertake business on the Web. X-EDI, ebXML, BTP, TPA-ML, cXML, and CBL are some of the B2B technologies that have been proposed to enable this paradigm with Web services.

In ebXML (ebXML, 2001; see Figure 3) parties that engage in business have collaboration protocol profiles (CPP) that they register at ebXML registries. Each CPP is assigned a GUID by the ebXML registry. Once a party discovers another party's CPP they negotiate a collaboration protocol agreement (CPA). The intent of the CPA is not to expose the parties' business process internals

Figure 3: ebXML service-to-service interaction.

but to expose the visible process that involves interactions between the parties. The messages exchanged between the involved parties or business partners may utilize ebXML messaging service (ebMS). The CPA and the business process specification document it references define a *conversation* between the parties. This conversation involves multiple *business transactions*. A business transaction may involve an exchange of messages as request and replies. The CPA may refer to multiple business process specification documents. Any one conversation will involve only a single process specification document, however. Conceptually, the B2B server between the parties is responsible for managing the CPAs and for keeping track of the conversations. It also interfaces the functions defined in the CPA with the internal business processes. The CPP contains the following:

- *Process specification layer*, which details the business transactions that form the collaboration, and also specifies the order of business transactions;
- *Delivery channels*, which describes a party's message receiving and sending characteristics, and can specify more than one delivery channel;
- *Document exchange layer*, which deals with the processing of business documents such as digital signatures, encryption, and reliable delivery; and
- *Transport layer*, which identifies the transport protocols to be used (e.g., SMTP, HTTP, and FTP) and the end point addresses.

Web Services Platforms

Web services platforms are the technologies, means, and methods available to build and operate Web services. Platforms have changed and developed over the course of time. A classification into five generations of platform technology should help to structure the space:

- *First generation (HTML/CGI)*: Web servers, static HTML pages, HTML FORMS for simple dialogs, and the CGI (common gateway interface) to connect Web servers to application programs, mostly Perl or Shell scripts.
- *Second generation (Java)*: server-side dynamic generation of HTML pages, user session support; the Java servlet interface became popular to connect to application programs.
- *Third generation (richer development and run-time environments)*: J2EE as foundation for application servers that later evolved toward the fourth generation.
- *Fourth generation (XML Web services platforms)*: the introduction of XML and WSDL interfaces for Web services with SOAP-based messaging, and the emergence of a global service infrastructure for service registration and discovery (UDDI).
- *Fifth generation (dynamic Web services aggregation)*: flow systems, business negotiations, agent technology, etc.

Technically, Web services have been built according to a pattern of an *n*-tier architecture (see Figure 4) that consists of: a front-end tier (firewall (FW) and load balancer

Figure 4: Basic four-tier architecture for Web services.

(LB)), a Web-server (WS) tier, an application (server) (AS) tier, and a back-end tier for persistent data, or the database tier (DB).

First Generation: CGI and Perl

The emergence of the World Wide Web facilitated the easy access and decent appearance of linked HTML markup pages in a user's browsers. In the early days, it was mostly static HTML content. Passive information services that provided users with the only capability of navigating through static pages could be built. However, HTML supported from the very beginning FORMS that allowed users to enter text or to select from multiple-choice menus. FORMS were treated specially by the Web server. They were passed onto an interface, CGI, behind which small applications, mostly Perl or Shell scripts, could read the user's input, perform respective actions, and return an HTML page according to the user's input that could then be displayed in the browser. This primitive mechanism enabled a first generation of services in the Web beyond pure navigation through static content.

Second Generation: Java

With the growth of the Web and the desire for richer services such as online shopping or booking, the initial means to build Web services quickly became too primitive. Java applets brought graphical interactivity to the browser side, and Java became the language of choice for Web services. Servlets provided a better interface between the Web server and the application. Technology to support the dynamic generation of HTML pages at the server side was introduced: JSP (Java Server Pages) by Sun Microsystems, ASP (Active Server Pages) by Microsoft, and PHP pages in the Linux world enabled the separation of presentation, the appearance of pages in browsers, from content data. Templates and content were then merged on the fly at the server in order to generate the final page returned to the browser. Since user identification was critical for business services, user login and user sessions were introduced. Applications were becoming more complex, and it turned out that there was a significant overlap in common functions needed for many services such as session support, connectivity to persistent databases, and security functions.

Third Generation: Richer Development and Run-Time Environments

The observation that many functions were shared and common between Web services drove the development toward richer development environments based on the Java language and Java libraries. A cornerstone of these environments became J2EE (Java 2 Platform, Enterprise Edition), which is designed for enterprise-scale computing

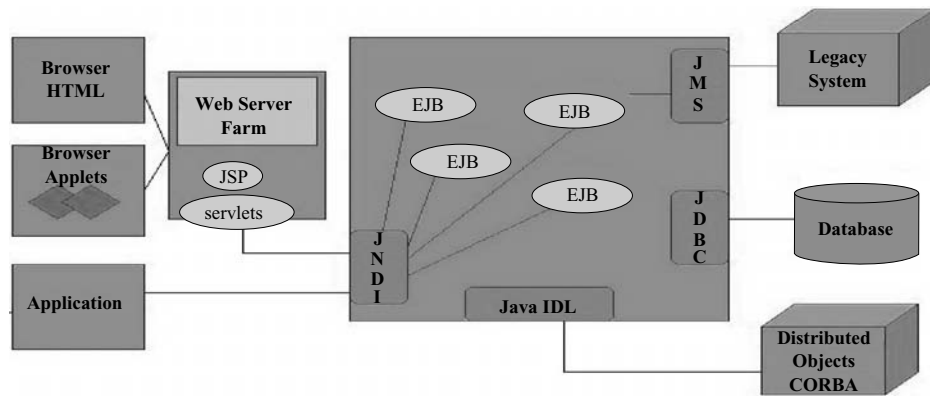

Figure 5: The J2EE platform.

(see Figure 5). Sun Microsystems (together with industry partners such as IBM) designed J2EE to simplify application development for Web services by decreasing the need for programming through reusable modular components and by providing standard functions such as session support and database connectivity.

Application Server. J2EE primarily manifests in a set of libraries used by application programs performing the various functions. Web service developers still had to assemble all the pieces, link them together, connect them to the Web server, and manage the various configurations, etc. This led to the emergence of software packages that could be easily deployed on a variety of machines. These packages later became application servers. They significantly reduced the amount of configuration work during service deployment such that service developers could spend more time on business logic and the actual function of the service. Most application servers are based on J2EE technology. Examples are IBM's WebSphere suite, BEA's WebLogic environment, the Sun ONE Application Framework, and Oracle's *9i* application server.

Fourth Generation: Web Services Platforms

Prior generations of Web services mostly focused on end users, people accessing services from Web browsers. However, accessing services from other services and not browsers turned out to be difficult. This circumstance has prevented the occurrence of Web service aggregation for a long time. Web service aggregation means that a user only has to contact one Web service, and this service then resolves the user's requests into further requests to other Web services.

HTML is a language defined for rendering and presenting content in Web browsers. It does not allow per se separating content from presentation information. With the occurrence of XML with its clean syntax and the capability to describe syntax in its own language as XML Schema, XML became the language of choice for Web services for providing interfaces that not only could be accessed by users through Web browsers but also by other services. XML is now pervasively being used in Web services messaging (mainly using SOAP) and for Web service interface descriptions (WSDL). In regard to platforms,

XML enhancements were added to J2EE and application servers. The introduction of XML is the major differentiator between Web services platforms of the third and the fourth generations in this classification.

A major step toward service-to-service integration was the introduction of UDDI, a global, XML-based registry infrastructure for businesses offering Web services. Its goal is to enable companies and individuals to find one another on the Web in a much more structured and classified manner than is possible through search engines. Microsoft, IBM, and Ariba spearheaded UDDI.

Two major platforms that explicitly aim for further Web services interaction and integration are currently offered: Sun Microsystems' Sun ONE (Open Net Environment) and Microsoft's .NET.

Sun ONE. Sun ONE is Sun's standards-based software architecture and platform for building and deploying services on demand. Sun ONE's architecture is built around existing business assets: data, applications, reports, and transactions, referred to as the DART model. Major standards are supported: XML, SOAP, J2EE, UDDI, LDAP, and ebXML. The architecture comprises several product lines: the iPlanet Application Framework (JATO), Sun's J2EE application framework for enterprise Web services development, application server, portal server, integration server, directory server, e-commerce components, the Solaris Operating Environment, and development tools.

IBM WebSphere. IBM WebSphere is IBM's platform to build, deploy, and integrate one's e-business, including components such as foundation and tools, reach and user experience, business integration and transaction servers, and tools.

Microsoft .NET. Microsoft's .NET platform aims to provide lead technology for future distributed applications inherently seen as Web services. With Microsoft .NET, Web services' application code is built in discrete units, XML Web services, that handle a specified set of tasks. Because standard interfaces based on XML simplify communication among software, XML Web services can be linked into highly specific applications and experiences. The vision is that the best XML Web services from any provider from around the globe can be used to quickly and

easily create a needed solution. Microsoft will provide a core set of XML Web services, called Microsoft .NET My Services, to provide functions such as user identification and calendar access.

Security and Web Services

Due to their public nature, security is vital for Web services. Security attacks can be classified as threats of information disclosure, unauthorized alteration of data, denial of use, misuse or abuse of services, and, more rarely considered, repudiation of access. Since Web services link networks with businesses, further attacks such as masquerading, stealing, or duplicating identity and conducting business under false identity, or accessing or transferring funds from or to unauthorized accounts need to be considered.

Security is vital for establishing the legal basis for businesses done over networks. Identification and authentication of business partners is the basic requirement. Integrity and authenticity of electronic documents is another. Electronic contracts must have the same binding legal status as conventional contracts. Refuse and repudiation of electronic contracts must be provable in order to be legally valid. Finally, payment and transferring funds between accounts must be safe and secure.

Security architectures in networks typically comprise several layers:

- *Secure data communication*: IPsec (Internet protocol security), SSL (secure socket layer), and TLS (transport layer security);
- *Secured networks*: VPN (virtual private networks);
- *Authenticity of electronic documents and issuing individuals*: digital signatures;
- *Secure and authenticated access*: digital certificates;
- *Secure authentication and certification*: PKI (public key infrastructure); and
- *Single sign-on and digital passports*.

Single Sign-On and Digital Passports

Digital passports emerged from the desire to provide an individual's identity information from a trusted and secure centralized place rather than repeatedly establish this information with each collaborating partner and maintain separate access credentials for each pair of collaborations. Individuals only need one such credential, the passport, in order to provide collaborating partners with certain parts of an individual's identity information. This consolidates the need to maintain separate identities with different partners into one single identification mechanism. Digital passports provide authenticated access to a centralized place where individuals have registered their identity information, such as phone numbers, social security numbers, addresses, credit records, and payment information. Participating individuals, both people and businesses, will access the same authenticated information, assuming trust in the authority providing the passport service. Two initiatives have emerged: Microsoft's .NET Passport and the Liberty Alliance Project, initiated by Sun Microsystems.

Microsoft .NET Passport (Microsoft .NET, 2002) is a single sign-on mechanism for users in the Internet. Instead of creating separate accounts and passwords with every e-commerce site, users, using an e-mail address and a single password, only need to authenticate with a single passport server. Then, through a series of authentications and encrypted cookie certificates, the user is able to purchase items at any participating e-commerce site without reverifying their identity.

Microsoft .NET Passport was initially planned for signing into Microsoft's own services. Expanding it toward broader use in the Web has been seen as critical and has given rise to the Liberty Alliance Project initiative, which is now widely supported by industry and public. The Liberty Alliance Project (Liberty Alliance Project, 2002), formed to create an open, federated, single sign-on identity solution for the digital economy via any device connected to the Internet, has three main objectives:

- To enable consumers and businesses to maintain personal information securely;
- To provide a universal, open standard for single sign-on with decentralized authentication and open authorization from multiple providers; and
- To provide an open standard for network identity spanning all network-connected devices.

Membership is open to all commercial and noncommercial organizations.

With the emergence of Web services, specific security technology has been emerging, the two major classes of which are:

- Java-based security technology, and
- XML-based security technology.

Both classes provide mappings of security technologies, such as authentication and authorization, encryption, and signatures as described in the following section, into their respective environments.

Java-Based Security Technology for Web Services

Java-based security technology is primarily available through the Java 2 SDK and J2EE environments in the form of sets of libraries:

- *Encryption*: JSSE (Java secure socket extension), the JCE (Java cryptography extension) provides a framework and implementations for encryption, key generation and key agreement, and message authentication code (MAC) algorithms. Support for encryption includes symmetric, asymmetric, block, and stream ciphers. The software also supports secure streams and sealed objects.
- *Secure messaging*: Java GSS-API (Generic Security Services Application Program Interface) is used for securely exchanging messages between communicating applications, and contains the Java bindings defined in RFC 2853. GSS-API offers application programmers uniform access to security services atop a variety of underlying security mechanisms, including Kerberos (Kohl & Neuman, 1993).

- *Single sign-on using Kerberos.*
- *Authentication and authorization: JAAS (Java authentication and authorization service) for authentication of users, to reliably and securely determine who is currently executing Java code, and for authorization of users to ensure they have the access control rights (permissions) required to do security-sensitive operations.*
- *Certification: Java certification path API.*
- *X.509 certificates and certificate revocation lists (CRLs) and security managers.*
- These libraries are available for use when Web services are built using Java. They are usually used when building individual Web services with application servers.

For Web services interaction, XML technology eliminates the tied binding to Java. Consequently, a similar set of XML-based security technologies that enables cross-services interactions is emerging.

XML-Based Security Technology for Web Services (Hallam-Baker & Maler, 2002)

The Organization for the Advancement of Structured Information Standards (OASIS) drives the idea of merging security into Web services at a level higher than that of the common Internet security mechanisms and practices described earlier. Proposals are primarily directed toward providing XML specifications for documents and protocols suitable for cross-organizational Web services interactions. XML-based security technology can be classified into the following:

- *XML document-level security: encryption and digitally signing XML documents;*
- *Protocol-level security for XML document exchanges: exchanging XML documents for authentication and authorization of peers; and*
- *XML-based security frameworks: infrastructures for establishing secure relationships among parties.*

XML Document-Level Security: Encryption and Signature. The (preliminary) *XML encryption specification* (Reagle, 2000) specifies how to digitally encrypt a Web resource in general, and an XML document in particular. XML encryption can be applied to a part or complete XML document. The granularity of encryption can be reduced to an element, attributes, or text content. Encryption can be recursive. The specification does not address confidence or trust relationships and key establishment, but does address both key-encrypting-keys and data keys. The specification will not address the expression of access control policies associated with portions of the XML document, which will be addressed by XACML.

XML signature defines the XML schema and processing rules for creating and representing digital signatures in any digital content (data object), including XML. An XML signature may be applied to the content of one or more documents. Enveloped or enveloping signatures are over data within the same XML document; detached

signatures are over data external to the signature element. More specifically, this specification defines an XML signature element type and an XML signature application; conformance requirements for each are specified by way of schema definitions and prose respectively. This specification also includes other useful types that identify methods for referencing collections of resources, algorithms, and keying and management information.

The XML signature (Bartel, Boyer, Fox, LaMacchia, & Simon, 2002) is a method of associating a key with referenced data (octets); it does not normatively specify how keys are associated with persons or institutions, nor the meaning of the data being referenced and signed. Consequently, although this specification is an important component of secure XML applications, it itself is not sufficient to address all application security/trust concerns, particularly with respect to using signed XML (or other data formats) as a basis for human-to-human communication and agreement. Such an application must specify additional key, algorithm, processing, and rendering requirements.

The *SOAP digital signature extensions* define how specifically SOAP messages can be digitally signed. The following fragment shows how message digest information, obtained from algorithms such as MD5 applied on a certain region in a document, can be included in the document according to the specification.

Protocol-Level Security for XML Document Exchanges.

Protocol-level security defines document exchanges with the purpose of establishing secure relationships among parties, typically providing well-defined interfaces and XML bindings to an existing public key infrastructure. Protocol-level security can be built upon document-level security.

The *XML key management specification* (Ford et al., 2001) defines protocols for validating and registering public keys, suitable for use in conjunction with the proposed standard for XML signature developed by the World Wide Web Consortium (W3C) and the Internet Engineering Task Force (IETF) and an anticipated companion standard for XML encryption. The XML key management specification (XKMS) comprises two parts: the XML key information service specification (X-KISS) and the XML key registration service specification (X-KRSS).

The X-KISS specification defines a protocol for a trust service that resolves public key information contained in XML-SIG document elements. The X-KISS protocol allows a client of such a service to delegate part or all of the tasks required to process <ds:KeyInfo> elements embedded in a document. A key objective of the protocol design is to minimize the complexity of application implementations by allowing them to become clients and thereby shielded from the complexity and syntax of an underlying public key infrastructure (PKI Forum, 2002) used to establish trust relationships-based specifications such as X.509/PKIX, or SPKI (Simple Public Key Infrastructure, 1999).

The X-KRSS specification defines a protocol for a Web service that accepts registration of public key information. Once registered, the public key may be used in conjunction with other Web services including X-KISS.

XML-Based Security Frameworks. XML-based security frameworks go one step further than those discussed earlier.

The *security assertion markup language* (SAML), developed under the guidance of OASIS (OASIS, 2002), is an XML-based framework for exchanging security information with established, SAML-compliant security services. This security information is expressed in the form of assertions about subjects, where a subject is an entity (either human or program) that has an identity in some security domain. A typical example of a subject is a person, identified by his or her e-mail address in a particular Internet DNS domain.

Assertions can convey information about authentication acts performed by subjects, attributes of subjects, and authorization decisions about whether subjects are allowed to access certain resources. Assertions are represented as XML constructs and have a nested structure, whereby a single assertion might contain several different internal statements about authentication, authorization, and attributes. Assertions containing authentication statements merely describe acts of authentication that happened previously.

Assertions are issued by SAML authorities, namely, authentication authorities, attribute authorities, and policy decision points. SAML defines a protocol by which relying parties can request assertions from SAML authorities and get a response from them. This protocol, consisting of XML-based request and response message formats, can be bound to many different underlying communications and transport protocols; currently it defines one binding: SOAP over HTTP.

SAML authorities can use various sources of information, such as external policy stores and assertions received as input in requests, in creating their responses. Thus, whereas clients always consume assertions, SAML authorities can be both producers and consumers of assertions

Web Services Security Standards

The WS security standard (Atkinson et al., 2002) was initially defined by an industry consortium centered around IBM, Microsoft, and Verisign in 2002. In 2004, WS security standards were adopted by the middleware standard of Grid Web Services, called the Web Services Resource Framework (WSRF, 2004).

The WS security standards, known as WS-Security, define enhancements to SOAP messaging by providing quality of protection through message integrity, message confidentiality, and single message authentication. WS-Security also provides a general-purpose mechanism for associating security tokens with messages. No specific type of security token is required by WS-Security. It is designed to be extensible (e.g., supporting multiple security token formats). For example, a client might provide proof of identity and proof that they have a particular business certification.

Additionally, WS-Security describes how to encode binary security tokens. Specifically, the specification describes how to encode X.509 certificates (Santesson et al., 1999) and Kerberos (Kohl & Neuman, 1993) tickets as well as how to include opaque encrypted keys. It also includes

extensibility mechanisms that can be used to further describe the characteristics of the credentials included with a message. These mechanisms can be used independently (e.g., to pass a security token) or in a tightly integrated manner (e.g., by signing and encrypting a message and providing a security token hierarchy associated with the keys used for signing and encryption).

By using the SOAP extensibility model, SOAP-based specifications are designed to be composed with each other to provide a rich messaging environment. By itself, WS-Security does not ensure security nor does it provide a complete security solution. WS-Security is a building block used in conjunction with other Web service- and application-specific protocols to accommodate a wide variety of security models and encryption technologies. Although implementing WS-Security does not mean that an application cannot be attacked or that the security cannot be compromised, the goal is to ensure that security protocols constructed using WS-Security are not vulnerable to a wide range of attacks.

The Web services security language must support a wide variety of security models. The following list identifies the key driving requirements for WS-security:

- Multiple security tokens for authentication or authorization;
- Multiple trust domains;
- Multiple encryption technologies; and
- End-to-end message-level security and not just transport-level security.

WS-security defines the following terminology:

- *Attachment*: additional data that travel with a SOAP message, but are not part of the SOAP envelope.
- *Claim*: a statement made by a client (e.g., name, identity, key, group, privilege, or capability).
- *Confidentiality*: the process by which data are protected such that only authorized actors or security token owners can view the data.
- *Digest*: a cryptographic checksum of an octet stream.
- *Integrity*: the process by which it is guaranteed that information is not modified in transit.
- *Proof-of-possession*: data used in a proof process to demonstrate the sender's knowledge of information that should only be known by the claiming sender of a security token.
- *Security token*: a collection of claims.
- *Signature*: a cryptographic binding of a proof-of-possession and a digest, which covers both symmetric key- and public key-based signatures. Consequently, nonrepudiation is not always achieved.
- *Signed security token*: a security token that is asserted and cryptographically endorsed by a specific authority (e.g., an X.509 certificate or a Kerberos ticket).

WS-Security defines a message security model in terms of security tokens combined with digital signatures as proof of possession of the security token (key). Security tokens assert claims and signatures provide a mechanism for proving the sender's knowledge of the key. As well, the signature can be used to "bind" or "associate"

the signature with the claims in the security token (assuming the token is trusted). Such a binding is limited to those elements covered by the signature. Furthermore WS-Security does not specify a particular method for authentication; it simply indicates that security tokens may be bound to messages.

A claim can be either endorsed or unendorsed by a trusted authority. A set of endorsed claims is usually represented as a signed security token digitally signed or encrypted by the authority. An X.509 certificate, claiming the binding between one's identity and public key, is an example of a signed security token. An endorsed claim can also be represented as a reference to an authority so that the receiver can pull the claim from the referenced authority. An unendorsed claim can be trusted if there is a trust relationship between the sender and the receiver. For example, the unendorsed claim that the sender is Bob is sufficient for a certain receiver to believe that the sender is in fact Bob, if the sender and the receiver use a trusted connection and there is an out-of-band trust relationship between them.

One special type of unendorsed claim is proof-of-possession, which proves that the sender has a particular piece of knowledge verifiable by appropriate actors. For example, a username/password is a security token with this type of claim. A proof-of-possession claim is sometimes combined with other security tokens to prove the claims of the sender. A digital integrity used for message integrity can also be used as a proof-of-possession claim, although such a digital signature is not considered as a type of a security token. This security model, by itself, is subject to multiple security attacks.

Message protection is an essential part of WS-Security. Protecting the message content from being intercepted (confidentiality) or illegally modified (integrity) are primary security concerns. The WS-Security specification provides a means to protect a message by encrypting or digitally signing a body, a header, an attachment, or any combination of them (or parts of them).

Message integrity is provided by using XML signature in conjunction with security tokens to ensure that messages are transmitted without modifications. The integrity mechanisms are designed to support multiple signatures, potentially by multiple actors, and to be extensible to support additional signature formats.

Message confidentiality uses XML encryption in conjunction with security tokens to keep portions of a SOAP message confidential. The encryption mechanisms are designed to support additional encryption processes and operations by multiple actors.

The message receiver should reject a message with invalid signature or missing or inappropriate claims as it is an unauthorized (or malformed) message. The WS-Security specification provides a flexible way for the message sender to claim the security properties by associating zero or more security tokens with the message. An example of a security claim is the identity of the sender; the sender can claim that he is Bob, known as an employee of some company, and therefore he has the right to send the message.

The WS-Security specification allows for multiple signatures to be attached to a message, each referencing different, even overlapping, parts of the message. This is

important for many distributed applications where messages flow through multiple processing stages. For example, a sender may submit an order that contains an orderID header. The sender signs the orderID header and the body of the request (the contents of the order). When this is received by the order processing subsystem, it may insert a shippingID into the header. The order subsystem would then sign, at a minimum, the orderID and the shippingID, and possibly the body as well. Then when this order is processed and shipped by the shipping department, a shippedInfo header might be appended. The shipping department would sign, at a minimum, the shippedInfo and the shippingID and possibly the body and forward the message to the billing department for processing. The billing department can verify the signatures and determine a valid chain of trust for the order, as well as who has taken what action.

The <Security> header block in a WS-Security SOAP message is used to carry a signature for the purpose of signing one or more elements in the SOAP envelope. Multiple signature entries may be added into a single SOAP envelope. Senders should take care to sign all elements of the message, but care must be taken in creating a policy that will not to sign parts of the message that might legitimately be altered in transit.

THE FUTURE OF WEB SERVICES

In the future we will see the unleashing of a Web services phenomenon that will involve the fulfillment of dynamic Web service composition and orchestration vision, the appearance of personalized Web services, concepts of Web service management, and the development of Web service infrastructure as a reusable, reconfigurable, self-healing, self-managing, large-scale system.

Dynamic Web Services Composition and Orchestration

The vision of Web services intelligently interacting with one another and performing useful tasks automatically and seamlessly remains to become reality. Major milestones have been achieved: XML as syntactic framework and data representation language for interacting Web services, the Web infrastructure itself providing ubiquitous access to Web services, the emergence of global registration and discovery services, the technology to support the creation and maintenance of Web services, just to name a few. However, major pieces such as the formalization and description of service semantic are still missing. The effort of creating a semantic Web (Semantic Web, 2001) is an extension of the current Web in which information is given well-defined meaning, better enabling computers and people to work in cooperation. Ontologies define the structure, relationships, and meaning of terms appearing in service descriptions. The semantic Web vision is that these ontologies can be registered, discovered, and used for reasoning about Web service selection before undertaking business. Languages like DAML + OIL (DAML, 2001) have been developed in this context.

In addition, sending a document or invoking a method and getting a reply are the basic communication

primitives. However, complex interactions between Web-services will involve multiple steps of communication that are related to each other. A conversation definition is a sequencing of document exchanges (method invocations in the network object model) that together accomplish some business functionality. In addition to agreeing upon vocabularies and document formats, conversational Web-services also agree upon conversation definitions before communicating with each other. A conversation definition consists of descriptions of interactions and transitions. Interactions define the atomic units of information interchange between Web services. Essentially, each service describes each interaction in terms of the documents that it will accept as input, or will produce as output. The interactions are the building blocks of the conversation definition. Transitions specify the ordering amongst the interactions. Web-services need to introspect other Web services and obtain each other's descriptions before they start communicating and collaborating (Banerji et al., 2002).

RosettaNet (RosettaNet, 2002) is a nonprofit consortium of major information technology, electronic components, and semiconductor manufacturing companies working to create and implement industry-wide, open e-business process standards, particularly targeting business-to-business marketplaces, and workflow and supply-chain management solutions. These standards form a common e-business language, aligning processes between supply chain partners on a global basis. Several examples exist. The centerpiece of the RosettaNet model is the partner interface process (PIP). The PIP defines the activities, decisions, and interactions that each e-business trading participant is responsible for. Although the RosettaNet model has been in development recently, it will be a while before Web services can start using them to undertake business on the Web.

Once these hurdles are overcome, the basis and platform for true Web services that would enable agent technologies to merge into Web services and provide the envisioned dynamic Web service aggregation on demand according to a user's specifications will exist.

Personalized Web Services

As Web service technology evolves, we anticipate that they will become increasingly sophisticated, and that the challenges the Web service community will face will also evolve to meet their new capabilities. One of the most important of these challenges will be the question of what

it means to personalize Web services. Personalization can be achieved by using user (other Web services or humans) profiles to monitor user behavior, devices, and context to customize Web services (Kuno & Sahai, 2002) to achieve metrics like quality of experience (QoE) (van Moorsel, 2001). This would involve providing and meeting guarantees of service performance on the user's side. Personalization could also result in creation of third-party rating agencies that will register user experiences and could be instructive for other first-time users. These rating mechanisms already exist in an ad-hoc manner, e.g., e-bay and Amazon allow users to rate sellers and commodities (books), respectively. Salcentral.com and bizrate.com are third-party rating agencies that rate businesses. These services could be also developed as extended UDDI services. These mechanisms will also render Web services more "customer-friendly."

End-to-End Web Service Interactions

Web services are federated in nature as they interact across management domains and enterprise networks. Their implementations can be vastly different in nature. When two Web services connect to each other, they must agree on a document exchange protocol and the appropriate document formats. From then on, they can interoperate with each other by exchanging documents. SOAP defines a common layer for document exchange. Services can define their own service-specific content on the top of SOAP. Often, these Web service transactions will span multiple Web services. A request originating at a particular Web service can lead to transactions on a set of Web services. For example, a purchase order transaction that begins when an employee orders supplies and ends when he or she receives a confirmation could result in ten messages being exchanged between various services as shown in Figure 6.

The exchange of messages between Web services could be asynchronous. Services sending a request message need not be blocked waiting for a response message. In some cases, all the participating services are like peers; in which case there is no notion of a request or a response. Some of the message flow patterns that result from this asynchrony are shown in Figure 7. The first example in Figure 7 shows a single request resulting in multiple responses. The second example shows a broker scenario, in which a request is sent to a broker but responses are received directly from a set of suppliers.

Figure 6: SOAP messages exchanged between Web services.

Figure 7: Asynchronous message patterns between Web services.

These Web services also interact with a complex Web of business processes at their back-ends. Some of these business processes are exposed as Web service operations. A business process comprises a sequence of activities and links as defined by WSFL and XLANG. These business processes must be managed so as to manage Web service interactions. Management of Web services thus is a challenging task because of their heterogeneity, asynchrony, and federation. Managing Web services involves managing business transactions by correlation of messages across enterprises (Sahai, Machiraju, & Wurster, 2001), and managing the business processes.

Also, in order to conduct real business on the Web, they will need to specify, agree, and monitor service level agreements with each other. As Web services will invariably have a large number of contracts and as little human intervention as desirable, it would necessitate automating the process as much as possible (Sahai et al., 2002b).

Web service to Web service interaction management can also be done through mediation. Web service networks vision is to mediate Web service interactions, so as to make it secure, manageable, and reliable. Such networks enable versioning management, reliable messaging, and monitoring of message flows (Flamenco Networks, GrandCentral, Transact Plus, and Talking Blocks).

Future Web Services Infrastructures

Deployment and operational costs are determinants in the balance sheets for Web service providers. Web service providers are optimizing their IT infrastructures to allow faster provisioning of new services and more reliable operation. Platforms and management solutions that reduce Web services' deployment and operational costs are emerging. Those platforms support the deployment of Web service (installation and configuration of software and content data), the virtual wiring of machines into application environments independently of the physical wiring in a data center. They allow rearrangements of Web services' applications among machines, the dynamic sizing of service capacities according to fluctuations in demands, and the isolation of service environments hosted in the same data center. Utility computing environments, like grid and data center environments, are good examples of such future Web service infrastructures.

CONCLUSION

The Web services paradigm has evolved substantially because of concerted efforts by the software community. Although the genesis of Web services can be traced to

projects like e-speak, Jini, and TSpaces, it has received a boost recently because of standardization of technologies for description (WSDL) and discovery (UDDI). Platforms like J2EE compatible application servers and .Net have appeared for the creation and deployment of these Web services. Standards for security and payment are being agreed upon. The full potential of Web services, however, remains unrealized. The future will see the realization of Web services as a means of doing business on the Web, the vision of dynamic composition of Web services, personalized Web services, end-to-end management of Web service interactions, and having dynamically reusable service infrastructure that will adapt to variations in resource consumption.

GLOSSARY

BPEL4WS (Business Process Execution Language for Web Services) Language used to describe workflows/business processes.

Client Utility The architecture that led to HP's e-speak technology, one of the technologies considered as a precursor to Web services

Composition Two or more Web services working together to fulfill a bigger task.

Conversation Exchange of messages between Web services in a particular context.

J2EE The architecture for a Java-based application server middleware developed by SUN with varied implementations.

.Net Microsoft's technology that is actually a set of tools for creating Windows-based middleware.

SOAP (Simple Object Access Protocol) The standard format and exchange protocol for messages exchanged between web services.

UDDI (Universal Description and Discovery Interface) A global registry for Web services that has not taken off as expected.

Web service Distributed services that are accessible via the Web through uniform resource locators (URLs).

WSDL (Web Services Description Language) Language used to describe Web service interfaces.

WS-Security A standard for Web services security that provides a general-purpose mechanism for associating security tokens with messages

XML (Extended Markup Language) Language used to describe the documents exchanged by Web services.

INTRODUCTION

The term *electronic commerce* came into widespread usage after the first graphical Web browser, Mosaic, was developed in 1993 and freely distributed around the world. Drawn by the browser's ease of use, millions of home consumers, businesses, and educators connected to the Internet, creating the conditions for Internet-based commerce. Indeed, Nielsen//Netratings estimates that there were over 200 million Americans, and more than 450 million people worldwide, who had access to the Internet from home in August 2004 (this number rises if we also include those who access the Internet from work or other public settings; see <http://www.nielsen-netratings.com> for the latest monthly estimates). Businesses, often backed by venture capital from investors enamored with the new opportunities created by Internet-based business, flocked to the Internet attracted by the ease of setting up electronic storefronts and the potential access to a global market of Internet subscribers. For example, Laudon and Traver (2003) estimate that more \$120 billion was invested in 12,450 Internet start-up companies between 1998 and 2000, a period of significant growth in e-commerce. Impressively, despite the highly publicized dot-com failures in 2000 and 2001, total Internet sales of goods and services to consumers (i.e., business-to-consumer, or B2C, e-commerce) have grown steadily, exceeding \$100 billion in 2003 (U.S. Department of Commerce, 2005). Even more dramatic has been the extent to which businesses have adopted the Internet for use to support exchanges with other firms such as suppliers and business customers. In the United States, business-to-business (B2B) e-commerce is predicted to grow to over \$5 trillion, or 36% of total business trade, by 2006 (Laudon & Traver, 2003).

With the rapid growth of the Internet-using population in general, and the use of e-commerce in particular,

have come increasing concerns about the security of online transactions. There has been a dramatic rise in the frequency and severity of all forms of Internet security incidents as reported by the Computer Emergency Response Team Coordination Center Coordination Center (CERT/CC) at Carnegie Mellon University (<http://www.cert.org>). CERT began tracking reports of Internet security incidents, such as attempted intrusions by hackers, in 1988 with six reported incidents. In 2003, the last year for which they collected these data, 137,529 incidents were reported (CERT/CC, 2004). Indeed, automated attacks against computers connected to the Internet have become so widespread and constant that it no longer makes sense to report individual incidents, and CERT has stopped publishing this number. A 2004 survey of U.S. firms found that 70% reported being a victim of at least one electronic crime or intrusion, resulting in approximately \$666 million in costs. Moreover, the Federal Trade Commission (FTC) also reports dramatic increases in Internet-related security problems and most notably complaints of identity theft—stealing an individual's personal information such as a credit card number and using this information illegitimately—as well as online fraud. The FTC's Consumer Sentinel (a consumer complaint database) received over a half million complaints about consumer fraud and identity theft in 2003, resulting in reported losses of over \$400 million. Total identity theft complaints rose from only 1,380 in 1999 to 214,905 in 2003 (Federal Trade Commission, 2004). The majority of fraud complaints were Internet related (55%), resulting in losses of \$200 million, and in 58% of the cases, consumers indicated they were contacted through the Internet. This dramatic growth in Internet-related security problems has the potential to derail consumers' trust in e-commerce and inhibit future growth. Hence, in addition to a broad overview of e-commerce history and research, this chapter includes an introduction to the types of security approaches in use in e-commerce.

¹ Adapted from Steinfield, C. (2004). Electronic commerce and electronic business. In H. Bidgoli (Ed.), *The Internet encyclopedia* (vol. 1, pp. 601–612). New York: Wiley.

Chapter Overview and Themes

This chapter examines the development of e-commerce and its influences on the way that companies work with their suppliers, market their products to customers, and compete with old and new rivals. The historical development of e-commerce suggests that it only emerged as a powerful force once a truly open and standard data network—the Internet—was coupled with easy-to-use software—the graphical Web browser. Many innovative business models evolved in an attempt to take advantage of this new platform, coupled with a host of clever new marketing strategies. E-commerce opened up new avenues for consumers as well, creating new consumer-centric markets in which their bargaining power has been enhanced. Given the inherently open environment of the Internet, however, significant efforts to ensure the security of online transactions are required if e-commerce is to continue to flourish.

Despite these developments, many expected impacts have not yet occurred. A review of research on several anticipated impacts highlights the need to critically assess the early hype about the effect of e-commerce on competitive strategy, market structures, business-to-business relationships, and prices of goods and services.

The chapter concludes with a brief summary and a look toward what the future might hold now that the dot-com era has evolved into e-commerce as a mainstream business activity.

Defining E-Commerce

Today the term electronic (or e-) commerce most commonly refers to the process of buying and selling goods—both information and tangible products—and services over the Internet. Earlier definitions (e.g. Clarke, 1999, para. 1) emphasized the “conduct of commerce in goods and services using telecommunications-based tools.” More recent definitions (e.g., Laudon & Traver, 2003, p. 10) emphasize the “use of the Internet and the Web to transact business” in what they call “digitally enabled commercial transactions,” where there is some “exchange of value across organizational or individual boundaries in return for products and services.” Narrower definitions require that complete transactions, including ordering and payment, occur entirely via the Internet, whereas broader definitions include information exchange in support of transactions, even if the actual payment occurs outside the Internet (often called an offline payment). More recently, the term *e-business* has become popular, which refers more broadly to the conduct of business over computer networks. E-business includes activities that are not purely commercial transactions, such as when two firms use the Internet to collaborate on product development or research or a firm provides customer service online. Some (e.g., Laudon & Traver, 2003) consider e-business to include only internal applications of a firm’s computer network and not transactions that span across to other firms. However, today, the terms *e-commerce* and *e-business* are often used interchangeably, and we follow this practice in this chapter.

A BRIEF HISTORY OF E-COMMERCE

Long before the World Wide Web, electronic networks were used to support transactions between businesses and their various external constituents (e.g., suppliers or customers). In the 1970s, forward-thinking manufacturers and wholesalers deployed proprietary data networks and simple terminal-based remote ordering systems out to the premises of business customers. The value of computer networks to link business buyers and sellers was soon well established, and efforts to create standard electronic documents to support trade were occurring across many industries. These latter standards were collectively called electronic document interchange (EDI). In some industries, such as automobile manufacturing and chemical production, EDI transactions proliferated because their use was mandated by large dominant manufacturers. However, because EDI standards were complex and costly to implement, especially for small businesses, the extent of its diffusion was limited (Steinfeld, Wigand, Markus, & Minton, forthcoming).

There were precursors to consumer-based e-commerce as well. The Home Shopping Network on cable television and the many 1980s era electronic information services collectively known as videotex in Europe and the United States resembled Web-based electronic retailing. The most successful of these systems in Europe was the French system popularly known as Minitel, named after the small terminal that initially was freely distributed to telephone subscribers. Beginning in 1983, French telephone subscribers could use their Minitels to look up a wealth of information, engage in home banking, and order a wide range of goods and services such as tickets, groceries, and other consumer products. Like the Internet, these services were offered over a public network to which anyone could connect, used a single standard, and relied extensively on graphical content. Unlike the Internet, a clear payment model was implemented, with France Telecom (at the time, the public administration responsible for the provision of all telecommunications networks and services in France) providing a billing and collection service for all companies that wished to sell via the Minitel. Consumers received the bill for their Minitel use on their regular phone bill, and France Telecom in turn paid the various service providers (Steinfeld, Kraut, & Plumer, 1995).

In contrast, American electronic information services of the 1980s were still based on closed, rather than open systems, using what has been called a walled-garden approach. That is, services such as CompuServe and America Online (which are now merged) used their own proprietary networks, and their content and services were only available to their own subscribers. It was not until commercial traffic was permitted on the Internet that e-commerce as we know it today was born.

The early years of e-commerce had all the characteristics of a gold rush, as companies flocked to the Web to set up their electronic storefronts. Lured by the rapid growth of first movers such as Amazon.com, more than \$125 billion in investment capital was poured into Internet initial public offerings (IPOs) between 1996 and 2000

Figure 1: Quarterly U.S. Retail e-commerce sales, 4th quarter 1999–4th quarter 2003, in US\$ billions. Source: U.S. Census Bureau, 2004.

(Laudon & Traver 2003). The birth of a new digital economy was proclaimed, characterized by a seemingly unending growth in productivity rooted in the supposedly frictionless commerce afforded by the Internet. The new Web-based businesses theoretically offered such benefits as access to a larger potential market, lower inventory and building costs, more flexibility in sourcing inputs, improved transaction automation and data mining capabilities, an ability to bypass intermediaries that added costs but little value, lower costs for adjusting prices (known as a menu costs) enabling more rapid response to market changes, increased ease of bundling complementary products, 24/7 access, and no limitation on depth of information provided to potential customers (Steinfeld, Mahler, & Bauer, 1999). With all these advantages, and the reduced search costs faced by consumers, prices were expected to be lower, while at the same time the Internet firms would prosper.

Despite the rosy projections for e-commerce, in late 2000 and early 2001 many of the dot-com companies began to fail. Few ever made any profits, as their business approach revolved around scaling up to increase market share (Hawkins, 2004). This approach was based on the belief that Internet businesses would enjoy positive network externalities—implying that the more people who used a site, the more value it would have for each user. The dot-coms that could attract the most users the fastest would thus have an insurmountable competitive edge. In search of the required scale, Internet firms kept prices too low and quickly burned through the cash raised from venture capitalists. At the same time, the U.S. economy began to slip into a recession, and venture capitalists began to lose faith in the viability of start-ups that failed to return any profits. Stock prices, which were far too high by normal investment standards, dropped precipitously, and the venture capital community lost interest in dot-com businesses. By the end of 2001, the dot-com era was over, and by one estimate only about 10% of the dot-coms created since 1995 still survived (Laudon & Traver, 2003).

Business-to-business (B2B) oriented dot-coms experienced much the same fate. Large numbers of B2B electronic marketplaces were created to help match buyers and sellers in many industries, and by early 2000, more than 750 B2B e-markets were operating worldwide (U.S.

Department of Commerce, 2000). Yet most of the new dot-coms in this arena failed as well.

Despite the problems of the dot-coms, statistics on e-commerce use do show steady gains, particularly as traditional companies have moved to enhance their offerings with Internet-based sales channels. According to U.S. Census figures, even as the dot-coms were failing and the economy went through a recession, retail e-commerce sales in the United States grew at a brisk pace (see Figure 1). Annual U.S. retail e-commerce sales nearly doubled between 2000, the first full year that the government tracked this statistic, and 2003, rising from approximately \$28.3 billion to more than \$54 billion (U.S. Census Bureau, 2004). In the all-important fourth quarter, when holiday shopping occurs, online sales exceeded \$17 billion in 2003, more than three times the total in the fourth quarter of 1999. Moreover, these figures are a low estimate, because they do not include sales from online travel, financial brokers, and online ticket sales. U.S. B2B online trade has also grown, rising to an estimated \$466 billion in 2001 and projected to be as high \$5.4 trillion in 2006 (Laudon & Traver, 2003).

INTERNET BUSINESS MODELS

Many innovative methods of doing business were created in the early years of e-commerce, which collectively came to be called Internet business models. Exactly what constituted a business model was the subject of much debate, as was the issue of which models were successful. Rappa (2004, para. 2), for example, defines a business model as the “method of doing business by which a company can sustain itself—that is, generate revenue. The business model spells-out how a company makes money by specifying where it is positioned in the value chain.” Timmer (1998) considers a business model to include three basic components: (1) the architecture for the product, service, and information flows, (2) the potential benefits for the various business actors, and (3) the sources of revenues. Weill and Vitale (2001) characterize models as the roles and relationships among a firm’s major stakeholders that result in flows of products, information, and money, leading to benefits for the participants. Other scholars offer what might be called an *ingredients* perspective on

Table 1 Taxonomies of Internet Business Models

Author(s)	Internet Business Models	Comments
Timmer, 1998	E-Shop E-Auction E-Mall Third-Party Marketplace E-Procurement Virtual Communities Value Chain Integrators Collaboration Platforms Value Chain Service Provider Information Brokerage Trust Services	In this early typology, Timmer organized observed models along two dimensions: (1) the degree of innovation (i.e., difference from traditional business models) and (2) the degree of functional integration. E-shops are simple translations from offline models, with low innovation and low integration of functions. Third party marketplaces provide a number of functions for both buyers and sellers and are seen as relatively more innovative.
Rappa, 2004	Brokerage Advertising Infomediaries Merchant Manufacturer Affiliate Community Subscription Utility	These models are largely organized by the primary source of revenue. For example, brokerage models such as eBay rely on fees or commissions. Infomediaries give discounted or free goods or services while they collect consumer information and sell to marketers. Affiliates derive revenue by referring customers to other e-commerce firms, who then provide a sales commission. Utility models refer to firms that charge customers on a metered, or pay-per-use, basis. In some cases, the models refer to a primary way in which value for customers is created—e.g., community models rely on users with common interests to provide content, so that they can charge for advertising. Also, within each model, Rappa defines many subtypes, such as the click-and-mortar versus virtual merchant business models in the merchant category.
Laudon and Traver, 2003	B2C Portal E-Tailer Content Provider Transaction Broker Market Creator Service Provider Community Provider B2B E-Distributor E-Procurement Exchange Industry Consortia Private Industrial Networks	These authors divide models by their consumer versus business focus. Within model types they describe the value proposition, as well as the many subtypes. For example, portals offer an integrated package of content and services and can be horizontal (targeting all users) or vertical (focused on a specific subject matter or market segment). Moreover, they illustrate that many Internet business models combine a number of sources of revenue, including advertising, subscription fees, transaction fees, margins on sales, and affiliate fees. In the B2B arena, they further illustrate the importance of private networks and industry consortia—models that suggest that existing business relationships are essential, even for Internet-based transactions.

Internet business models, suggesting that they each contain many facets such as a value proposition, sources of revenue, a market opportunity, a competitive landscape, a competitive advantage, a strategy for promotion in the market, an organizational development plan, and a management team (Afuah & Tucci, 2001; Laudon & Traver, 2003).

Along with the numerous definitions of business models can be found many taxonomies of models that are commonly seen on the Internet. Three well-known taxonomies are summarized in Table 1. These lists provide an illustration of the many complex business models that have appeared. Despite some superficial similarities, direct comparisons of models are difficult given the varying perspectives the authors have used in forming categories (Wang & Chan, 2003).

After the dot-com crash, attempts to list the many observed Internet business models gave way to analyses focusing on what was wrong with the models. For example, early in the e-commerce boom years, many felt that revenue from advertising would sustain e-commerce. This made some sense for content firms, such as online newspapers, magazines, radio stations, and other media-oriented companies that were accustomed to reliance on sponsors to bring down the costs for their viewers, listeners, and readers. However, one failed Internet business model, pursued somewhat by Buy.com, involved the use of advertising revenue to subsidize product sales, so that consumers could buy products at heavily discounted prices. Another problematic business model in the B2C arena involved manufacturers of products selling directly to end consumers and bypassing wholesale and

traditional retail channels. Levi's, for example, attempted to sell its blue jeans directly to online shoppers. Existing retailers, however, threatened retaliation. Given the relatively small percentage of sales generated by the Internet, Levi's soon gave up on the direct-sale model and now uses its Web site mainly to promote sales of Levi's at traditional retail outlets or to sell online through its retailers' Web sites.

Hawkins (2004) criticizes the notion that the Internet required altogether new business models, arguing instead that it simply enabled some firms to apply models that heretofore had not been used by them in their particular market, but that had been common in markets for other types of goods and services. Moreover, he argued that a model does not convey competitive advantage in and of itself, but only if there were reasons to expect that a firm could prevent others from easily imitating it.

Critics of the early business model literature also point out that the dominant focus on revenue streams can encourage firms to ignore other benefits that e-commerce offers, such as cost reductions, improved customer relations, or enhanced performance of traditional channels (Steinfeld, Bouwman, & Adelaar, 2002). For example, a virtual merchant (also sometimes called a digital pure-play) may be able to offer goods at lower prices due to its lower inventory holding costs and lower selling costs. However, a click-and-brick firm may use its Web site to help generate more traffic in its physical stores by offering coupons or searches of in-store inventory.

Despite the critiques, it is clear that the development of online commerce has enabled the application of many innovative strategies. One way to view the dot-com crash was simply as an inevitable shakeout that always follows the rapid entry of firms into a new area of business. In this perspective, those models that survived represent the winning approaches, promising significant opportunity for the firms that have successfully adopted them.

MARKETING STRATEGIES FOUND IN E-COMMERCE

Electronic commerce offers many new opportunities for firms to interact with customers. It enhances firms' abilities to offer many customer services in a cost-effective manner. Moreover, e-commerce companies have experimented with a wide range of innovative marketing strategies made possible through software, data mining, and other information technology (IT) capabilities. Several of the more popular e-commerce marketing techniques are briefly highlighted below.

- **Personalization.** An e-commerce vendor can personalize its interaction with customers, creating what some call a one-to-one marketing relationship. Personalization generally requires that the online shopper provide some information about his or her interests or preferences to the vendor. This information is then used to tailor the Web site so that it reflects these interests. Cookies are often used rather than requiring a login to identify particular customers, and each customer then receives his or her own dynamically constructed

page. Yahoo! and other search engines and portals were among the first to develop these techniques. More elaborate techniques use purchase histories, clickstream information, and other data to personalize e-commerce services.

- **Customization.** Many e-commerce vendors offer customers a build-to-order option that allows some degree of customization of the products to suit buyer tastes. This is common for computer vendors, but other types of e-commerce companies have also used e-commerce to offer this value-added service to customers. Lands' End, for example, offers hem-to-order pants. Even Levi's, in their initial foray into e-commerce, attempted a made-to-measure blue jean product.
- **Upselling and Cross-selling.** Using simple automated rules as well as more sophisticated data-mining techniques, merchants can enhance their ability to both upsell and cross-sell to customers. Upselling involves convincing customers to trade up to a more expensive option or to add a complementary product to an order. Cross-selling involves suggesting other products that customers might like that are similar to the ones in an existing order.
- **Recommender Systems and Collaborative Filtering.** Many e-commerce sites use a variety of data-mining techniques to provide better product recommendations to customers and enable even more powerful cross-selling (Schafer, Konstan, & Riedl, 2001). Purchase histories and various association rules are often used to refine such product recommendations. In collaborative filtering, the purchases of other customers who have similar profiles are used as a source of recommendations. Amazon.com was one of the first to implement such a service. Whenever a customer selects a particular book, he or she is presented with a list of related books to consider. These recommended books were purchased by other shoppers who had also bought the initial book selected by the customer.
- **Affiliate Programs.** Vendors can use the wider Web community to help sell products. This involves more than simple reciprocal linking and can include payments to Web affiliates that refer a customer who purchases a product. Amazon.com was a pioneer in this area as well, allowing virtually anyone with a Web site to become an Amazon.com affiliate. For example, an author might provide a link from his or her personal Web site to the book's purchase page on Amazon.com. The link is coded to identify the referrer, who then earns a slight commission on any purchase originating from the referring site.
- **Incentive Programs.** In an effort to inspire greater customer loyalty, many e-commerce sites followed the lead of airlines and offered various types of incentive marketing programs. Frequent shoppers could build up points that entitled them to discounts and other benefits. Because all transactions are automated and it is so easy to collect information via the Web, these types of programs became much more accessible to all online merchants. As with airline frequent flyer programs, these techniques create switching costs, because customers who do not return know they will lose accumulated benefits.

- **Direct E-mail.** E-mail, the most popular application of the Internet, is a valuable e-commerce marketing tool. Companies obtain e-mail addresses of visitors and customers and regularly send targeted letters with new product information, announcements of sales, and other promotional content. Although diminished in usefulness today due to the overwhelming presence of spam, customers may still opt-in to receive information on product updates via e-mail.
- **Viral Marketing.** Increasingly, companies rely on customers to help spread the word about their products and services. Such a strategy is known as viral marketing, because the marketing material is carried by customers and spread throughout a target population. Often, dissemination is accomplished by giving users access to free services or games that require the participation of others. PayPal, for example, lets its customer send payments to others for free. Recipients must open an account with PayPal to transfer the funds into their regular bank account. This strategy has helped grow the number of PayPal account holders, which in turn entices more merchants to accept PayPal payments. Merchants, however, do pay a fee to receive funds.
- **Multichannel Marketing.** Brick-and-click firms and catalog companies capitalize on the synergies that arise from the integration of traditional and online channels (Steinfeld et al., 2002). Traditional retailers, for example, can provide detailed product information online, immediate pickup in a store, and extensive support after the purchase online. Traditional catalog companies can refer to their Web site in every printed catalog mailed to customers. In this way, they can gain the benefit of a regular reminder to look at their merchandise, with the cost-savings that accrue when customers fill out online forms instead of calling a call center.

The various marketing strategies mentioned above are by no means an exhaustive list, but they do illustrate a number of possibilities to extend and enrich relationships with customers using network-based, computer-mediated transactions.

CONSUMERS IN E-COMMERCE

Up to now, the discussion has focused mainly on e-commerce companies. However, e-commerce also has implications for the way in which consumers interact with each other and with businesses. One of the most successful, and profitable, e-commerce businesses is eBay, which began as an auction broker for consumer-to-consumer transactions, providing the equivalent of a nationwide online garage sale. However, unlike real garage sales, buyers could not physically inspect merchandise, and there was no equivalent process to handing over the item in return for cash. eBay's innovative solution to this problem was to develop a feedback mechanism whereby buyers and sellers rate each other after each transaction. Buyers rate the promptness with which sellers actually delivered the purchased items, the quality of the items, how well they were packaged, the accuracy of the online description, and anything else that might help future buyers decide

whether to do business with this particular seller. Sellers also rate buyers, scoring them well if they pay promptly and deal honestly. Privacy is protected because people use pseudonyms. There is an incentive to behave properly, because buyers and sellers develop a reputation (hence, these are often called reputation systems—see Resnick, Kuwabara, Zeckhauser, & Friedman, 2000). If someone develops a bad reputation, then he or she can only return to the system under a new pseudonym, and others may be less willing to deal with someone with no reputation.

eBay relies on an auction pricing format (although buyers now have the option to click on a Buy It Now button and forego the bidding process). Unfortunately, even with the elaborate reputation system, there remains some potential for fraud. Some unscrupulous sellers, for example, may fake numerous transactions with others to build a reputation. Others may have others make false bids on an item to artificially raise prices—this practice is known as shilling. Bidders can also cheat—for example, by using a confederate who makes a high bid to discourage other bidders. The fake bid is then retracted near the bidding deadline, so that the item can be acquired at a lower price. Even with a certain degree of fraud, however, eBay remains highly successful, perhaps in part due to the entertainment value associated with bidding on items.

Consumers play an important role in another well-known e-commerce service run by Priceline.com. Priceline also uses a form of electronic brokerage, in which they match consumers' bids for various goods and services with vendors willing to accept the bid. Priceline mainly deals with travel-related services, and especially airline tickets, although they attempted to expand this model to other sectors. In this way, airlines and others with perishable products have another outlet for goods and services that would otherwise go unsold. This business approach is called a reverse auction broker model and is sometimes referred to as consumer-to-business (C2B) e-commerce since the consumer initiates the transaction.

INFORMATION SECURITY AND ONLINE PAYMENT IN E-COMMERCE

Ensuring the security of online transactions is a fundamental requirement for e-commerce. Lack of trust in an online store, fear of financial loss through theft of a credit card or other banking information, and other concerns over the privacy of information transmitted to and stored by an online store are just some of the concerns faced by consumers in e-commerce transactions. In the earliest years of e-commerce, fears that credit card information would be intercepted while in transit over the Internet prompted most online stores to implement secure servers relying on Secure Socket Layer (SSL) transmission. However, e-commerce security involves much more than secure transmissions. Among the many requirements are needs to authenticate both consumers and online stores, preserve the confidentiality of information related to online transactions, and ensure the integrity of transaction-related information. Public and symmetric key encryption systems are the main methods for accomplishing these needs. The following sections provide a brief introduction

to these topics, which are all described in more detail in other chapters in this Handbook.

Encryption Methods in E-Commerce

There are two basic approaches to encryption that form the foundation for secure transactions in e-commerce: secret or symmetric key encryption and public or asymmetric key encryption. Many of today's more sophisticated e-commerce vendors use a combination of both approaches (Juels, 2004).

Secret or Symmetric Key In a symmetric key system, the same code is used to encrypt a message (i.e., the credit card number or the order for a product) as to decrypt it. Hence, the sender and receiver must both possess the secret key needed to decode the encrypted text (also called ciphertext, as opposed to a plaintext message). One of the early and well-known symmetric systems was the Data Encryption Standard (DES), although today a common symmetric standard in wide use in e-commerce is called RC4 by RSA Laboratories (<http://www.rsasecurity.com>) (Juels, 2004). The main problem with symmetric key approaches is that it is difficult to distribute the secret key safely. Among a small trusted group, for example employees in a common work team, secret keys might be safely passed in person to each other, but this is not viable for an online store and all of its unknown potential customers. Simply sending the key in plain text gives eavesdroppers the chance to capture the key and decode all future encrypted transmissions. Nonetheless, symmetric key encryption is more efficient and rapid than the asymmetric approaches described below.

Public or Asymmetric Key In public key encryption systems, a pair of codes is needed to encrypt a plaintext message into ciphertext and then decrypt it to plaintext again. Essentially, the code pairs are numbers that have a special mathematical relationship—the second one is the only number that can possibly decrypt plaintext that has been encrypted with the first, and vice versa (Juels, 2004). Moreover, knowing one number in the pair does not enable potential thieves to determine the other—depending upon the size of the numbers (1024-bit keys are now common), it can take enormous processing power to uncover the matching key. In a public key system, a person or a store is assigned both a public key that is published and available to anyone (often called a certificate) and the matching private key that only its holder possesses. In this way, public key encryption systems are able to accomplish the needs for authentication and confidentiality noted above, without suffering from the problem of how to send secret keys over the insecure Internet. Suppose a buyer sends an order to an online store and encrypts it with his or her private key. Then, the only way that the store can read the order is to use the buyer's public key to decode it. If the buyer's public key does indeed work, it proves that the order did come from that buyer—demonstrating the authenticity of that buyer. In the same way, an online store may have a public key (its certificate) that the buyer can use to verify that the store is authentic. Note, though, that in both situations, confidentiality is not ensured, since anyone should be able to access public keys, as these should be published. To ensure confiden-

tiality, the buyer would use the online store's public key to encrypt the message. Then, only the store would possess the matching private key, ensuring that only it would be able to decrypt the order. The combination of these two situations—the buyer encrypting with his or her private key and the store's public key—authenticates the buyer, since the store needs the buyer's public key, and ensures confidentiality, since only the store has its own private key.

Public Key Infrastructure To enable such systems in practice requires a trusted system to assign the keys in the first place and make sure that only the rightful owners obtain them. In addition, keys may need to be revoked in the event they are abused or appropriated by the wrong entities. Such a trusted party is often called a certificate authority, and the system to accomplish this is called a public key infrastructure (PKI; Housely, 2004). More on the PKI can be found in other chapters in this Handbook.

Combined Approaches and Digital Signatures In practice, public key encryption is processing intensive and is therefore impractical for large transmissions. The solution is to use a combination of symmetric and asymmetric systems, which can together enable the transmission of digital signatures. In this process, the buyer's computer uses an algorithm on his or message called a hash function to create an extract of it called a message digest. The idea behind such a function is that if there are any changes to the message, then the same algorithm would produce a different digest, revealing possible evidence of tampering with the contents. Then, the buyer encrypts this digest with his or her private key to create a digital signature guaranteeing that he or she sent the message. The full message, plus the digest/signature, could further be encrypted with a symmetric key. Now, the symmetric key must be encrypted with the store's public key, forming what is called a digital envelope. These envelopes, plus the encrypted message + digest/signature are then sent to the receiver. The receiving firm must use its private key to first obtain the symmetric key. Then it can decrypt the message and use the buyer's public key (which may have been also sent to the store in the symmetric key encrypted package, since we do not yet have published directories of public keys) to verify the signature. Finally, it can apply the same hash function to the unencrypted message and match the results to the digest to verify that no tampering occurred.

The above examples illustrate how encryption technology is evolving to help establish a more secure line of communication between online vendors and their buyers. However, some of the most well-known breaches of security have occurred outside the buyer-seller transaction link. In particular, one critical issue is the need to secure buyer information such as a credit card number once the vendor receives it. Servers storing thousands of credit card numbers are more desirable targets for hackers than an individual transaction. In fact, the most widely publicized e-commerce security breach to date occurred when a hacker compromised CD Universe's database, reportedly stealing 350,000 credit card numbers (Wolverton, 2000). The hacker attempted to extort \$100,000 from CD Universe and, when that failed, posted thousands of stolen card numbers on a public Web site. This illustrates that e-commerce security encompasses more than secure

transactions and must include a broad range of security practices that protect customers' information even after purchases take place.

E-Commerce Payment Methods

As alluded to above, to support complete transactions online, the e-commerce infrastructure must be capable of handling the financial settlement. Since the dawn of e-commerce, many financial and technology companies have worked to establish secure methods of electronic payment. In this section we group most forms of electronic payments into three broad categories: (1) closed user group systems, (2) systems that use secure transmissions of traditional payment methods, and (3) token-based systems for digital money. Each of these is briefly described below.

Closed User Groups A closed user group approach relies on payment occurring outside of the Internet. In general, this approach is used when online shoppers have an account and then are billed on some periodic basis for their usage or purchases. For example, an America Online (AOL) subscriber has made arrangements to pay AOL via a check each month or via his or her credit card. Any online purchases can then be appended to this regular bill. Likewise, a customer may have a private account with a vendor that offers products online. The customer then logs in with his or her account ID and password, purchases items, and receives a bill at the end of the month for all activity on the account. These are both closed groups—only members are able to make purchases, and a billing relationship is already established so that payment happens offline.

B2B exchanges often take place within a closed user group. For example, it is common for suppliers to have long-term contracts with their buyers with prenegotiated prices. Supply chain management systems can permit online ordering of needed supplies, while payment occurs through the normal offline billing and account management process.

Secure Transmission of an Existing Payment Method Many e-commerce vendors sell products to new customers who do not have accounts, and hence a closed user group approach would not work. Rather, the most common method of payment in e-commerce is to set up a secure transmission link to accept an existing form of payment, such as a credit card or an electronic check. One elaborate standard, known as the Secure Electronic Transaction (SET), was developed and supported by the credit card firms, including Visa and MasterCard. However, the system so far has proved to be too costly and cumbersome, and most sites simply use some variation of the original SSL approach to enable shoppers' browsers and e-commerce servers to set up a secure link. Credit card information is encrypted to prevent interception and theft as it travels over the Internet. Merchants must verify the credit card, and consumers, of course, must pay their credit card bill through normal offline means each month.

B2B payments may also occur using secure transmissions, even when the companies are not in a closed user group as described above. Secure transmission of electronic checks, such as offered by eCheck, have been

promoted as a safe means of transferring funds between businesses. Consumers may also use echecks for their payment needs.

Token or Digital Money Systems One problem with credit cards is that the fees charged by credit card companies makes them less viable for inexpensive purchases. Content-oriented e-commerce companies are particularly interested in better methods of low-value payment. Some music sites, for example, might find it viable to charge just a few pennies to play a song, counting on generating millions of transactions so that the total translates into real money. In these cases, one solution is to have users set up accounts and then provide a periodic bill that aggregated usage. However, such an approach sets up a barrier to spontaneous usage. Instead, researchers have attempted to develop digital money that could reside in an electronic wallet on a hard drive or in a mobile device. The basic idea is to have the consumer download some funds into his or her computer. This electronic cash could then be spent online, with appropriate controls so that once handed over to a vendor, it is properly debited from the shopper. Ideally, digital money could support micro-payments (even fractions of a penny), enable anonymous transactions, and prevent anyone from using the same tokens to pay more than one recipient. A famous example of an electronic cash system is the now defunct eCash from a company known as Digicash. Most of the digital money systems have not met with much success in the market (McCullagh, 2001).

One of the most successful e-commerce payment systems actually combines some elements from the above types of systems. PayPal, a payment service provider used on such services as eBay, *operates somewhat* like a closed user group, a credit card system, and digital money. *It also operates somewhat* like an online bank account, from which customers can make purchases from vendors who use it. They can put funds into their accounts using a credit card or through funds transfer from their regular bank account. But PayPal is more open than other closed systems and relies on more than simple secure transmissions of card numbers. As noted earlier, account holders can send money to anyone with an e-mail address. This is an excellent example of what is called a viral marketing strategy, because anyone receiving payment by PayPal has to open up an account to actually obtain the money.

EMERGING TECHNOLOGIES

The technologies that support e-commerce are constantly evolving, creating new capabilities and opportunities. Here we mention a few of the many technological developments that are shaping the future of e-commerce, including some that are now in widespread use and others just beginning to emerge. We briefly highlight six areas: 3D and virtual environments, software agents, mobile commerce, location-based services, extensible markup language (XML), and Web services.

There is a continuing focus on enhancing the richness and vividness of the e-commerce experience, in an attempt to make it as compelling as shopping in real life (Daugherty, Li, & Biocca, 2005). Work on virtual and 3D environments is ongoing, in anticipation of the day when

consumers will have computers with fast processors and 3D video cards coupled with broadband Internet access. Early approaches have been used by clothing catalog companies such as Lands' End, which allows shoppers to create their own 3D model that can try on clothes. Each shopper can modify the shape and appearance of his or her model and then get some idea how particular articles of clothing might look without personally trying them on. Virtual reality approaches go one step further, placing the online shopper into a synthetic environment. This is ideal for tourism, real estate walkthroughs, museum visits, and other types of products or services requiring a more experiential selling approach.

Another set of technologies influencing e-commerce involves software agents that act on behalf of an online shopper or vendor. One early type of agent was known as a shopping bot (short for robot), which could search out items and provide price comparisons (Brynjolfsson & Smith, 2000). Agents can be programmed to perform such tasks as tracking and placing bids at auctions, finding and negotiating prices on desired items, and buying and selling stocks. Research today explores how agents behave, especially when interacting with other agents in multiagent systems.

One exciting new e-commerce development to watch is the extension of online shopping into the mobile arena. Mobile handset manufacturers such as Nokia are building cellular phones with Web browsing capability. Next-generation cellular networks support packet switching and Internet protocol traffic. Protocols such as the wireless application protocol, wireless mark-up language, and compact hypertext markup language (CHTML) were developed to enable the quick translation of Web pages into a format readable on small cellular phone and personal digital assistant screens. As next generation cellular infrastructures speed up access times, and this user and network infrastructure is in place, people will no longer be tied to a desktop computer to surf the Internet and shop online. They are free to engage in e-commerce anytime and anyplace. Surprisingly, even before Web-enabled phones have achieved widespread adoption, early forms of mobile commerce have occurred with simple text messaging (e.g., via short message service or SMS). With hybrid models, cell phone users can make requests or respond to advertisements by sending SMS messages. Clearly, mobile or m-commerce is generating much interest, and not the least because the global number of cellular subscribers is more than a billion, which exceeds the number of people who have computers connected to the Internet (International Telecommunication Union [ITU], 2004).

Many m-commerce services will be based upon the particular location of shoppers, allowing someone in a car, for example, to find the nearest vendor of a particular product (Steinfeld, 2004). These types of services are collectively known as location-based services. In the United States, the Federal Communications Commission has mandated that all cellular operators be capable of determining the location of cell phone users to support emergency 911 services. However, there are numerous e-commerce uses of location data, and we are likely to see a wide range of services appear. Users may use their mobile device to search for available vendors in an area, receive directions

from their current location to a vendor, make payments at the point-of-sale device, and receive advertisements based upon their interests when they are near particular locations. Location-based services thus blend e-commerce and physical commerce in new ways, blurring the traditional online/offline distinctions of the past.

XML has had a significant impact on e-commerce, helping to move it from a basic presentation focus to a transactional focus. Like HTML, XML relies on tags to mark up text files. However, the emphasis is not on tags that define how information is to be formatted and presented, but on tags to describe data (see Dorfman, 2004, for a detailed description of how XML works). Moreover, users can define their own tags (hence, the notion of extensibility) based on the data they are providing. XML makes databases portable over the Internet and has been the basis for a growing family of transaction standards. As more firms use XML-based standards, particularly for B2B transactions, a new opportunity has arisen to develop industry-wide data standards. Essentially, XML has become an enabler for EDI over the Internet. Steinfeld and colleagues (forthcoming) have documented the growth of vertical industry standards using XML, illustrating the many challenges that industries face in agreeing on such factors as data definitions and transaction formats.

Building upon XML, the last development to highlight here is the growth in what has come to be called Web services. Web services are self-contained, modular e-commerce applications built on standardized protocols, made available over the Internet to e-commerce users and vendors through standardized XML messaging (Ritsko & Davis, 2002). They are helping to complete the transformation of the Web from a presentational medium into a transactional medium (Gottshalk, Graham, Kreger, & Snell, 2002). For example, a shopping cart function is a common Web service that a merchant may use to support its e-commerce site, rather than writing its own cart software. To enable Web services, standards for making XML-based requests (e.g., simple object access protocol, SOAP), describing the services that are available (e.g., Web Services Description Language, WSDL), and publishing service descriptions in online directories in a manner that permits requesters to search for needed services (e.g., universal description, discovery, and integration, UDDI) are required (Gottshalk et al., 2002). Some of the most famous Web vendors now enable business partners to link to their service via a Web services architecture (e.g., see Amazon.com's Web services offerings at <http://www.amazon.com/gp/aws/landing.html>). As the notion of Web services continues to expand, so too are efforts by major software vendors to provide development platforms to speed up service deployment. Microsoft's .NET platform and Sun's J2EE are the two most well known today (Sahai, Graupner, & Kim, 2004).

BARRIERS TO E-COMMERCE DEVELOPMENT

E-commerce has grown rapidly, but still accounts for only a small fraction of purchases due to a number of critical barriers. Three mentioned here include lack of

infrastructure access in some parts of the world, problems associated with online trust, and consumers' needs for immediate fulfillment for some types of products.

Economic and technological barriers can explain low e-commerce usage in many parts of the world. Obviously, e-commerce, especially when directed at consumers, has little relevance in places where there is limited computer penetration and most households do not have phone lines. Yet even in countries such as the United States, where 94% of households have telephone service, two thirds have computers, and more than half of the population now uses the Internet, less than 2% of retail trade occurs online. Among the more frequent explanations for low take-up of e-commerce are lack of trust in online vendors, security concerns, and incompatible consumer needs and desires.

How to establish trust in online commerce is one of the most heavily researched e-commerce areas, which became an issue when thousands of new and unfamiliar dot-com companies flooded the Internet (Grabner-Kräuter & Kaluscha, 2003; Koufaris & Hampton-Sosa, 2004; Tan & Thoen, 2002). Consumers are reluctant to shop at unfamiliar online stores for fear that their orders may not be fulfilled or they may not be able to return defective merchandise. The same problem prevents businesses from buying from unfamiliar suppliers, who have not proved that they are both trustworthy and competent to handle the business. Much of the research has attempted to identify factors that influence the formation of trust, such as Web site quality, presence of Web assurance seals (verification from trusted third parties—firms like Verisign or Trust-E that vouch for the legitimacy of an online vendor), use of secure servers for transactions, and specification of privacy policies (Kim, Sivasailam, & Rao, 2004). To some extent, the growing familiarity of e-commerce brands and movement of established firms into e-commerce has helped. However, consumers have new concerns about how e-commerce companies will use the information they collect. This is a privacy issue on its face, but also reflects a lack of trust that online vendors will behave responsibly.

A related issue is the fear that many online users have over the security of online transactions. Theft of credit card numbers and personal information are chief concerns, and the statistics reported earlier on online fraud by the Federal Trade Commission suggest that trust and security remain a significant problem (Federal Trade Commission, 2004). Clearly, the continued use of strong encryption measures, such as those outlined in the section on information security and online payment, will help bridge the trust gap. Secure transactions are not enough—they must be accompanied by sound information security practices in all aspects of a firm's infrastructure. The cases of hackers breaking into corporate networks and stealing entire databases of credit card numbers stored on servers reminds us of the importance of an overall information security policy (Laudon & Traver, 2003). Other measures for establishing trust, however, are also needed for consumer-to-consumer markets such as eBay, as noted above. Reputation and feedback systems, as well as escrow systems, are some of the measures used to generate trust among strangers in such auction markets (Resnick et al., 2000).

Finally, for many purchases, e-commerce may not be the best approach given consumers' needs, desires, or home situations (Steinfeld et al., 1999). For example, when people need a product immediately, they are much more likely to pick it up at a local store than wait one or more days for delivery. Click-and-mortar firms such as Best Buy recognize this need and now offer in-store inventory search and pick-up options for online shoppers. Other consumers see shopping as a social and entertainment activity, and a visit to the mall with friends is hardly replaceable by e-commerce. Finally, some services simply require too much of consumers to be viable. For example, to buy groceries including perishable items online, someone needs to be home at the time of delivery. This scheduling may be difficult, and to get around it, some companies attempted to use refrigerators in garages to which the deliverers had access. Yet this also requires consumers to open up their private space to strangers, and the costs of installing appliances at customer premises proved to be impractical. Moreover, not everyone had a garage, which limits the market. These are just a sampling of shopping situations for which e-commerce might not be the best option.

THE ECONOMIC AND COMPETITIVE IMPACTS OF E-COMMERCE

E-commerce represents both a threat and an opportunity for most companies. It can be expensive to implement, and firms must carefully evaluate the competitive benefits they might achieve. In this section, we examine some of the competitive and economic issues raised by the advent of e-commerce.

Competitive Advantage and E-Business

Information systems researchers have long recognized that information technologies are important competitive weapons (Porter & Millar, 1985). Innovative IT applications and networks help firms to lower costs and allow them to offer new value-added services that serve to differentiate a company from its competitors, which are the two basic competitive strategies discussed by Porter (1985). Information technologies and networks can be deployed throughout every firm's value chain, which is the set of activities through which any company converts inputs such as raw materials and labor into products that can be sold to customers. E-commerce can permeate the value chain, reducing the costs of acquiring supplies, enabling firms to reach into new markets via the Internet, and supporting such value-added services as product customization and the personalization of the information made available to customers.

By enabling access to distant markets without requiring expensive brick-and-mortar investments, e-commerce lowers important barriers to enter new markets. Moreover, because it is so easy to bundle new products over the Web, e-commerce can introduce new competitors into existing industries. Hence, one effect of e-commerce is that incumbent firms in any industry have faced new competitors that were formerly kept out by virtue of geography or other high cost factors. New technologies may also

substitute for existing ones, such as when consumers use new music formats in place of purchasing compact discs at stores or online.

Yet, e-commerce has another effect due to its ability to help companies pursue a differentiation strategy. Companies that gather information from customers and then use this to help offer highly personalized services, or that provide incentives to keep customers returning to their Web site, create what has been called sticky e-commerce (Shapiro & Varian, 1999). In this way, e-commerce raises customers' switching costs (the costs to move to a different supplier of a good or service), raising a new barrier that can help prevent other firms from successfully attacking a particular market. Network externalities, which create positive feedback loops so that the larger the service is, the more attractive it is, also work to make it difficult for new firms to attack established players. For example, eBay is so attractive because its large user base increases the likelihood that people can always find the specific product they are seeking. This in turn draws more sellers, which attracts more buyers, and so on. Smaller systems have trouble competing with this dynamic. Such differentiation effects demonstrate that e-commerce does not make exchanges frictionless, and this result would not, in any case, be in the interest of merchants.

Alternative perspectives point out other reasons new entrants may find it difficult to dislodge incumbents in any industry. Afuah and Tucci (2001) point out that incumbent firms normally possess crucial resources that new entrants may not have. These are often called complementary assets and include such factors as established relationships with suppliers, experience, access to retailers, powerful information systems, and strong distribution networks. Indeed, the rise of click-and-brick e-commerce shows forcefully how incumbent retailers can better capitalize on e-commerce than the new dot-coms that do not possess the required complementary assets.

There are many other potential impacts of e-commerce on the competitive dynamics of industries. In addition to the rivalry among competitors in an industry, and the potential threat from new entrants and substitute products noted above, Porter (1980) directs our attention to threats arising from elsewhere in the value chain, including suppliers and buyers. A good example of e-commerce enhancing the bargaining power of suppliers occurs when manufacturers threaten to bypass retailers to sell directly to customers. To the extent this threat is credible, it may reduce the ability of retailers to capture more of the value when they resell products and services to end consumers. The threat of disintermediation is discussed in more detail below. Good examples of the ways that e-commerce can enhance buyer power are noted in the section on consumers in e-commerce. Reverse auctions such as Priceline illustrate how a market can become more buyer-centric. Other enhancements to buyer power through e-commerce occur when individual consumers band together to obtain the types of volume discounts normally only offered to larger business buyers. Third parties that organize this co-buying capability are known as buyer aggregators.

E-Commerce and Transaction Costs

The primary way that e-commerce helps companies reduce costs and enter new markets enable the entry into new markets is by reducing what economists call transaction costs (Williamson, 1975). Every commercial exchange, including those between consumers and businesses and business-to-business exchanges, is a transaction that can be broken into a number of discernible stages, each with its own set of costs to the participants. At the simplest level, we can consider any purchase to require an information or prepurchase phase, a purchase phase, and an after-sales or postpurchase phase. During the information phase, for example, buyers face search costs and sellers have costs to supply purchase information to buyers. During the purchase phase, other costs are associated with negotiation, monitoring contracts, and actual financial settlement. Postpurchase costs include repairs, returns, and other types of customer services. When transaction costs get too high, markets become inefficient, and prices can be higher than they should be. For example, imagine a small town with one seller of some product. Without the Internet, customers in this town face high search costs (e.g., driving to another city to look in stores there) with uncertain payoff. So they pay the higher prices charged by the local monopoly provider. With the Internet, customers' search costs for finding lower-priced suppliers are dramatically reduced, forcing the local monopoly seller to lower its prices. Because of this effect, many economists believe that the Internet will help reduce prices across all industries (Bakos, 1997). Indeed, it became popular to talk about the *death of distance* as a barrier to commerce due to the reduced transaction costs afforded by e-commerce. However, such an analysis overlooks many important influences on the price of any product, including the fact that online products differ in many ways from their counterparts in a store. Online products are not immediately available; cannot be touched, smelled, or otherwise physically examined; and perceived risks—e.g., ease of returns—may be higher. It further ignores the importance of established relations between buyers and sellers, a notion discussed next. Transaction cost frameworks must be extended to deal with these issues.

Market Structure and Buyer–Seller Relations

The reduction in transaction costs afforded by e-commerce is proposed to have another big economic effect, primarily at the B2B level. If transaction costs can be reduced, then market mechanisms may be used where they were not feasible beforehand, based on an early theoretical argument proposed by Malone and colleagues (Malone, Yates, & Benjamin, 1987). For example, suppose a company needed a very specific type of input, only available from one particular supplier in its area. In the past, this company was at a disadvantage. Due to information asymmetries (the supplier knew what it cost to make the goods, but the buying company did not) and lack of alternative providers, the supplier could charge higher prices. However, the reduced search costs and greater information available on the Internet reduce these asymmetries

and increase choice. Hence, firms can avoid being locked into long-term relationships and use more spot-market buying behavior to source the inputs they need. The theoretical prediction was that such uses of e-commerce would give rise to large electronic marketplaces in which businesses could buy inputs based purely on the best available offers.

Although e-commerce did result in the formation of large B2B electronic marketplaces that offered both manufacturing (vertical) inputs and commodities (horizontal) supplies, the above prediction has not been entirely supported. First, most of the third-party-developed B2B markets have failed (Laudon & Traver, 2003). Substantial empirical evidence suggests that firms are more likely to use e-commerce to increase the efficiency of transactions with trusted suppliers than to enable spot transactions with new suppliers (Steinfeld et al., 1995). Hence they were less likely to allow new third-party firms to position themselves as profit-making intermediaries in these well-established relationships. Instead, the bulk of B2B e-commerce occurs over private industrial networks typically organized by larger buyers or sellers. Often a large company will function as the leader in a value network that encompasses firms up and down the value chain. These value networks compete with other value networks as an extension to simple firm to firm competition. The B2B e-commerce links permit more than just simple buy-and-sell transactions—they enable collaborative e-commerce among networks of firms, allowing such activities as co-design of components and joint marketing efforts.

Intermediation and E-Commerce

As noted above, e-commerce can enable producers of goods and services to bypass intermediary firms such as wholesalers and retailers and sell directly to end customers. This effect has come to be called disintermediation and is often anticipated because of the belief that the Internet reduces producers' transaction costs for accessing end customers. Many producers were swayed by this logic and began to sell products directly from their Web sites. For some companies, such as Dell and Cisco, the direct-sale business model made a great deal of sense, and the Internet provided a cost-effective way to manage it. Most of their customers were businesses already connected to the Internet and accustomed to doing business in this way. For others, especially those selling to consumers, this approach made less sense. Sarkar and colleagues showed early on that, in fact, the Internet provided as much or more opportunity for new forms of intermediation and also helped to strengthen the role of existing intermediary firms (Sarkar, Butler, & Steinfield, 1995). They argued that intermediaries' transaction costs were also reduced, and the gains they get from e-commerce may negate any advantages producers might gain. They also note that intermediaries provide many functions to both buyers and sellers, such as needs assessment and evaluation, market information, and risk reduction, which are critical for many purchases. Many subsequent analyses demonstrated the fallacy of the disintermediation hypoth-

esis (e.g., Schmitz, 2000). Marketing theorists caution that although any particular intermediary might be eliminated, their functions cannot be, suggesting that a role remains for intermediaries even in the age of e-commerce (Stern, El-Ansary, & Coughlan, 1996).

Pricing and E-Commerce

Because of the reduction in transaction costs, and access to information about prices of alternative vendors, a primary effect of e-commerce was supposed to be lower and more homogenous prices relative to traditional channels. Up to now, the evidence for lower prices is rather mixed, especially when the added costs for shipping are taken into account. Moreover, price dispersion remains high, contrary to the expectations of economists (Smith, Bailey, & Brynjolfsson, 2000). It appears that because it is so easy to change prices (referred to as menu costs), Internet companies make more changes in smaller increments to respond to the market.

Another reason there is variability in prices is that e-commerce makes it easier to engage in price discrimination, whereby vendors sell the same product to different customers at different prices. The goal, of course, is to learn what each customer's willingness to pay is and then charge him or her that price. One way that this can happen is through auction pricing, which allows customers to submit their willingness to pay in the form of bids. Another popular price discrimination approach is to charge different prices for different versions of the same product or service (e.g., a student version of software versus a professional version) (Shapiro & Varian, 1999). Sometimes e-commerce companies have tried to estimate willingness to pay based upon some aspect of online behavior. Amazon.com, for example, once angered its customers when it was revealed that the online vendor had attempted to charge higher prices to returning customers, based on the assumption that these loyal customers would be less likely to switch to other online sellers. They soon stopped this practice. Another method of price discrimination is to make assumptions about willingness to pay based upon the referring site. Thus, if a shopper arrives at an online retail site by way of a comparison shopping agent or a discount shopping site, he or she may be presented with a lower price than a shopper who had clicked on an ad in an upscale investment journal.

Collectively, the research in this area shows that e-commerce effects are not so straightforward as was once believed. Many popular notions about e-commerce effects, such as the rise of disintermediation, the death of distance, and the emergence of frictionless commerce are now viewed as myths.

CONCLUSIONS

In this chapter, we have defined and provided a broad overview of e-commerce and showed how the creation of a ubiquitous, easy-to-use, and open data network helped e-commerce emerge as a powerful force from the many precursor systems and technologies. We discussed the development of innovative business models, but noted the problems that dot-coms faced when they attempted to

delay profits in exchange for market share. Many powerful marketing strategies were introduced, as well as the rise of consumer-centric markets. Ancillary technologies needed to enable e-commerce, such as encryption and payment systems and emerging technologies such as mobile commerce, XML, and Web services that will extend e-commerce were also discussed.

A critical theme of the chapter is that e-commerce impacts are not straightforward, and claims of revolutionary changes must be carefully scrutinized. Important barriers to its development remain. Research on the competitive and economic impacts yields many findings that run counter to early expectations.

Despite these barriers and unanticipated impacts, we expect that e-commerce will become increasingly pervasive, even without the headlines that tracked every new dot-com in the early years. There are a number of reasons for this expectation. First, as noted earlier, e-commerce usage is continuing to grow, even in what many consider to be a sluggish economy. Moreover, even though IT spending is down and telecommunications firms have recently struggled to stay profitable, the high pace of investment throughout the 1990s means that the infrastructure is now in place to support e-commerce. The Internet backbone networks are fully capable of supporting more traffic and can accommodate the growth in broadband access. It is hoped this will improve the responsiveness of e-commerce sites, encouraging more use. New technologies, such as the extension of e-commerce to mobile devices and increasing availability of Web services, will increase the pervasiveness of e-commerce. The dot-com bust may have caused some to be pessimistic, but it can also be viewed as a normal evolutionary process at the start of any new industry. Poor business models have failed, but viable ones have survived and are now prospering. Moreover, the entry of established companies into e-commerce is lending more legitimacy to the sector and is helping to overcome trust problems, as is the increasing use of powerful public key encryption systems to protect transaction data. These firms also have the resources and alternative sources of income to enable their e-commerce channels to develop appropriately, without reckless moves aimed at capturing market share at the expense of profits. Finally, continued B2B e-commerce development is enhancing efficiency in the supply chain, which can also carry over to B2C e-commerce. In summary, e-commerce will continue to spread throughout the economies of the world and will certainly require careful managerial attention given the complex outcomes uncovered in the research to date.

GLOSSARY

B2B Electronic Hub Electronic marketplaces where business buyers can acquire goods from suppliers. Vertical hubs focus on the provision of manufacturing inputs bringing together firms operating at various stages inside a particular industry value chain. Horizontal hubs focus across industries, bringing buyers and sellers of a wide range of maintenance, repair, and operation goods to the market.

Buyer Aggregation The process of organizing small buyers into a cooperative buying group to obtain volume discounts.

Collaborative E-Commerce A form of B2B e-commerce among cooperating networks of firms that involves more than just purchases, but also such activities as the co-design of components and joint marketing efforts.

Complementary Assets Resources possessed by a firm that enable it to take better advantage of innovations like e-commerce. These resources include established relationships, product know-how, existing business processes and systems, and distribution systems.

Disintermediation An effect of e-commerce whereby producing firms bypass traditional intermediaries to sell directly to end consumers. Hence, intermediaries such as wholesalers or retailers find their position in the market, and thus their very survival, threatened.

Dot-com A name given to Internet companies because their network name ended in “.com.”

Electronic Document Interchange (EDI) A standard for transmitting business documents over computer networks.

Intermediary An entity that facilitates trade between buyers and sellers in markets. Wholesalers and retailers are considered to be intermediaries that help manufacturers sell their products to the end consumers. Real estate agents are intermediaries who bring together home buyers and sellers.

Internet Business Model A generic term referring to a variety of specific methods of doing business and generating revenue on the Internet.

Network Externalities A term describing the changes in benefit that an agent receives from a good or service due to changes in the number of other people using that good or service. The word externality implies that these benefits are not internalized by the seller (i.e., captured in the price). They may be negative (e.g., congestion effects) or positive (e.g., more potential contacts). Often the term *network effect* is used to refer to the increasing benefits to customers associated with a larger user base in an online business.

Price Discrimination A pricing strategy whereby vendors sell the same product to different customers at different prices in an attempt to maximize overall revenue by matching prices to customers' willingness to pay.

Public Key Encryption An asymmetric method of encryption that requires two separate keys, one public and one private. Data encrypted with a public key can only be decrypted by the corresponding private key and vice versa. Asymmetric systems are in contrast to symmetric, or private, key systems that use the same key at either end to decrypt transmissions. Public key systems solve the problem of how to avoid the need to send keys over an insecure network and are often used in concert with symmetric systems—encrypting the symmetric key prior to sending it to the other party.

Switching Costs In e-commerce, such costs are the additional costs a user (or buyer) faces when changing to a different supplier of a good or service, caused by such

factors as learning costs, loss of accumulated benefits, or contract requirements.

Transaction Costs Costs incurred by buyers and sellers as they complete a commercial exchange, including search and information gathering costs, monitoring and settlement costs, and after-sales and service costs.

INTRODUCTION

Electronic data interchange (EDI) is the computer-to-computer exchange of business transactions in standardized formats. It is used for business-to-business (B2B) electronic commerce, the largest and fastest growing type of electronic commerce. EDI involves electronic links from one organization to another, classifying it as a type of interorganizational information system (IOIS). EDI includes support for a variety of business transactions. For example, Bell Helicopter (2002) uses EDI for invoices, payments, shipping schedules, and requests for quotes in conducting business with its suppliers. EDI uses standard formats for the electronic exchange of business transactions.

There are over 100,000 companies using EDI in the United States today (Cooke, 2002) and 200,000 users worldwide (Angeles, Corritore, Basu, & Nath, 2001). The viability of secure EDI over the Internet will increase the number of EDI users significantly (Cullinane, 1998). Security of EDI is one of the factors contributing to its successful implementation by U.S. firms for domestic and international EDI (Angeles et al., 2001).

The use of EDI includes administrative components such as the establishment of business relationships, modifications to business processes, and the execution of business transactions. Various technologies for implementing EDI, including file transfer protocol (FTP), electronic mail, Web services, and private service providers, are available. The general security mechanisms for EDI transactions are the same regardless of the technology used to implement EDI. The specific steps an organization takes to secure its EDI process will depend in part on the technologies it employs in its deployment of EDI. This chapter concerns the EDI security but the reader may wish

to examine other chapters in this *Handbook* for more detailed information on particular technologies. Other relevant chapters in this *Handbook* are "Business-to-Business Electronic Commerce," "Electronic Commerce and Electronic Business," and "E-Commerce Safeguards."

THE BUSINESS ROLE OF EDI

The use of EDI to exchange business transactions does not occur until after two organizations have established a business relationship with each other. This characteristic is markedly different from business-to-consumer (B2C) electronic commerce. In B2C electronic commerce, the relationship often begins with an online transaction. The two organizations develop a trading partner agreement that specifies the terms and conditions for using EDI with each other before implementing EDI. Briefly, the process involved in conducting a transaction via EDI is for an organization to translate a business transaction into the agreed-upon EDI standard format, transmit the transaction electronically to the trading partner, and for the trading partner to translate the EDI format transaction into the format required by its information system. Refer to a later section of this chapter for a detailed discussion of the EDI process.

Traditionally, organizations have used communication service providers to act as intermediaries in communication exchanges with trading partners. The communication service provider would act as an electronic post office, directing messages to the appropriate electronic mail box, and allowing organizations to receive their messages. The introduction of the Internet has created other alternatives for sending and receiving EDI transactions: electronic mail, file transfer, and Web-based alternatives.

Often, these alternatives cost less than traditional EDI. Because the Internet is a public network, these EDI alternatives also introduce security risks for EDI transactions.

The following is a brief description of how a company might use EDI. The company's inventory management system detects that the quantity on hand of an item has fallen below the reorder point and generates an order for the item. The order moves electronically to an EDI software system that converts the order to the standard EDI format and sends it to the company's supplier. The supplier receives the order via its EDI system, converts it to the format required for its order processing system, and sends it to the order processing system for processing.

The fact that EDI uses standard formats permits businesses to convert the electronic documents to formats that their business systems use. The business systems can then process them in the same way other transactions are processed. Similarly, an information system could generate a transaction. When companies fully integrate EDI systems with their information systems, there is no need for human involvement in processing paperwork. EDI software can convert the transaction to the format needed by the application and send it to that system.

Companies have realized many benefits from the use of EDI. Lower transaction costs are frequently mentioned, and other benefits include increased accuracy, lower inventory costs, reduced labor costs, more timely information, and reduced cycle times (Copeland & Hwang, 1997; Raghunathan & Yeh, 2001; Waksunski, 1996). EDI can improve accuracy by eliminating the rekeying of data. Because EDI transactions move electronically, it can eliminate paper costs and reduce communications costs.

Smaller organizations may adopt EDI to satisfy the requirements of a larger trading partner and may not reap similar benefits (Lee, Clark, & Tam, 1999). Implementing EDI involves both administrative and technical adjustments, and the technical expertise required to implement EDI may challenge small companies (Iacovou, Benbasat, & Dexter, 1995; McGowan & Madey, 1998). Larger trading partners should consider providing technical help to smaller organizations to ensure the process is secure at both ends.

THE EDI PROCESS

The first step for two trading partners to use EDI to exchange business documents is for them to establish an agreement specifying the terms and conditions for the use of EDI. Oftentimes the company initiating the EDI process has a standard agreement. Refer to the chapter on "Security Obligations in Vendor Contracts" for additional information.

EDI uses a standard format for exchanging business documents. Most company information systems do not directly support standard EDI formats, necessitating a translation to or from the formats used by the information system. Figure 1 illustrates the EDI process for an invoice from a supplier to a buyer. In this scenario, the supplier creates an invoice within its billing system, then extracts and formats the invoice information before sending it to EDI translation software. The EDI translation software takes the invoice information, formats it in the

Figure 1: The EDI process for a supplier invoice.

EDI standard format, and sends it to the EDI document management software. The EDI document management system prepares the addressing information and transmits the EDI formatted electronic documents to the buyer via a communications network. On the buyer side, the buyer's EDI document management software receives the invoice and forwards it to EDI translation software. The EDI translation software formats the EDI transactions into the format required for the buyer's accounts receivable system for processing. The following section discusses the threats to EDI systems.

EDI VULNERABILITIES

The primary threats to EDI systems include interception (unauthorized access to data), interruption (prevention of transaction completion), modification (intentional or unintentional loss or destruction of data), and fabrication (fraudulent transactions). This section identifies threats to EDI data. Subsequent sections of this chapter identify countermeasures. Figure 1 provides a frame of reference for the discussion of EDI vulnerabilities.

Interception

EDI data are subject to interception at any point in the EDI process. The greatest threats occur when the data are in transit, particularly if the EDI process uses the Internet as the communications network. The originating system (billing system in Figure 1) and destination system (accounts receivable system in Figure 1) also provide opportunities for interception. Data interception is also possible if the data reside on a computer accessible to the Internet during the EDI process, for example, a server connected to the Internet.

Interruption

The EDI process often involves several software systems and multiple hardware platforms. If any one of these

components is unreliable, it could lead to an interruption of the EDI process. For example, a denial of service attack on the computer used to send or receive EDI documents could lead to an interruption of the EDI process. Companies that initiate EDI with smaller trading partners may need to provide technical assistance to ensure the EDI process does not suffer interruption.

Modification

Modification to EDI data can be intentional or unintentional. The largest unintentional threats come from problems in the systems used for EDI. For example (refer to Figure 1), incorrect information might enter the originating system (billing), the system might not extract and format the data properly, the translation to the correct format may be improperly specified, or data may not be properly loaded to the destination system (accounts receivable). Using EDI can actually help reduce error rates in these business processes because data exchanges are electronic and do not involve rekeying. The most likely threats of intentional modification are from people who work with the source (billing) and destination (accounts receivable) systems.

Fabrication

Fraudulent transactions are one of the greatest threats associated with EDI. The threat is not due to the use of EDI. Proper administrative controls and system controls can reduce this threat significantly. One example of fraudulent transactions is a supplier who intentionally creates an invoice with one number and then creates a second invoice using a different invoice number for a shipment. Another form of fraud is to place a transaction and then deny that the transaction occurred.

The following section includes a discussion of security mechanisms that can help reduce the threats to the EDI process.

EDI SECURITY MECHANISMS

There are five general types of security mechanisms for reducing the security risks for EDI systems: access control, authentication (originator and receiver), nonrepudiation (originator and receiver), data integrity (content and sequence), and auditable history/paper trail. The EDI security mechanisms are summarized in Table 1 and discussed in detail in the following paragraphs. Later parts of the chapter include discussion of mechanisms related to particular EDI technologies.

Access Control

Access control concerns the issue of who is able to obtain and view the transaction and in what circumstances. Access controls must be in place for transaction origination, the duration of the transaction transmission, and transaction receipt. Transaction origination and receipt should be restricted to authorized users or applications. Organizations frequently employ controls requiring user identification and a password to gain access to such systems. This type of control can help prevent fabrication or modification of transactions.

Transactions in transit can be secured by using encryption. Although encryption does not prevent unauthorized access to the transactions, it limits the impact of such a compromise. This type of mechanism can reduce modification or interception. The threat of interception of transactions will vary according to the technologies used to implement EDI. The reader may wish to reference the chapter on “Access Control: Principles and Solutions” for additional information.

Authentication

Authentication is the process that verifies that the transaction is genuine and is authorized by the trading partner. Authentication of the transaction origination protects both the sender and receiver (Waksmunski, 1996). For example, the receiver of a purchase order does not want to send an unauthorized shipment. Similarly, an organization would not want to pay an invoice for a product that was never shipped. Authentication can help deter fabrication, and some authentication techniques allow detection of modifications.

Organizations use several techniques to authenticate transactions. One approach is to include a digital signature in the transmission of the transaction. A second approach is to present a certificate that the trading partner may validate with a trusted party. The authorization process may be a part of the authentication process. For example, an organization may require user identification and a password to originate a transaction online. Trading partners should also use acknowledgments for transactions. This provides feedback that the trading partner received the transaction. If an organization were to receive an acknowledgment for an unauthorized transaction, it could notify its trading partner. Organizations can achieve greater levels of security by using multifactor authentication, which is becoming more common today. For example, a file transfer of documents might require a user id and password to submit the documents, and the

Table 1 EDI Security Mechanisms

Mechanism	Description
Access control	Limit who is able to obtain and view the transaction and in what circumstances.
Authentication	Verify that the transaction is genuine and authorized by the trading partner.
Nonrepudiation	Validate through undeniable proof that the partner participated in the transaction.
Data integrity	Ensure the content and sequence of the transaction is valid, accurate, and complete.
Auditable history	Maintain a complete record of the transaction process.

documents themselves could contain a different identifier and password. Refer to the following *Handbook* chapters for additional information: “Digital Certificates” and “Digital Signatures and Electronic Signatures.”

Nonrepudiation

Nonrepudiation (of origination) provides the recipient of the message with proof that a message has been sent and the proof should withstand any attempt by the originator to deny sending the message (Humphreys, 1995). Similarly, there is a need for authentication on the receiver side of the exchange so that the receiver cannot deny that it received the transaction.

To ensure nonrepudiation, an organization should keep a record of transactions received and sent, including any digital signatures or other authentication codes. Trading partners can use acknowledgments (and save these) as proof of transactions. These measures can assist in detecting fabrication or modification. If a company does not receive an acknowledgment, it could be an indicator of interruption.

Data Integrity

Data integrity refers to whether the content and sequence of the message is valid, accurate, and complete. Since EDI transactions are sent electronically, there is the possibility of transmission errors. EDI transactions may also be subject to tampering. The EDI transaction process needs to include a mechanism for ensuring data integrity.

EDI requires transactions to be in a structured, predetermined format. One check of data integrity is to validate that the transactions meet these requirements. A second technique for ensuring data integrity is for the originator to use hash totals (Sterling Commerce, 2003; Waksmunski, 1996). The transaction originator calculates a hash total based on summing certain fields, and then sends the total to the recipient. Upon receipt of the transactions, the recipient independently calculates the hash total and compares it to that sent by the originator. If the totals do not match, then there is an error (intentional or accidental) in the transmission. These techniques can detect modification.

Auditable History

Auditable history relates to the extent to which one can verify the entire transaction process. An audit trail is frequently necessary for accounting purposes. An audit history may be useful in detecting or recovering from fabricated or modified transactions. Traditional business transactions often leave a paper trail. By its very nature, EDI offers little in the way of a paper trail. EDI transactions should be stored for nonrepudiation, but audit needs often require organizations to keep records for longer periods. Another issue for electronic audit trails is ensuring that the auditors can access the electronic records. As new systems replace old systems, an organization may need to migrate audit records.

The following section explains the details of EDI and discusses several technological approaches to EDI.

COMMUNICATIONS NETWORK ALTERNATIVES

There are several alternatives for the communications network implemented for EDI. A company needs to choose which communications transmission technique to use and whether to use a value-added network (VAN) service provider. The exact configuration will depend on the specific arrangement the trading partners have agreed to implement, and many companies use more than one approach to accommodate different trading partners.

The security issues would be the same regardless of the communications network used. However, different types of communications networks would present different threats. For example, the public Internet offers less security than a private network. Security considerations for various EDI configurations are discussed in this section. The reader is encouraged to examine other chapters of this *Handbook* for more complete security information on various technologies.

The three most common transmission methods are the public Internet, a private line connection, and a public switched line (dial-up). The Internet is an unsecured, public network, so it poses various security risks, particularly related to access control. Alternative approaches to using the Internet for EDI are discussed in a later section. Private lines and dial-up connections are difficult for unauthorized users to penetrate, and thus provide a greater inherent degree of access control. However, EDI is moving toward the Internet because of the cost and connectivity benefits.

Value-Added Network Services (VANs)

Traditionally, most companies have opted to use VAN service providers to implement EDI. Among the services VANs provide are connectivity, electronic mailboxes, translation services, security features, and an audit trail (Copeland & Hwang, 1997). The VAN can act as a postal service by accepting EDI transactions from a company and storing them in its trading partners' mailboxes or forwarding them to the trading partners' VAN service providers. The electronic mailbox allows the company to retrieve its EDI documents as needed. A VAN service provider can also provide translation services. This would mean a company could send information from its business systems to the VAN and the VAN would translate the documents into EDI formats, an approach slightly different from that shown in Figure 1.

VAN service providers can assist with security. VAN services can include access control, authentication, and encryption (Copeland & Hwang, 1997). VANs normally restrict access by requiring a user identification and password to access a mailbox. Encryption services help limit the threat of information compromise. A VAN may provide secure connectivity options, including private line connections, dial-up connections (avoiding the Internet), or a virtual private network (VPN) connection for secured access via the Internet.

The VAN can assist with authentication by checking that only authorized trading partners sent transactions. VANs can also help with authentication and

nonrepudiation by acting as a certification authority (Humphreys, 1995). The VAN can help ensure data integrity by examining transactions to see that they are complete and in valid formats. The VAN can assist with nonrepudiation and auditable history by providing and storing tracking information for documents.

Internet-Based EDI

The widespread availability of the Internet combined with its low cost as a communications network has led many companies to use EDI over the Internet. Some researchers believe that the use of the Internet will eliminate the need for VAN service providers (Threlkel & Kavan, 1999). VAN service providers have had to adjust their strategies to concentrate on other services besides communication services, including Internet-based services. Companies can use the Internet for EDI either with or without a VAN service provider.

Companies that use the Internet as a communications network for EDI can choose among several approaches: exchanging files of transactions using the file transfer protocol (FTP) (dmx.com, 2002; Threlkel & Kavan, 1999); exchanging transactions via e-mail using multipurpose internet mail extensions (MIME) (Chan, 2002); using VPNs (Threlkel & Kavan, 1999); or simply using the Web as a means of entering transactions via HTML (Bell Helicopter, 2002) or through extended markup language (XML) (Karpinski, 2001). The following chapters in the *Handbook* may provide additional information: "Internet Security Standards," "TCP/IP (Transmission Control Protocol/Internet Protocol) Suite," "Internet E-mail Architecture," "S/MIME (Secure MIME)," "VPN Basics," and "Firewall Architectures."

XML Exchanges

XML is becoming a popular way to use the Internet for exchanging business documents and may permit smaller businesses to participate (Cooke, 2002; Witte, Grunhagen, & Clarke, 2003). Some XML configurations permit entry of business documents via a Web browser. Many companies have delayed implementing XML because of a lack of standards for business documents in XML format (Cooke, 2002). Vendors of EDI software are adding translation functions into their software packages that allow conversion between EDI and XML formats (Witte et al., 2003). The lack of standards, including standards for data content and security, has been a barrier to widespread implementation of XML for document exchange (Witte et al., 2003). The Organization for Advancement of Structured Information Standards (OASIS; see <http://www.oasis-open.org>) is one organization involved with the development of such standards.

OASIS and the United Nations Center for Trade Facilitation and Electronic Business jointly developed the electronic business XML (ebXML; see <http://www.ebxml.org>) standard. The ebXML standard is a standard for conducting secure, reliable data exchange over the Internet (Sullivan, 2004). Tony Scott, chief technology officer at General Motors, believes that ebXML will become the de facto method by which companies do business (Sullivan, 2004). The automotive industry is one of the

early adopters of ebXML, and the Automotive Industry Action Group formed a working group to figure out how to use ebXML and other Web-services standards for the automotive industry (Sullivan, 2004). Refer to the chapter on "Web Services" for additional information.

Security Threats of Internet-Based EDI

Security is one of the largest concerns about using the Internet for business communications, including transmission of business documents (Witte et al., 2003). The Internet is a public network, so companies must not only try to prevent interception, but work to ensure that if interception does occur, the interceptor cannot interpret the message. Businesses need to implement firewalls for any computer involved with Internet-based EDI to prevent unauthorized access to the information stored there. An organization could configure its firewall to block traffic that does not come from a valid IP (Internet protocol) address of a trading partner.

Various types of encryption mechanisms can help protect documents in transit (reference the "Encryption Basics" chapter elsewhere in the *Handbook*). A VPN uses encryption to provide a secure, "private" link over the Internet. None of the other Internet-based EDI approaches include encryption, but an encryption mechanism could be used with any of them to provide message confidentiality should an EDI document be intercepted on the Internet. Organizations can use secure socket layer (SSL) or secure electronic transaction (SET) to provide security for Web-based EDI. Companies that use Internet-based EDI also need to be concerned about threats to their systems because of connections to the public network. Internet threats can include hackers attempting to access systems, worms or viruses penetrating the system, and denial of service attacks.

XML Security

XML uses tags to describe data elements in a document and to define the structure of a document. The tags make it easy to locate information in the document, a beneficial feature of XML that also makes it a potential security hole (Kay, 2002). XML documents can be secured in transit via SSL or through the use of VPN, but that does not eliminate the threat of hackers accessing data stored in XML formats on a server (Kay, 2002; Witte et al., 2003). There is commercial software available to encrypt data directly from an application (Kay, 2002) so that it is not stored in a vulnerable format.

EDI STANDARDS

EDI uses standard formats for the exchange of business documents. Early users of EDI such as Wal-Mart and K-Mart used proprietary formats for EDI (Choudhury, 1997). Using proprietary formats for EDI creates a problem for some trading partners because it means that they need to convert transactions into a variety of formats (Chan, 2002). Using a common standard means that a company needs only one translation process for each type of business transaction done via EDI instead of using different formats for different trading partners.

Common standards also ensure that trading partners have a common understanding and are more likely to result in correct use. The transportation industry was one group that saw the benefit of using common standards and used industry associations to develop industry standards. This consequently led to national and international standards.

There are two principal sets of standards for EDI, the United Nations Electronic Data Interchange for Administration, Commerce, and Transport (EDIFACT) standard, and the American National Standards Institute Accredited Standards Committee X12 (ANSI ASC X12, or more usually, X12) standard. Organizations in the United States more commonly use the X12 standard.

The ANSI X12 Standard

ANSI developed the X12 standard to help facilitate EDI in the United States. The X12 standard defines the data structure, syntax, content, and sequencing for business documents. The standard defines transaction sets for more than 275 different types of documents such as invoice, purchase order, and payment/remittance advice.

The X12 standard defines the following components for each transaction set: data dictionary, data segment, data segment directory, and data elements. The data dictionary defines the content and format of data elements that make up the transaction sets. For example, the data dictionary could define a data element representing the customer name as an alphanumeric field of up to 120 characters. A data segment is a collection of related data elements. For example, one data segment might include the data elements related to the customer’s shipping address, and another data segment might include data elements related to the customer’s billing address.

The segment directory defines the formats and contents of the data segments in transaction sets. For example, the purchase order transaction set may specify a purchase order identifier of 6 to 30 alphanumeric characters. A loop is a repeating group of segments or segment groups that belong to a transaction. For example, a purchase order transaction segment may contain loops consisting of line items for that purchase order.

The X12 standard specifies transmission control standards for the transmission format (interchange envelope) required to exchange data. A single interchange envelope may contain several types of transaction groups destined for the same recipient. Figure 2 illustrates the X12 interchange format. In this example, a single interchange envelope includes two purchase orders and one payment advice for transmission to a single customer. There is only one functional header for the purchase order documents. Each purchase order has its own transaction set header and transaction set trailer.

The X12 standard transaction sets provide users with a large number of possible data elements to include for a transaction. The purchase order transaction set specifies more than 160 possible data segments, with each segment having up to 6 data elements (dmx.com, 2002). Because of this overwhelming flexibility, many industries have developed conventions to specify the segments and data elements they will use. The airline industry has a set

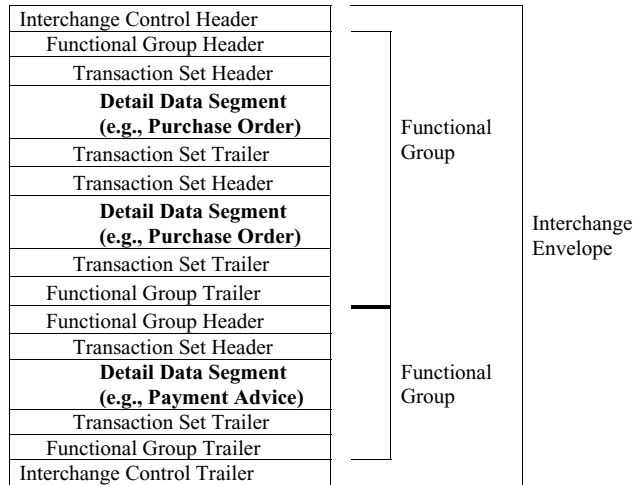

Figure 2: X12 EDI interchange format.

of conventions to specify the standards of use for industry transactions.

The X12 standard continues to evolve, with new transaction sets being added to those already defined. In the United States, the organization responsible for managing EDI standards is the Data Interchange Standards Association (<http://www.disa.org>). The organization is also responsible for managing EDIFACT standards for the United States (Houser, Griffin, & Hage, 1996).

EDIFACT

The United Nations developed EDIFACT as an international standard to help facilitate EDI for international commerce. The International Standards Organization (ISO) and the United Nations Economic Commission for Europe are jointly responsible for development and maintenance of the EDIFACT standard (Chan, 2002). The EDIFACT standard combines the trade data interchange (TDI) standard developed in the United Kingdom with the X12 standard from the United States (Chan, 2002). The EDIFACT standard is similar to the X12 standard. EDIFACT uses a different syntax and its design allows reuse of components. It has fewer and shorter segments than the X12 standard. Some users have criticized EDIFACT as being less robust than the X12 standard, but it is widely accepted and used extensively for international commerce (Witte et al., 2003).

Security Features of EDI Standards

The complexity of EDI standards provides some measure of security for EDI transmissions. For example, if someone intercepted an EDI transmission, it would still be necessary to interpret the contents. That would mean being able to translate the information from the EDI format into a format more readily accessible by people. Since that is readily accomplished by commercially available software, one could compromise the transmission by using such software to “decode” the information.

EDI standards provide some degree of protection against tampering. The EDI translation software can ensure that the EDI documents are in strict compliance

with the EDI standards during the process of assembly and disassembly (Waksmunski, 1996). This will not eliminate someone from tampering with an EDI document and keeping its structure sound. However, it can help detect tampering when the standards are violated or the transmission compromises the integrity of the documents.

The X12 standard allows for inclusion of references for information such as user identification and passwords and sender/receiver authentication (Waksmunski, 1996). This control might prove ineffective unless trading partners employ it in conjunction with encryption or secure communications.

SECURE EDI APPLICATION EXAMPLES

Organizations are reluctant to share information about security because it can lead to a breach of security. The following examples provide some insights into steps organizations take to protect EDI transactions.

Navy Exchange Service Command (NEXCOM)

The description of the NEXCOM EDI implementation is a summary of information presented in Dennis Waksmunski's (1996) paper on EDI security at NEXCOM. NEXCOM manages a retail operation with over 400 selling locations worldwide. The retail outlets include small, medium, and large general merchandise stores, auto service centers, mini-marts, gas stations, and other retail outlets that together have sales over \$2 billion. Nearly 200 suppliers receive purchase orders daily via EDI. In the early stages of EDI implementation NEXCOM was already realizing over \$250,000 in annual savings from reduced document handling costs and improved order cycle times, and anticipated annual savings in the millions of dollars when its EDI system became fully operational.

The NEXCOM implementation plan calls for the automatic movement of data between internal business application systems and the software that translates data to and from EDI formats. NEXCOM uses a trusted VAN service provider for its communications services and data repository services. The VAN helps provide technical assistance to NEXCOM's trading partners and ensures that data sent by EDI maintains its integrity.

Its trading partners must agree in writing to terms and conditions that include a statement of responsibility, accountability, and liability. The agreement specifies that suppliers

1. must retrieve purchase orders from the VAN;
2. transmit functional acknowledgments within 48 hours of NEXCOM's transmission date;
3. not put merchandise on backorder;
4. not substitute other merchandise; and
5. not deviate from the purchase order.

NEXCOM designates one system as the primary computer for interfacing with the automated business systems. The system is fully redundant, and automatically switches to a mirror backup system if it fails. NEXCOM

still supports a facsimile system for trading partners who are not EDI-capable, and trading partners can use that system as a backup to the EDI system. NEXCOM believes that it has implemented appropriate security measures to protect its EDI data.

Mayo Clinic

Threlkel and Kavan (1999) describe the EDI experiences of the Minnesota-based Mayo Clinic. The Mayo Clinic uses Internet-based EDI for ANSI X12 claim and payment transaction sets, and submits about 85% of patient claims via EDI to its trading partners who are responsible for payment. Mayo Clinic uses FTP in conjunction with Pretty Good Privacy (PGP) software to encrypt the data and uses several communications mechanisms to support EDI: the public Internet, a private healthcare network, and VPNs.

The electronic commerce specialist for the Mayo Clinic indicated that the implementation addressed four security objectives: privacy (access control), authentication, non-repudiation, and data integrity. The encryption scheme helps limit the consequences of transmission interceptions so data remain private. The transmissions include digital signatures for authentication. The Clinic's EDI process uses hash totals to address data integrity. Trading partners respond to the Clinic's transmissions with acknowledgment transactions, closing the loop for the transaction process, and providing nonrepudiation.

Mayo Clinic decided not to use Web-based EDI because there are a high number of payers (over 5000) and each Web site has a different look and feel and different user identification and passwords. Using the Web-based EDI approach, Mayo Clinic employees would have had to become familiar with the Web interface offered by its many payers. The electronic commerce specialist for the Clinic believes that Internet-based EDI has reduced communication costs and the security measures implemented protect the data appropriately. The Health Insurance Portability and Accountability Act requires healthcare organizations to protect patients' privacy and specifies organizations must meet security requirements by April 2005.

Bank of America (BA)

Lankford and Johnson (2000) provide the following account of Bank of America's Internet-based EDI system with Lawrence Livermore National Labs (LLNL). LLNL sends payment information to BA via the Internet, and BA executes the payments to LLNL's vendors. The secure payment process takes minutes.

The process begins with LLNL extracting accounts payable information and translating it into payment orders that use the X12 standard 820 format. The EDI-formatted payment orders are routed through the secure Internet server where they are encoded in MIME format and encrypted using privacy-enhanced mail (PEM). LLNL sends the encrypted messages to the BA server. The firewall software on the BA server authenticates the access privileges contained in the messages, and then the secure Internet EDI server decrypts the messages and authenticates the digital signatures applied by LLNL. The secure Internet EDI server checks authenticated messages to ensure that they are consistent with the X12 standard.

The system creates an acknowledgment for validated messages, then encrypts the acknowledgment and sends it to LLNL using PEM/MIME. The BA Electronic Commerce System translator translates valid messages into BA-readable payment orders. The BA system performs additional edits to ensure that payment orders have the required data to execute a payment instruction. BA debits LLNL's account and credits the trading vendors' accounts. This system includes authentication mechanisms to prevent fabrication. The use of acknowledgments helps ensure nonrepudiation and can help detect interruption. The system reduces the risk of interception or modification by encrypting data.

GUIDELINES FOR MANAGING EDI SYSTEMS RISKS

Organizations may not realize the benefits of EDI if someone compromises their data or systems. By its very nature, EDI involves movement of data past organizational boundaries. Organizations need to ensure that their data remain secure throughout the EDI process. Electronic transactions create an opportunity for fraud because there is little or no human intervention in processing some transactions. Waksmunski (1996) mentions a supplier that intentionally submitted multiple electronic invoices for the same shipment using different invoice numbers each time. Systems risk concerns the extent to which systems have protection against loss or damage (Straub & Welke, 1998). All computer systems have some risks, but there are several risks common to EDI systems. Security experts recommend four sequential activities in security programs to decrease systems risk: deterrence, prevention, detection, and remedy (Straub & Welke, 1998).

Organizations can take actions to deter potential systems abusers by developing guidelines for proper use, educating users and managers of security benefits, and punishing abusers for their actions (Straub & Welke, 1998). For EDI systems, this might include the development of policies that limit access to EDI systems, and educating users about the security mechanisms (discussed previously in this chapter) for EDI systems.

The second activity in reducing systems risk is prevention. Organizations should establish good business relationships with trusted trading partners before they implement EDI systems. A written agreement should spell out the responsibility, accountability, and liability of each party. VAN service providers can help provide EDI security, but there should also be agreements with VANs and other vendors specifying their roles in securing EDI. Companies can employ EDI security mechanisms (access control, authentication, nonrepudiation, and data integrity) to prevent improper use of EDI systems. The use of hashing techniques, digital signatures, or certificates can prevent modified or fabricated transactions from being completed.

The third step in reducing EDI systems risks is to establish procedures for detecting misuses. Maintaining an auditable history of EDI transactions provides a tool to assist in detection. A company could use an audit trail reactively to document a security breach, or proactively

as part of a system audit or for generating a suspicious activity report (Straub & Welke, 1998).

The final component of effective EDI system security is to remedy the effects of a misuse and to penalize the offender (Straub & Welke, 1998). Since EDI involves business-to-business transactions, one possible punishment would be to reduce the amount of business with that trading partner. That might also serve as an effective deterrent for other trading partners. Two planning tools that organizations can use to develop appropriate EDI security programs are to establish security requirements by data class and to assess system risks.

Establish Security Requirements by Data Class

Not all data have the same security requirements. Organizations need to implement security measures appropriate for the value of the data (Humphreys, 1995). The security program should identify classes of data and develop security requirements based on those classes (Cullinane, 1998). In developing classes of data, organizations need to consider the potential consequences if data are compromised (Cullinane, 1998). The amount of information someone could learn from a single transaction could be very small if the transaction were merely an acknowledgment of another transaction, or could be somewhat greater if the transaction were a shipping schedule. Even if someone were to access and translate the transaction, one might not be able to use the information obtained from such a transaction. If the transaction involved a shipping schedule for weapons, there could be more severe consequences if someone were to use the information to intercept the shipment. The risks may vary by industry and type of transaction (Cullinane, 1998), and there may be industry-wide controls available for these risks (Straub & Welke, 1998).

Assess Risks

The security program should also assess the potential risks and vulnerabilities in deciding on the appropriate EDI approach (Cullinane, 1998). Potential risk factors include the nature of the company, the type of technology used for EDI, and employees. Certain organizations may be popular targets because of their size, the nature of the business, political reasons, or other reasons.

Companies must consider the risks inherent in the various technologies used for EDI. Internet-based EDI (or XML) systems need to use firewalls to prevent hackers and denial of service attacks on the server. They should also use some form of encryption or secure protocol to protect the data in transit. For example, a company could use secure HTTP in conjunction with XML exchanges.

Organizations should not overlook the potential for risks internally. Appropriate administrative controls should limit users based on individual responsibilities (Waksmunski, 1996). Audit trails can help identify the culprit if there is fraud. Refer to the following chapters for additional information on risks and security policy: "Risk Assessment and Risk Management" and "Security Policy Guidelines."

CONCLUSIONS AND RECOMMENDATIONS

EDI is one of the oldest forms of electronic commerce. Companies have realized many benefits from EDI including reduced transaction costs and support for various business strategies. The use of the Internet reduces the cost of EDI further and makes it affordable even for small companies. The availability and use of affordable and effective security features will result in the long-term success of EDI (Humphreys, 1995).

Internet-based EDI introduces new threats to EDI, but solutions are available to organizations that address security in their implementation of EDI. Organizations need to consider the value of the data sent via EDI and assess the risks of data compromise. EDI security mechanisms include access control, authentication, nonrepudiation, data integrity, and auditable history. It is possible to achieve the business benefits of EDI using cost-effective, secure solutions.

GLOSSARY

DISA (Data Interchange Standards Association) The organization responsible for the development of EDI standards in the United States.

ebXML (Electronic Business XML) An extension to XML designed to accommodate electronic business.

EDI (Electronic Data Interchange) The computer-to-computer exchange of business transactions in standardized formats.

EDIFACT A set of standard formats for EDI transactions developed by a committee from the United Nations.

Internet-Based EDI The use of the Internet as the communications mechanism for electronic data interchange.

IOIS (Interorganizational Information System) An automated information system that involves information sharing between two organizations.

VAN (Value-Added Network) A company that provides a network and various other services for EDI.

X12 A set of standard formats for EDI transactions developed by the American National Standards Institute (ANSI).

XML (Extensible Markup Language) A Web data language designed for representing data structures and data values.

INTRODUCTION

Throughout the ages, from ancient times to the present day, money has played a very important role in the ordinary business of the life of different people. Money can be best defined as “anything that is widely used for making payment and accounting for debts and credits” (Davies, 2002). All sorts of things have been used as money at different times in the history of mankind including amber, beads, cowries, drums, eggs, feathers, gongs, hoes, ivory, jade, kettles, leather, mats, nails, oxen, pigs, quartz, rice, salt, thimbles, umiacs, vodka, wampum, yarns, and zapozats (decorated axes) (Davies, 2002). In recent times, we are witnessing the emergence of more intangible form of money, namely, electronic money. In fact, although much of the money used by individuals in their day-to-day transactions is still in the form of notes and coins, its quantity is miniscule compared to the intangible electronic money that exists only as records in the books of financial institutions. With the progression of technology we can envision a society, in the not too distant future, where physical money in the form of notes and coins will become as obsolete as amber and beads and cowry shells.

In this chapter, we will look at electronic payment systems. These systems enable the payment for goods and services over a computer network using some form of electronic money. We begin by identifying the requirements for such systems. We observe that the major technical challenge for developing such a system is ensuring its security. We discuss the different types of electronic payment schemes available to us, identifying, in the process, any special security requirement of each system. However, we do not cover the different technologies used to provide security services. These are covered elsewhere in this book. Interested readers are directed to Volume I, Parts 1 (Key Concepts and Applications Related to Information Security) and 3 (Standards and Protocols for Secure Information Transfer), and to Volume II, Part 3 (Foundations

of Information, Computer and Network Security). We discuss some of the more important commercial products available today. Finally, we conclude by providing pointers to some of the resources available today to learn more about electronic payment systems.

REQUIREMENTS FOR ELECTRONIC PAYMENT SYSTEMS

Electronic payment systems have more or less the same set of requirements as traditional paper-based systems. The difference is that owing to the unique nature of electronic payment transactions, these requirements impose different types of challenges on the payment system design. Security is of paramount importance in electronic payment systems, more so probably than in traditional paper-based system. The reasons for this are numerous. First, a major portion of these transactions is carried out over open networks, which are rather easy to eavesdrop on even with a limited amount of resources. Thus, confidential financial information may no longer remain confidential if adequate protection mechanisms are not implemented. Second, since the transacting parties can remain faceless, it is quite easy to forge identities of end users and systems in the Internet. Anybody can masquerade as somebody else and continue on a transaction with impunity. Gathering evidence of a crime is also more difficult. Third, electronic payments are often carried out over an inherently unreliable medium. This implies that messages exchanged for execution of the transaction can be corrupted or altered during transit, resulting in unforeseen results. Last, but not the least, electronic payment transactions can span both geographical and judicial boundaries. Whereas this is also possible for traditional payment transactions, the implications for electronic payments are different. It is more difficult to identify a felon in an electronic payment crime and bring her/him to justice.

We begin by summarizing the requirements (from computer security perspective) for electronic payment systems in general and identifying the differences in challenges they impose for the design of the system. Later, as we discuss different types of payment systems, we identify the specific challenges for each system.

Need to Ensure Integrity for Payer, Payee, and Payment System

This is the first major rule of thumb in designing any payment systems. There is need to ensure that (i) nothing happens without authorization, and (ii) nothing happens without generating sufficient pieces of evidence. Moreover, technical and legal procedures for dispute handling should be made part of the system.

Ensuring proper authorization by itself is not a very large challenge. All that is needed is a provision for signatures, maybe notarized, at the right place for the authorization to be recorded. This needs to be accompanied by proper identification of the signatory and correct association of the signature to the signatory. Techniques for authentication and authorization are discussed in more details in Volume III, Part 2 of this book (Prevention: Keeping the Hackers and Crackers at Bay). However, in the context of electronic payment systems, authentication and authorization are more easily said than done. To begin with, although a digital counterpart of traditional signatures has been available for some time, some with nonforgeability properties even stronger than those of traditional signatures, the technology and infrastructure for these are not yet widely available. Many communities have yet to establish laws that recognize the validity of such digital signatures. Compounding the problem is the technical difficulty associated with identifying and authenticating the signatory. Users of computer systems remain faceless throughout a transaction. Thus, although it is easy to authenticate the process employed in the transaction, it is extremely difficult to associate the process with a real-life entity. This implies that it is quite easy for the digital signatory of a document to refute a signature later.

Generating sufficient pieces of evidence for electronic payments is also considerably difficult. This requires a proper audit trail of a transaction to be maintained at all times during the entire transaction life cycle and until such time as it is no longer needed. In addition, we must ensure that such audit trails are not tampered with after generation. This is quite difficult to ensure specially if we impose the requirement that such audit trails and other associated information may often need to be transmitted over open, unreliable networks. With currently available technology, it is not possible to prevent the tampering of audit trails completely. We must accept that there will be times when such tampering occurs. Obviously, this creates a number of technical challenges when disputes need to be handled based on audit trail data. Thus, in the event of audit trail tampering, we should be able to detect and prove the tampering. Further, we should have proper contingency plans for such eventuality. Although the technology for performing these individually has been available for many years, an integrated mechanism that

incorporates the individual technologies into a cohesive framework that is also supported by proper legal and procedural methodologies is still not widely available.

Privacy for Payer and Payee

The requirement for ensuring payer and payee privacy arises in much the same way in electronic payment systems as in traditional payment systems. Users of the electronic payment system need the assurance that their financial information remains confidential throughout the transaction, that only such information that the user deems needed to be revealed is actually revealed. Further, the user needs the assurance that the piece of confidential information revealed is not misused by the recipient. Each of these requirements is extremely difficult to ensure in the electronic world.

To begin with, many electronic payment transactions are carried over open networks like the Internet. Such networks are susceptible to eavesdropping. Thus, if appropriate precautions are not adopted, any transmitted financial information is available to whoever is eavesdropping. The solution to this problem is to encrypt the information in an appropriate manner before transmission. Many people believe that proper encryption is the panacea of all confidentiality problems. This, however, is not really the case. To begin with, we need to remember that a brute force approach can always, in principle, break the strongest of currently available encryption technology. This is assuming that there is no hidden trapdoor in the encryption algorithm that makes the technique vulnerable. We can take some solace from the fact that such brute force approach is beyond the technical and physical capabilities of even the most powerful, however, we should realize that it is extremely difficult to prove formally that an encryption algorithm is strong. In fact, there is no theory that guarantees the strength for any conventional cryptographic system. Traditionally, encryption systems have been considered strong when they have been used and tested for a reasonably long period of time without anybody knowing how to break them efficiently, in a practical and practicable manner. Such testing can prove weakness of a particular scheme for a given level of effort; this cannot prove that there is no simpler approach to breaking the scheme. In addition, encryption technology is sometimes implemented incorrectly just like buggy software. Thus, there can be loopholes in the software that performs the encryption operation that can be exploited to breach confidentiality. Ensuring that encryption software is foolproof is not an easy task.

Assuming that we can protect confidential information from prying eyes while in transit, we note that it is very difficult to ensure that confidential information is treated in a confidential manner by the recipient. For example, many of us use credit cards for purchasing services. The merchant stores such credit card numbers electronically in its computer system. However, there is no guarantee that the merchant's computer systems are adequately protected. Although this is also the case for traditional financial transactions, we at least know to whom we are revealing confidential information. In the electronic world, the end parties are faceless. We may easily be led

to believe that we are revealing information to trusted parties when we are not. In addition, we do not know whether the recipient handles the information in the appropriate manner.

A related problem is how to ensure the anonymity of the user of the electronic payment system. A user may want that not only its financial information remain confidential but also that it remain anonymous in the transaction. If a user is using traditional cash in a transaction, the user remains anonymous. It is not possible to link a transaction that has been paid for by traditional cash to a particular customer. It is also not possible to derive any personal information about the customer from this transaction. In the electronic world, this is more difficult to achieve. Part of the reason is that every message used in the transaction can be traced to a source address. Complex cryptographic protocols for achieving such anonymity or unlinkability are needed. At the same time allowing anonymity creates additional problems, namely in the way of ensuring authenticity, proper authorization, and *fair exchange*.

Fair Exchange

In the classical business environment, a transaction essentially involves fulfillment of some obligation by two parties; a contract describes the penalties if either party fails to meet its obligation. Since each transacting party has an identifiable place of doing business, if any party behaves unfairly, that party can be physically approached and held accountable for its unfair behavior. In the electronic world, on the other hand, a party does not always have a physically identifiable place of doing business. After behaving unfairly in the electronic transaction, a party can simply vanish without a trace. In such cases, it may be next to impossible to enforce the penalties of the contract, leading to losses for the other party. For example, let a customer buy a product from a merchant. The customer pays for the product in some electronic manner. However, once the merchant receives the payment the merchant never delivers the product. This causes financial loss for the customer. Thus, any electronic payment scheme must ensure that at the end of the protocol execution, each transacting party receives the other's product or none does. This is often referred to as the problem of fair exchange and is quite difficult to achieve particularly if this needs to be accompanied by anonymity for the payer or the payee.

In summary, it is fair to say that though electronic payment systems make it easier to perform commercial transactions over the Internet, there are a number of challenges remaining to make the scheme successful. In the following, we discuss some of the different types of electronic payment systems available today. We discuss some of the unique challenges to each scheme.

TYPES OF ELECTRONIC PAYMENT SYSTEMS

Electronic payment systems broadly use one of three different forms of electronic money: (i) token money, (ii) notational money, or (iii) hybrid money.

Token money is similar to real cash. It is used in a token-based or cash-like system. Transactions that have a certain value are performed with token money, and must be brought to a central authority before consumers are able to make any transaction. These systems do not support the notion of debt. Electronic cash and electronic purse are the two major types of token money systems. Notational money is used in credit/debit systems. The system consists of having an account and a central authority keeping a record of the amount in that account. Consumers exchange documents that are equivalent to value transfers. These exchanges consist of debiting the consumer's account and crediting the merchant's account. Systems using notational money can support the concept of fiscal debt. Electronic payment orders over the Internet and credit card billing over the Internet are the two most well-known systems that use notational money. Hybrid money combines the features of both token money and notational money. Automated clearing house and electronic checks form the major system using hybrid money. In the following, we discuss each of these systems in more detail.

Electronic Cash

Electronic cash (or e-cash) (Weber, 1998) is a payment method in which a unique number or identifier is associated with a given amount of money at a financial institution. It is often suggested as an alternative method to credit cards for purchases made over the Internet. Some definitions of electronic cash are much broader, describing it as any form of "prepaid, stored value that can be used for electronic purchases" (van Slyke & Belanger, 2003). However, these systems are better categorized as electronic purse systems. The use of electronic cash requires the customer to open an account in a bank and then deposit money into this account. The bank provides the customer with a unique digital coin (essentially a unique identifier) that is used for all electronic payments.

Any electronic cash system needs to possess five characteristic if it is to be usable and universally accepted. First, it must be ensured that the electronic cash is spendable only once; that is, double spending should be prevented at all costs. This is needed to ensure that both parties involved in the transaction know that the e-cash currency being received is not counterfeit or being used in two different transactions. Second, the e-cash system must be independent of any particular proprietary storage or transmission mechanism. Third, electronic cash must be portable; it should be able to pass transparently across international borders and be automatically converted to the recipient country's currency in all forms of peer-to-peer transactions. Fourth, electronic cash must be divisible. Divisibility determines the size of payment units. Both the number of different electronic cash units and their values can be defined independently of real currency. The denominations are up to the definers and are not limited to the typical breakdowns of a traditional cash system. Fifth and last, e-cash system should be anonymous, very much like their paper world counterpart. The consumer (and sometimes the seller) should be able to use e-cash without

revealing her or his identity. However, as explained later, ensuring the last property also makes the prevention of double spending rather difficult.

Double spending can neither be detected nor prevented with truly anonymous electronic cash. Anonymous electronic cash is electronic cash that, like bills and coins, cannot be traced back to the person who spent it. To ensure anonymity or unlinkability of the customer, the payment protocol cannot associate any form of the customer's identification mark with the cash system—much in the same way as traditional cash systems. This implies that the bit string that represents electronic cash is not traceable to the customer who spends it. Since it is rather trivial to make multiple copies of the bit string representing cash, anybody can make counterfeit electronic cash, without fear of being caught and prosecuted. One way to be able to trace electronic cash (to prevent money laundering) is to attach a serial number to each electronic cash transaction. That way, cash can be positively associated with a particular consumer. This does not, however, solve the double spending problem completely. Although a single issuing bank can detect when two deposits of the same electronic cash are about to occur, it is impossible to ascertain who is at fault—the consumer or the merchant. If the duplicate electronic coins are presented to two different banks, the problem is exacerbated. Further, it is not easy to develop an electronic cash system where the cash can be traced back to its origin. Complex cryptographic algorithms are needed to create tamperproof electronic cash that can also be traced back. Electronic cash containing serial numbers additionally raises a number of privacy issues, because merchants could use the serial number to track spending habits of consumers. The whole purpose of electronic cash systems—namely the ability of a customer to remain anonymous—is lost. It is important that a procedure is available both to protect the anonymity of electronic cash users and to provide built-in safeguards to prevent double spending.

Electronic Purse or Stored-Value Card

Electronic purse, as defined by the United Kingdom Banking Code, is “any card or function of a card which contains real value in the form of electronic money which someone has paid for in advance, and which can be reloaded with further funds and which can be used for a range of purposes.” These are essentially prepaid stored-value cards. As with electronic cash systems, the consumer needs to deposit real money with the issuer of the purse. The amount of money deposited is then encoded into the card. As purchases are made using the electronic purse, the value in the card is reduced and the amount is credited to the merchant's account. The development of electronic purses has been driven almost wholly by commercial and technological organizations rather than by demand from consumers. The organizations operating electronic purse systems gain from the use of the money stored on the cards. For banks, there are advantages in reducing the handling of cash and checks, which must be transported securely and are labor intensive to handle. For the retailer, the advantages are the reduction in handling of currency and checks. This includes reducing the delay in money being credited to

the retailer's bank account. Another advantage is reducing the risk of theft.

A stored-value card can be as elaborate as a smart card or as simple as a plastic card with a magnetic strip. One of the most common stored-value cards is a prepaid phone, copy, subway, or bus card. These cards can be recharged with more value by inserting them into special machines, inserting currency into the machine, and withdrawing the card. Unlike smart cards, magnetic strip cards are passive. That is, they cannot send information such as a customer's digital certificate, nor can they receive and automatically increment or decrement the value of cash stored on the card. Smart card evolved from magnetic strip cards. Instead of encoding and storing data using magnetic strip, a computer microchip is embedded on the card itself containing information about the owner such as financial facts, private encryption keys, account information, credit card numbers, and so on. Like magnetic strip cards, smart cards can be used online and offline. Smart cards are better suited for Internet payment transactions because they have more processing capability than the magnetic stripe cards.

Electronic purses have gradually become one of the most widely used electronic payment systems for consumers. The advantages include ease of use, ability to pay the exact amount without fiddling for change, no authorization requirement, and the possibility of depositing additional value as and when required. However, a major disadvantage from the consumer's point of view is that the purse is as good as real money. If it is lost or stolen, the consumer loses. To protect against such losses, smart card technology that allows units of credit to be reloaded is now being more widely used.

Electronic Wallets

Today's online shoppers have begun to tire of repeatedly entering details about shipping and payment information each time they make an online purchase. Research has shown that filing out forms rank high on online customer's list of grievances about online shopping. Electronic wallet technology is intended to solve this problem. At the same time, an electronic wallet provides a secure storage place for credit card data and electronic cash. In short, an electronic wallet (or e-wallet) serves a function similar to a physical wallet; it holds credit cards, electronic cash, owner identification, and owner contact information and provides that information at an electronic commerce site's checkout counter. Occasionally, an e-wallet may contain an address book. Some wallets also hold an encrypted digital certificate, which securely identifies the wallet's owner. E-wallets make shopping more efficient. An e-wallet simplifies the online checkout process. A simple click inserts the e-wallet information into the payment forms on the merchant's site. E-wallets can also provide many additional services. They can keep track of the owner's purchases by saving receipts. An enhanced digital wallet can even suggest where a consumer may find the best price on an item that he or she purchases on a regular basis.

E-wallets are of two types based on where they are stored. A client-side e-wallet stores a consumer's information on the consumer's own computer. This shifts the

Figure 1: Payment using electronic check.

responsibility for ensuring the e-wallet’s security to the end user. This can be regarded as both an advantage and a disadvantage. It is an advantage because the user has more control in keeping the e-wallet securely; it is a disadvantage because users may not always take appropriate measures. Many of early e-wallets were client-side wallets and required lengthy downloads, which was one of their chief disadvantages. Another disadvantage of client-side e-wallet is that they are not portable. They are not available when the owner is making a purchase at a location other than the computer on which the wallet resides. A server-side electronic wallet alleviates this problem; it stores a customer’s information on a remote server belonging to a particular merchant or belonging to the wallet’s publisher. The main weakness of server-side e-wallet is that a server-side security breach could reveal personal information for thousands of users. Server-side e-wallet systems typically employ strong security measures that minimize or eliminate the possibility of unauthorized disclosure.

For a wallet to be useful at many online sites, it should be able to populate the data fields in any merchant’s form at any site that the customer visits. This accessibility means that the e-wallet manufacturer and merchants from many sites must coordinate their efforts so that a wallet can recognize what consumer information goes into each of a given merchant’s form.

Electronic Check

Electronic checks are a comparatively new and still emerging technology that combines high security, speed, convenience, and processing efficiencies for online transactions. They are based on the premise that electronic documents can be substituted for paper, and public-key cryptography-based digital signatures can replace handwritten signatures. Thus, the attraction is that electronic checks can replace paper checks without the need to create a new payment instrument together with the implied

legal, regulatory, and commercial practice changes. The technology promises several advantages. It leverages the time-tested paper-based check payment system and uses the same legal and business protocols. It works like a paper check but in a pure electronic form with all the associated efficiency. It can be used by all bank customers who have check-signing privileges. Last but not the least it includes enhanced security features that allow automatic verification of content and validity, thereby helping to reduce check fraud.

Electronic checks work the same way as a traditional paper check does (see Figure 1). The steps involved in an electronic check processing can be summarized as follows:

1. The payer retrieves an electronic check from an “electronic checkbook” and fills in the check just as he/she would fill in a paper check.
2. The payer digitally signs the check and includes any necessary certificates with the check.
3. The payer then gives the electronic check to the payee using one of several secure electronic means (for example, through secure e-mail or over secure Web connections).
4. The payee endorses the electronic check by putting its digital signature on the check.
5. The payee then electronically deposits the endorsed check in the payee’s bank and receives credit.
6. The payee’s bank submits the electronic check to the paying bank for clearing.
7. The paying bank validates the electronic check and then charges the payer’s account for the check.

Automated Clearing House

The automated clearing house (ACH) system was developed in the United States in the 1970s by the banking industry in an effort to allow automatic fund transfer by

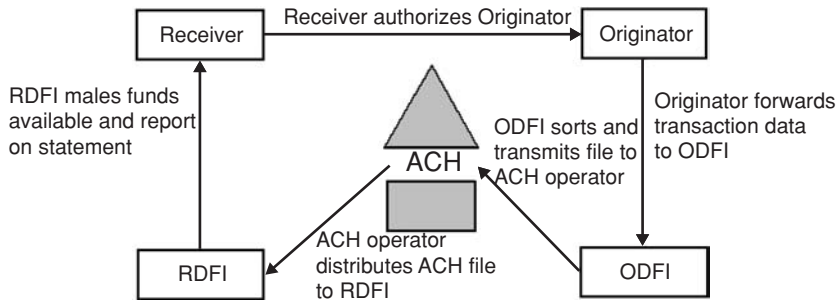

Figure 2: Automated clearing house operations. The ACH operations figure is courtesy of NACHA, the Electronic Payments Association, available from the NACHA Web site (http://www.nacha.org/About/what_is_ach_.htm).

replacing the paper check. The ACH system supports both debit and credit transactions. ACH payments include direct deposit of payroll, social security, and other government benefits tax refunds; direct payment of consumer bills such as mortgages, loans, utility bills, and insurance premiums; business-to-business payments, e-checks, and e-commerce payments.

The ACH system is a batch processing store-and-forward system. Transactions received by the financial institution during the day are stored and processed later in batch mode. ACH transactions are accumulated and sorted by destination for transmission. Typically, five participants are involved in an automated clearing house transaction (see Figure 2):

1. The originating company or individual (originator) initiates a fund transfer from its account.
2. The originating depository financial institution (ODFI) receives a payment instruction from an originator and forwards it to the ACH operator.
3. The receiving depository financial institution (RDFI) receives ACH entries from the ACH operator and posts the entries to the accounts of receivers.
4. The receiving company, employee, or customer (receiver) authorizes an originator to initiate an ACH entry into the receiver's account with the RDFI.
5. The ACH operator is the central clearing facility to or from which participating depository financial institutions transmit or receive ACH entries.

Electronic Bill Presentment and Payment Systems

These systems allow companies to bill customers for their services and in turn receive payments from them electronically over the Internet. There are two types of presentment models:

1. *Direct model:* A company (that is, a seller of a service) delivers the bill to customers (buyers of services) via either the company's own site (seller-direct model) or the customer's site (buyer-direct model).
2. *Consolidator model:* Bills from multiple issuers are delivered to a single site to be presented later in aggregate to the consumer for payment. A consolidator acts as an intermediary, collecting or aggregating invoices from multiple sellers for multiple consumers. Consolidators are generally third parties who may additionally provide a variety of financial services such as escrow, insurance, and credit ratings.

The following steps are involved in systems based on the direct model:

1. *Enrollment:* For seller-direct model the consumer enrolls in the company's bill-processing system using a standard Web interface. For buyer-direct model, the seller enrolls in the customer's Web site that has been set up for this purpose. The site at which bill information is exchanged is henceforth called the bill processor.
2. *Presentment:* This occurs in the following steps:
 - a. The seller generates and/or transfers the invoice information to the bill processor.
 - b. The consumer is informed that a bill is ready.
 - c. The consumer accesses the bill-processing site to review and analyze the invoice information.
3. *Dispute handling:* The consumer may optionally dispute a bill. To do this the consumer contacts the seller for review of the bill.
4. *Payment:* This occurs in the following steps:
 - a. The consumer authorizes either full or partial payment for the bill.
 - b. If it is the seller-direct model, then the seller's financial institution processes the payment transaction; otherwise, the buyer's financial institution processes the transaction.
 - c. The appropriate financial institution confirms payment execution—credit to account for seller-direct model and debit from account for buyer-direct model.
 - d. The respective financial institution reports payment return or rejection information.

The consolidator model is very similar to the direct models. The differences are as follows:

1. *Enrollment:* Both the seller and the buyer must register at the consolidator's bill-processing system.
2. *Presentment and dispute handling:* These steps are done using the consolidator as the intermediary.
3. *Payment:* The following steps are performed:
 - a. The consolidator initiates the payment and reports the activity to the buyer and the seller.
 - b. The payment transaction is processed by either the buyer's or the seller's financial institution. Sometimes the consolidator assumes the role of a financial institution.
 - c. The financial institutions confirm execution of the payment.

- d. Payment return or rejection information may be reported to both buyer and seller by their respective financial institution.

Electronic bill or invoice presentment and payment systems are gaining considerable popularity between both buyers and sellers. The major reason is that these are much faster and efficient than traditional systems. The advantage of the consolidator model over the direct model is that in this model both the seller and the buyer reduce the number of bill-processing sites each must interact with. The disadvantage is that each may have to pay a fee to the consolidator to avail of its services.

Credit Card-Based Systems

Credit cards are by far the most popular form of online payments for consumers. Credit cards are widely accepted by merchants around the world. Credit cards offer a number of benefits for both the consumer and the merchant. A consumer is protected by a grace period in which he or she can dispute a credit card purchase. A merchant has a high degree of confidence that a credit card can be safely accepted from an unknown and not trusted purchaser. Paying for online purchases with a credit card is just as easy as in a conventional purchase from a store. Merchants who already accept credit cards in an offline store can accept them immediately for online payment because they already have a merchant credit card account. Online purchases require an extra degree of security. This is because a credit card holder is not present and cannot be identified as easily as he or she can be when standing at the cash register. Online credit card services must somehow authenticate the purchaser as well as protect sensitive information as it is transmitted on the Internet.

A credit card, such as that offered by Visa or MasterCard, has a preset spending limit based on the user's credit limit; the credit limit is determined by the customer's credit history, income level, and total wealth. The limit ranges from few hundred dollars to several thousand dollars. The user uses these cards to purchase goods and services or obtain cash from the participating financial institutions. The user is required to pay his or her debt during the payment period. He or she can pay off the entire credit balance or pay a minimum amount each billing period. Credit card issuers charge interest on any unpaid balance. A *charge card*, such as one from American Express, is similar to a credit card except that it does not carry preset spending limit, and the entire amount charged to the card is due at the end of the billing period. Charge cards do not involve lines of credit and do not accumulate interest charges. The distinction between credit cards and charge cards is unimportant in the discussion of processing credit and charge cards for electronic payment; the collective term *credit card* is used here to refer to both types.

Payment using credit cards generally involves one or more financial institutions for the processing of payment information. For some credit card systems, banks and other financial institutions serve as a broker between card users and the merchants accepting the cards. These types of arrangements are called closed loop systems because no other institution (local bank, national bank, or other

clearinghouse) is involved in the transaction. American Express¹ and Discover Card are examples of closed loop systems because there is exactly one franchise for each of those systems. Open loop systems can involve three or more parties. Besides the customer's and the merchant's banks, a third party, called an acquiring bank, is involved. The acquiring bank passes authorization requests from merchant's bank to the customer's bank to obtain authorization for the credit purchase from the customer's bank. A response is sent back to the acquiring bank and onto the merchant. Similarly, the acquiring bank is responsible for contacting the merchant's bank and the many customers' banks to process sales drafts. The merchant's bank usually plays the role of the acquiring bank. Systems using Visa or MasterCard are the most visible examples of open loop systems because many banks issue both cards. Unlike American Express or Discover, neither Visa nor MasterCard issue cards directly to consumers. Member banks are responsible for handling all the details of establishing customer credit limits. For this discussion, we will assume that there are four players involved in a payment-card transaction: the customer that uses a credit card, the merchant that accepts a credit card toward a payment, the acquiring bank, and the issuing bank.

The following steps are involved in credit card processing:

1. The customer provides the credit card information to the merchant using a secure online communication channel. The communication channel needs to be previously established between the customer and the merchant and needs to provide such security services as authentication, confidentiality, and integrity.
2. The merchant processes the credit card using software provided by the acquiring bank. The software enables the merchant to submit electronically the credit card information to the acquiring bank. Usually the merchant submits the information via a dedicated communication channel to the acquiring bank.
3. The acquiring bank sends an authorizing request to the issuing bank authorizing payment for the particular charge incurred by the customer. This request is typically sent over a protected financial services network.
4. The issuing bank either approves or declines the charge. If the charge is approved, the issuing bank puts a hold on the customer's account for the funds needed to satisfy the current charge and forwards an approval code to the acquiring bank. If it is declined the acquiring bank is notified as such.
5. The acquiring bank sends the transaction (either the approval code or the decline information) back to the merchant.
6. The merchant completes the payment transaction.

Credit cards have several features that make them an attractive and popular choice with both consumers and merchants in online and offline transactions. For merchants, credit cards provide fraud protection. When a

¹ As of the time of this article going to the press. American Express is no longer considered an example of a closed loop system.

merchant accepts credit cards for online payment, he or she can authenticate and authorize purchases using a credit card-processing network. For consumers, credit cards are advantageous because various consumer credit protection acts limit the cardholder's liability to small amounts if a card is used fraudulently.

The largest advantage of using credit cards is their worldwide acceptance. A user can pay for goods with credit cards anywhere in the world, and the currency conversion, if needed, is handled by the card issuer. For online transactions, credit cards are particularly advantageous. When a consumer reaches the electronic checkout, he or she enters the credit card's number and his or her shipping and billing information in the appropriate fields to complete the transaction. The consumer does not need any special hardware or software to complete the transaction.

Credit cards have very few disadvantages; they do have one when compared to cash. Credit card service companies charge merchants per-transaction fees and monthly processing fees. For example, MasterCard charges \$0.29 plus 2% of transaction value for each transaction. This is besides any fee that the acquiring bank may charge the merchant. Thus, credit card transactions are quite expensive. However, online (and offline) merchants view them as a cost of doing business. Any merchant who does not accept credit cards for purchases is probably losing significant sales because of it. In addition, credit cards typically provide a built-in safety net for merchants as merchants have a higher degree assurance that they will be paid through companies that issue credit cards. This makes credit cards generally lucrative to merchants for online payments. The consumer often does not pay any direct fees for using credit cards, but the price of goods and services are slightly higher than they would be in an environment free of credit cards altogether.

Debit Card-Based Systems

Debit cards are another form of electronic payment system that falls somewhere between credit cards and personal checks. Although they look very much like credit cards, they operate differently. Unlike credit cards, which make funds available through a financial institution, debit cards are a way to pay now and to subtract money automatically from the cardholder's bank account. There are two types of debit cards—PIN-based or online debit cards and signature-based or offline debit cards. They differ in the ways debit payments are processed.

PIN-based debit transactions are fast, convenient, and secure. It calls for customers to endorse payments by submitting a personal identification number (PIN) at the point of sale. The transaction is authorized in real time. Funds in the customer's account are set aside immediately to pay for the transaction. The money is transferred into the merchant's account in two to three business days. Merchants pay a nominal transaction fee, much lower than that for a typical credit card transaction. The fact that customers authorize charges with PINs, which are known only to them, virtually eliminates the risk to merchants of chargebacks. However, this type of debit transaction is currently available only in the physical world. This is because customers need access to a physical, discrete

PIN-entry device (the PIN pad) that must be integrated with the payment system. A number of financial institutions are introducing technologies that attempt to mimic the functionality of PIN pads. However, widely accepted operating standards have yet to be established.

Signature-based debit cards do not involve PINs. These are typically offered by credit card companies and may be used everywhere that credit cards are accepted. Merchants complete the debit sale much in the same way as credit sales. The transaction is processed through a credit card-processing network for authorization. The customer signs the sales draft that authorizes the merchant to charge the customer's account. Transactions normally settle in two to three business days. Because these transactions are processed through the same networks as credit cards, they often incur the same transaction fees for the merchant.

Electronic Fund Transfer Systems

The discussion on different types of electronic payment systems would remain incomplete without discussing electronic fund transfer (EFT) systems. An EFT transaction provides for electronic payment and collection. It transfers funds initiated through an electronic terminal, telephone, computer, or magnetic tape that instructs a financial institution to either credit or debit a consumer's asset account. The term EFT itself does not refer to a specific product. Rather, it is a descriptor that defines payment vehicles that use electronic networks to conduct a transaction. Historically the core of consumer EFT networks has been the automated teller machine (ATM) and associated access cards. Currently, an EFT transaction involves payment processing through one or more of the electronic payment systems discussed earlier. The following are the most common EFT systems:

1. *Automated teller machines or 24-hour tellers:* These electronic terminals let a customer perform banking almost any time. Services offered through these computer systems, though limited, are quite comprehensive. Customers can withdraw cash, make deposits, query account balances, or transfer funds between accounts at the same bank. The customer initiates the transaction by inserting an ATM card and entering a PIN. The ATM card is encoded with the customer's account information on a magnetic strip. This information is transmitted to the bank's central computer by modem. After proper authentication, the bank's central computer allows the ATM to complete the transaction. Banks have formed global networks so that a customer of one bank can use an ATM of another. Often ATM networks are also connected to credit card- and debit card-processing networks. In these cases, the ATM machine allows a customer to use a credit or debit card; however, the customer is limited to withdrawing cash only. Such transactions are processed as typical credit card or debit card transactions.
2. *Direct deposit:* This lets the customer authorize specific deposits such as paychecks, stock dividends, and pensions to the customer's bank account either on a regular basis or on an ad hoc basis. It also allows the customer

to preauthorize direct withdrawals so that recurring bills such as insurance premiums, mortgages, and utility bills are paid automatically. By completing a standard enrollment form, a customer authorizes a company or organization to make a credit payment to or a debit payment from one or more of his accounts. The actual transaction is then processed over the ACH system as an ACH transaction.

3. *Pay-by-phone systems*: These systems let a customer call his or her financial institution with instructions to pay certain bills or to transfer funds between accounts. The customer must have a previous agreement with the bank for such transactions. Usually these transactions are limited to within the customer's bank only. That is, the customer cannot use a pay-by-phone system to transfer money to a different bank's accounts. For services such as bill-pay, the bank uses a system such as ACH to complete the transaction. To use pay-by-phone, the customer dials a special phone number on a touch-tone phone to access the central computer of the bank. After proper authentication of the customer, usually through a PIN, the computer allows the customer to proceed with the rest of the transaction. Pay-by-phone systems typically offer a limited number of services. Moreover, these systems are not very secure, which is due to the inherent vulnerability of the public telephone network. The popularity of these systems is gradually waning and being replaced by personal computer banking.
4. *Personal computer banking*: This allows the customer to handle many banking transactions over the Internet via a remote computer. The system works very much like pay-by-phone systems. The customer uses a computer to connect to the central computer of his or her bank. After proper authentication, the customer is allowed to view account balances, request transfer between accounts, and pay bills electronically. Bill payment is processed offline as ACH transactions. The ability to use strong cryptographic techniques makes these systems more secure than pay-by-phone systems.
5. *Electronic check conversion*: This system converts a paper check into an electronic payment at the point of sale or elsewhere, such as when a company receives the customer's check in the mail. Electronic check conversion links two existing technologies—a magnetic ink character recognition (MICR) scanner and the ACH network. The paper check is processed through a MICR scanner to capture the check number, the number that identifies the customer's bank, and the customer's account number. The information is used to make a one-time electronic payment from the customer's account. The check itself is not the method of payment. This means that the canceled check is not returned to the customer with his or her account statement.

1995) began as an offline direct cash-like scheme that guaranteed customer anonymity. The CAFE project ended in mid-1997, but continued in the follow-up project OPERA. The partners in OPERA, i.e., banks that support CAFE, are continuing the trial of and improving the CAFE system. About 13 partners from several European countries are involved, DigiCash and Siemens among them. The system is designed for use in shops rather than over the Internet. In a way it is the offline, portable version of the DigiCash eCash system, and is based on the system proposed by the brand's cash. The protocol has been disclosed for public review. The important feature of CAFE is the multiparty security. No mutual trust between parties of conflicting interest is assumed.

CAFE is an open secure system. It supports multiple issuers of electronic value and multiple currencies, including currency exchange during a payment. It provides the customer with a history log of their payments. The system uses public key signature and encryption and allows for offline purchase transactions. The basic purchase transaction mode is anonymous and untraceable for the customer and is performed offline; there is no need to connect to a third party online. Withdrawals and deposits are identified, traceable, and online. If payments exceeding a certain level must be confirmed, then some online interaction becomes necessary.

CAFE provides recovery of lost, stolen, and damaged cards. Although prepaid, it is loss tolerant and allows customers to recover their money if they lose their wallet. For this, an encrypted version of all tokens issued to the customer is held in a saved place. The customer must surrender its anonymity and untraceability, then the issued token backup can be decrypted and matched against the redeemed token database. To provide some loss tolerance for stolen wallets, the customer must authenticate itself to the wallet via a pass phrase (PIN) prior to a purchase.

The device receives coins by withdrawing them from the issuer account via an ATM using the blind signature method known from eCash. CAFE is prepaid and the tokens on the device do not exist as currency anywhere else. When the customer spends money the device transmits one or more tokens to the merchant and marks them as spent on the device. Transmissions are performed contactless via infrared channels. The merchant then owns the value of those tokens, which need to be deposited with an acquirer and accepted by the issuer for that value to be realized for the merchant. Thus, the primary flow of value in CAFE is that of withdraw, pay, and deposit; i.e., the payment model is the typical direct cash-like approach.

The basic Hardware device is a pocket calculator like electronic wallet, to be used for customer payments, access to information services and also identification. It aims to be non-proprietary. The electronic wallets and smart cards, i.e. the hardware, should become standardized and be available in shops just like other electronic consumer goods. The wallet contains a so-called guardian, a smartcard with a dedicated cryptographic processor. The wallet protects the interests of the customer, the guardian protects the interests of the money issuer, and both are holding part of each token withdrawn. No transactions are possible without the cooperation of the guardian; the guardian maintains a record of all the

REPRESENTATIVE TECHNOLOGIES

Electronic Cash Systems

CAFE

The European Union project CAFE (Conditional Access for Europe) (European Community's ESPRIT Program,

tokens spent to avoid double spending. The guardian chip authorizes each payment by signing it. CAFE tokens do not remain in circulation like real cash tokens do. Respendability is broken explicitly, the wallet signs to whom it pays a token and so only that payee can deposit the token.

As fallback—when the guardian is compromised—CAFE uses so-called offline digital coins that provide a once-concealed, twice-revealed feature. The money is encrypted and the identity of the customer signed by that customer is encoded into the token number. This is done in a way that the identity of the customer can only be recovered if the customer double spends. This feature works as follows: When the customer uses a token in payment, it is challenged by the merchant to reveal a certain part of the encoded customer identity. One part on its own, however, does not reveal anything useful. If, however, the customer tries to respend the same token a part of the customer identity is revealed again to the merchant, and now with a high probability the identity of the customer can be traced. For this, the issuer must hold a database of all reimbursed tokens that it already needs for the fault tolerance feature.

As a fixed denomination token system that distinguishes between customers and merchants, CAFE needs to address the making change problem. It allows the construction of coins that can be split into smaller coins if need be and of coins that—being more expensive than their denomination—may be spent more than once. These measurements reduce the unlinkability of the payments but not their integrity. For repeated very small payments to the same merchant, so-called phone ticks, CAFE provides a special way of surrendering a token in installments.

In CAFE transactions appear atomic to the user but not to the merchant. The tokens a merchant accepts in payment must be deposited with an acquirer and accepted by the issuer before their monetary value can be realized by the merchant. The value leaves the customer, but does not immediately arrive at the merchant.

PayPal

PayPal (eBay Inc., 2002) is a very popular electronic cash payment system for consumers to pay for online purchases. Owned by eBay Inc. and touted as the world's first e-mail payment service, PayPal.com is a free service that earns a profit on the float, which is money deposited in PayPal accounts. It is currently the number one electronic cash system used by eBay auction customers. PayPal eliminates the need to pay for online purchases by writing and mailing checks or using credit cards by allowing consumers to send money instantly and securely to anyone with an e-mail address, including an online merchant. It is a convenient way for auction bidders to pay for their purchases, and sellers like it because it eliminates the risks of accepting other types of online payments. When the transaction occurs, the sender's and receiver's accounts are instantly reduced and credited, respectively. Anyone with a PayPal account—online merchants and eBay auction participants alike—can withdraw cash from his or her account at any time.

To use PayPal, merchants and consumers first must register for a PayPal account. There is no minimum

amount that a PayPal account must contain. Customers add money to their PayPal accounts by sending a check or using a credit card. Once members' payments are approved and deposited into their PayPal accounts, they can use their PayPal money to pay for purchases. Merchants must have a PayPal account to accept PayPal payments, but consumer-to-consumer markets such as eBay are more flexible. A consumer can use PayPal to pay a seller for purchases even if the seller does not have a PayPal account. When one uses PayPal to pay for purchases from a seller or merchant who does not have a PayPal account, the PayPal service sends the seller or merchant an e-mail message indicating that a payment is waiting at the PayPal Web site. To collect PayPal cash, the seller or merchant who received the e-mail message must register and provide PayPal with payment instructions.

Stored-Value Card Systems

Mondex

The most well-known example of an electronic purse or stored-value card system is the Mondex smart card (MasterCard International, 2004), a service of MasterCard International. It was introduced in the early 1990s, and had the largest pilot program of an electronic purse product to date. The Mondex smart card contains a microcomputer chip, and thus can accept electronic cash directly from a user's bank account. Cardholders can spend their electronic cash with any merchant who has a Mondex card reader. Two cardholders can even transfer cash between their cards over a telephone line. A single card works in both the online world of the Internet and the offline world of ordinary merchant stores. Another advantage of Mondex is that the cardholder always has the correct change for vending machines of various types. Mondex electronic cash supports micropayments as small as 3 cents, and Mondex has per-transaction costs lower than those of credit or debit cards since value transfer takes place locally just like cash. Thus it is a good choice for mini/micropayments. Finally, Mondex has the ability to provide user anonymity. This is because, just like cash systems, Mondex does not maintain any audit record. Mondex has some disadvantages too. The card carries real cash in electronic form, and the risk of theft of the card may deter users from loading it with a significant amount of money. Moreover, Mondex cannot compare with credit cards in the area of deferred payment. One can defer paying his/her charge or credit card bill for almost a month without incurring any interest. Mondex cards dispense their cash immediately. Last but not the least, a Mondex card requires special equipment; merchants who accept it must have a specific card reader at their checkout counter. A Mondex card must also be in physical contact with a special card reading-and-writing device during a merchant or recharge transaction. Internet users can transfer cash over the Internet using Mondex, but they must attach a Mondex reader with their PC in order to use the card. These requirements have proven to be barriers to the widespread use and success of Mondex.

A Mondex transaction consists of several steps that ensure that the transferred cash reaches the correct destination in a safe and secure manner. The following are

the steps to transfer electronic cash from the buyer to the seller:

1. The card user inserts the Mondex card into a reader. The merchant and the card user are both validated to ensure that both the user and the merchant are still authorized to make transactions.
2. The merchant's terminal requests payment while simultaneously transmitting the merchant's digital signature.
3. The customer's card checks the merchant's digital signature. If the signature is valid, then the transaction amount is deducted from the cardholder's card.
4. The merchant's terminal checks the customer's just-sent customer digital signature for authenticity. If the cardholder's signature is validated, the merchant's terminal acknowledges the cardholder's signature by again sending back to the cardholder's card the merchant's signature.
5. Once the electronic cash is deducted from the cardholder's card, the same amount is credited to the merchant's electronic cash account. Serializing the debit and credit events before completing a transaction eliminates the creation or loss of cash if the system malfunctions in the middle of the process.

Currently only a few cities in United States accept Mondex. Worldwide, Mondex is available in several countries on the North and South American continents, Europe, Africa, the Middle East, Asia, Australia, and New Zealand. As a whole, stored-value cards are not yet very popular in the United States. People there still prefer credit cards rather than smart cards.

Electronic Check Systems

ECheck

The most well-known among the electronic check systems is eCheck (Financial Services Technology Consortium, 2002). It combines "the security, speed and processing efficiencies of all-electronic transactions with the familiar and well-developed legal infrastructures and business processes associated with paper checks" (from <http://www.echeck.org/overview/what.html>). An eCheck is the electronic version of a standard paper check. It contains the same information as paper checks, and is based on the financial services markup language (FSML). It provides strong authentication, strong encryption, and duplicate detection features. It can be used with existing checking accounts, has unlimited but controlled information carrying capability, and has some enhanced capabilities, such as effective dating, that are not provided in traditional checks. In addition, eCheck is often considered more secure than traditional paper checks. In eCheck, each electronic checkbook is assigned a unique eCheck account number that only the bank can map into the actual underlying account number. This account number is part of the distinguished name in the bank-issued account certificate, so it cannot be modified but is easily verified by anyone who receives an eCheck. Thus, compromise of an eCheck does not lead to possible compromise of the

underlying account. Revoking an eCheck account number has no impact on the underlying account.

ECheck is the first and only electronic payment mechanism chosen by the U.S. Treasury to make high-value payments over the Internet. It is currently under enhancement in Singapore and is being considered for many on-line systems.

Electronic Bill Presentment and Payment Systems

CheckFree

CheckFree (CheckFree Corporation, 2004) is the largest online bill processor, and provides online payment processing service to both large corporations and individual Internet users. CheckFree Corporation provides a wide range of electronic commerce solutions, including online share portfolio management (in conjunction with the PAWWS system (<http://www.pawws.com>)) and general online bill payment systems. CheckFree provides the infrastructure and software to permit users to pay all their bills with online electronic checks. It offers an electronic check payment service as replacement for traditional paper checks. This payment system results in a service similar to that of money orders. Their software is compatible to the wallet software from Cybercash. For bill processing, the customer receives a bill from a service provider and sends the payment information to CheckFree. The customer creates an account with CheckFree linked by direct debit to the customer's bank account. CheckFree pays the bill on the customer's behalf in the form of electronic checks. If required, CheckFree can also pay the bill in the form of a traditional paper check.

Electronic Wallet Systems

Many electronic wallet systems are commercially available for pocket, palm-sized, handheld, and desktop PCs. The current technology trend is to produce electronic wallets in the smart cards. In the electronic payment system developed in the CAFE project, the electronic wallet can be either in the form of a small portable computer with an internal power source or in the form of a smart card. Electronic money can be loaded into the wallets online and used for payments at point of sale (POS) terminals. Example of e-wallet applications include Microsoft's .NET Passport (Microsoft Corporation, 2004) (the system is used mainly as a form of single sign-on framework rather than as an electronic payment system), Ilium Software's eWallet (Ilium Software, 2004), VeriFone's Vwallet (<http://www.verifone.com>—now integrated into its integrated payment solutions payment software), and Qwallet.com's Q*Wallet (Qwallet.com, 2004). Numerous banks and companies have now developed their own e-wallets, such as AT&T's e-wallet or MasterCard's e-wallet.

Credit Card Payment Systems

Secure Electronic Transaction (SET) Protocol

Secure electronic transaction (SET) is a secure protocol jointly developed in 1996 by MasterCard and Visa with the backing of Microsoft, Netscape, IBM, GTE, SAIC, and other companies to facilitate credit card transactions over

the Internet (Schneider & Perry, 2001). SET specifications were published in 1997 as an open standard, which allows all companies developing related applications to use this protocol and make their products work together successfully.

The objective of SET is to provide security for credit card payments as they traverse the Internet from the customer to the merchant sites and onto the processing banks. SET has been developed to secure the entire credit card payment process, including verifying that the consumer is indeed the owner of the credit card. Although Visa and MasterCard have publicly stated that the goal of proposing the SET protocol is to establish a single method for consumers and merchants to conduct payment card transactions on the Internet, acceptance of the standard has been slow. SET Co. is the consortium that manages and promotes the SET standard, which assumes an already established public key infrastructure. The SET specification uses public key cryptography and digital certificates for validating all participants in the transaction. In contrast to the SSL protocol, which only provides confidentiality and integrity of credit card information while in transit, the SET protocol provides confidentiality of information, payment data integrity, user and merchant authentication, consumer nonrepudiation, and payment clearinghouses (certificates).

The major components of SET are as follows:

1. The *issuer* (or customer's bank) is a financial institution that issues bankcards (credit cards or debit cards).
2. The *customer* (or cardholder) is an authorized user of the bankcard who is registered with SET. The customer participates in the SET transaction by use of an electronic wallet. SET calls this the cardholder wallet. This is where the customer/consumer's credit card information is stored in an encrypted manner. The wallet software is able to communicate and interoperate with other SET components.
3. The *merchant* is the seller of goods and services. The merchant uses the merchant server software to automatically process credit card authorizations and payments.
4. The *payment gateway* processes merchant authorization requests and payment messages including payment instructions from cardholders. It is operated by either an acquirer or some other party that supports acquirers (for example, the merchant's bank). It interfaces with financial networks to support the capture of SET transactions.
5. One or more *certification authorities* issue and verify digital certificates related to public keys of customers, merchants, and/or the acquirers or their gateways. The SET public key infrastructure proposes a top-down hierarchy of certification authorities comprising the following types:
 - *Root certification authority*: All certification paths start with this authority's public key. It is operated by an organization that the entire industry agrees to trust. The initial root key is built into the SET software with provision for replacing it in the future. It issues certificates to brand certification authorities.
 - *Brand certification authority*: These authorities are operated by different credit card brand owners like Visa and MasterCard. Each brand has considerable autonomy as to how it manages the certificate subtree rooted at it.
 - *Geo-political certification authority*: This is an optional level of certification authority. It allows a brand to distribute responsibility for managing lower level certificates across different geographic or political regions. This is to account for variations in how financial systems operate in different regions.
 - *Cardholder certification authority*: These authorities generate and distribute cardholder certificates to cardholders. Depending on brand rules, the certification authority maybe operated by an issuer or other party.
 - *Merchant certification authority*: These authorities issue certificates to merchants based on approval by an acquirer.

The SET infrastructure is deliberately planned not to interoperate with any other payment infrastructure other than the bankcard system. Although this maybe considered a restriction of SET, it ensures that the operating organizations are not subjected to any unknown risks. The main steps of SET are described in Figure 3. The sequence can be summarized as follows:

1. *Customer and merchant registration*: In this step (messages 0 in Figure 3), the customer and the merchant acquire relevant certificates from the corresponding authorities that will allow them to participate in the transaction. This needs to be done once before any SET transaction and needs to be re-executed if the certificates expire or are revoked.
2. *Browse and negotiate purchase*: This step (message 1) proceeds in an offline manner; it allows the customer to select the product and negotiate on a price. SET is not involved in this phase.
3. *Purchase request*: Once the customer has completed the product selection process, it invokes the cardholder wallet software on its machine. This is where the main SET protocol starts (message 2). The cardholder wallet initiates a SET session with the merchant server; it sends its certificate to the merchant and requests a copy of the merchant's certificate and the payment gateway's certificate. On receipt of these, the cardholder wallet creates a payment information (PI) and an order information (OI). The PI includes the cardholder's credit card account information and public key certificate, among others. The OI includes necessary information about the order. Two digests are computed, one each for PI and OI. They are concatenated and signed by the customer's private key. The PI is encrypted with the payment gateway's public key. Next, the OI and encrypted PI are together encrypted with the merchant's public key. Finally, the entire message is signed and sent to the merchant server. The merchant server verifies the cardholder's certificate. It verifies the signature on the PI and OI. If it agrees to OI, it forwards the encrypted PI to the payment gateway for authorization (message 3). While waiting for authorization, the

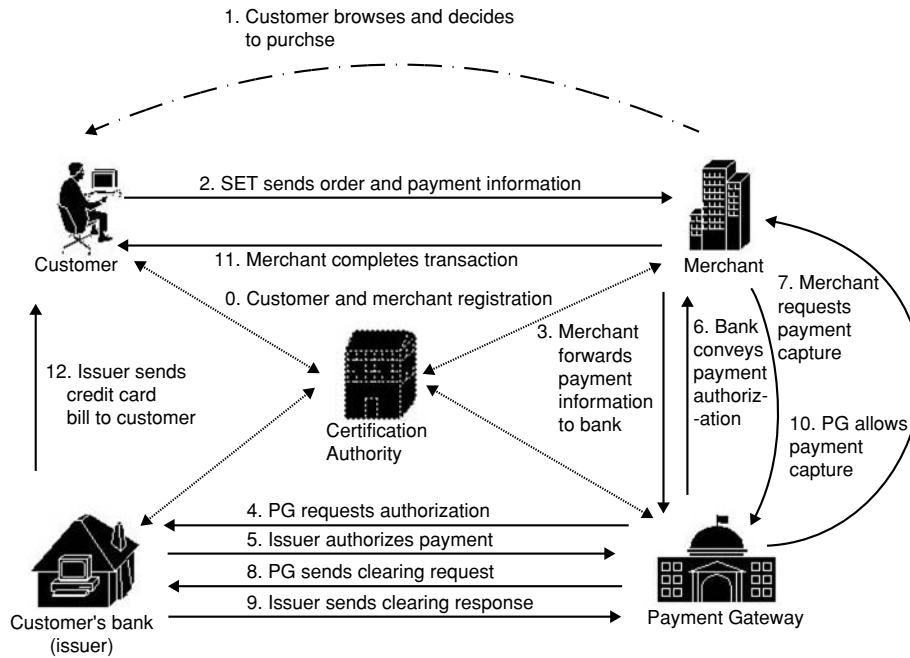

Figure 3: SET steps.

merchant prepares an order confirmation (OC), signs it with its private key, and sends it encrypted with the customer's public key.

4. *Payment authorization:* To request payment authorization, the merchant sends the encrypted PI (received in step 3) signed with its private key (message labeled 3) to the payment gateway. The payment gateway verifies the merchant's signature on the message, decrypts the PI with its private key, and retrieves the customer's certificate. It then verifies the relevant signature, and performs an authorization at the issuer (message 4). When the issuer authorizes payment (message 5), the payment gateway generates an authorization response (AR) and a capture token (CT). Both are signed by the payment gateway's private key and sent to the merchant encrypted with the latter's public key. The merchant, on receipt, stores the payment authorization response and capture token for later use.
5. *Payment capture:* The merchant prepares a payment capture request with the transaction identifier from the original OI and the CT obtained earlier. It signs the capture request (CR) and sends it encrypted with the payment gateway's (PG) public key (message 7). The payment gateway verifies the capture request message and sends a clearing request message to the issuer (CLR) (message 8). When the issuer clears the payment (message 9), the payment gateway generates a capture response (CR) and sends it encrypted with the merchant's public key. The merchant stores the CR and completes the transaction with the customer.

A major advantage of using SET over the SSL protocol for electronic credit card payment is that SET does not allow the merchant to view the customer's complete credit card information, which provides an additional degree of protection. In addition, SET prevents the payment

gateway and/or the issuer bank from being able to view the terms of the transaction established between the merchant and the customer. This way the privacy of the customer is also enhanced. However, SET has received a lukewarm reception in the United States and, so far, has not attracted a large number of merchants and consumers, though it seems to be the "best" protocol for securing payment over the otherwise unsecured Internet. The major SET activities are in Asian and European nations. Part of the problem with the acceptance of SET is that apparently it is not as easy to implement nor as inexpensive as most banks and merchants had expected. The typical reaction of many banks has been that SET is clumsy and not tried and tested. The future might prove brighter for SET, though. After a few years of testing and trials, SET's supporters believe it is ready for widespread deployment.

Micropayment Systems

MilliCent

Micropayment fundamentally creates a new billing model, under which the individual items downloaded can be billed separately and individually. With micropayment methods, consumers can download a song or a chapter of a book and be billed as little as 50 cents or a dollar, with that small amount being charged to their Internet service provider (ISP) or phone bill. Security issues with micropayments are primarily centered on the premise that a small charge would not require extensive use of encryption technology or other means of fraud prevention. The widespread use of micropayments is a potential breeding ground for fraud that today is not apparent. The lack of an authoritative infrastructure standard, coupled with strong network externalities, has limited micropayments from becoming a dominant means of value transfer.

Micropayment models are not static in nature. Fundamentally, they will provide a means of transferring value

for incremental items. The 900-telephone number system is considered the first successful micropayment method, but more online models will need to develop to feed the demand for quick and instant payment for performance. Technology will have to evolve to allow for things like a clear identification when a person is at the office, using a corporate ISP, and when that person is at home. Technology infrastructure is thus the first micropayment enabler. Merchants willing to provide content over a micropayment system for a large number of users are the second fundamental enabler for micropayments. Beyond path dependencies, external factors must be in place for the platform to be adopted. Content providers must have viral growth of their product through micropayments; this is the last enabler. Once these are achieved, the micropayment model will be ensured a key part of online success.

MilliCent (Glassman, Jones, & Manasse, 1997) is the most the widely known micropayment scheme. MilliCent is a proprietary voucher-based digital microcommerce system from the erstwhile Digital Equipment Corporation (acquired by Compaq and now part of HP Invent). It aims at the micropayment segment of electronic commerce and supports transactions with values of fractions of a cent. MilliCent considers that coins are treated differently than paper money, in the same manner that small denomination notes are treated differently from large denomination notes. As MilliCent represents very small coins, it uses lightweight security measures. A public trial of the MilliCent system involving toy money started in December 1997.

The system uses merchant-specific vouchers, the so-called scrip, a form of token only valid with a particular merchant for a limited period of time. Brokers act as intermediaries between merchant and customers. The fact that any type of scrip is only valid at a particular merchant means the merchant does not need to connect to a central issuer to validate the token. This reduces network traffic and the validation cost. To avoid customers having to maintain separate accounts with the individual merchants for mostly short-term relationships, brokers act as intermediaries. The long-term relationships are between brokers and customers, and brokers and merchants. A consumer registers with one broker and buys broker scrip in bulk—generic scrip. Brokers receive payment from consumers in a variety of ways, but the most common way the consumers pay brokers is with a credit card. When a consumer locates a product on a merchant's Web site that he or she would like to purchase, the consumer converts the broker scrip into vendor-specific scrip. Vendor-specific scrip is scrip that a particular merchant will accept. The consumer's new scrip is stored in an electronic wallet on the consumer's computer. Paying for an item involves simply transferring a merchant's scrip, which is in a consumer's wallet, to the merchant in exchange for a purchased item. Merchants can then send a broker their own scrip and obtain a check. The basic sequence of interactions is as follows:

1. The customer obtains a quantity of broker scrip at the outset.
2. The customer requests some specific vendor scrip that they will pay for later with the broker scrip.

3. The broker obtains the required vendor scrip from the vendor.
4. The broker sells the vendor scrip to the customer.
5. The customer buys the service with the vendor scrip.
6. The vendor gives change in vendor scrip.

Steps 1 to 4 are not required for every transaction; the customer can buy sufficient scrip from the broker for a period. Likewise, the broker can store enough vendor scrip to serve many customer requests or it can have a license from the vendor to create that vendor scrip directly. Although at first glance a lot of message passing seems to be required, there is no bottleneck from one single currency issuer being contacted during each transaction, especially once steps 1 to 4 are completed. Experiments at Digital indicate that MilliCent is efficient enough for transactions as low as 1/10 of a cent. A broker is required in the protocol for two reasons. First, the system of very small payments works because transactions can be aggregated so they are significant. That is, when a consumer buys a few dollars worth of scrip, there is little profit in the deal. However, when several consumers purchase scrip, the aggregate amount—even discounted so that the broker can make money—does make economic sense. The second reason for a broker is that it makes the entire system easier to use. A consumer must deal with only one broker to satisfy his or her scrip needs for many merchants. The broker buys the scrip in bulk and does all the hard work of organizing the retail selling to customers.

A significant feature of the MilliCent protocol is the trade-offs attempted at different points in the design. For example, MilliCent offers three different protocol versions—"private and secure," "secure without encryption," and "scrip in the clear." The least secure is "scrip in the clear," where the scrip is transferred between customer and vendor without any encryption or protection; thus the protocol is the most efficient and cheapest to implement. However, this allows any observer to change the scrip or replay it and spend it itself. Thus the customer can potentially suffer financial loss. Although amounts stolen this way will be quite small, it can be rather annoying to the customer to find their small changes to be invalid. The next level of security is provided by "secure without encryption," where personal information about the customer carried by a field in the scrip is available to the player involved in the scrip system. However, the scrip itself is protected from replays that allow an observer to spend the scrip itself. The most secure version of the protocol is the "private and secure." However, it too uses lightweight encryption technology, which is probably not too difficult to break. The philosophy is that the cost of breaking the protocol should be greater than the value of the scrip itself. Scripts can be minted at very low value. Thus, loss of scrip due to confidentiality or integrity breaches does not cause significant financial loss to the end user.

CONCLUSION AND FURTHER READING

In this chapter, we attempted to present an overview of electronic payment systems. One of our objectives has

been to identify the technical challenges, mostly security related, that hinder the widespread deployment of such systems. We also surveyed some of the more well-known instances of electronic payment systems. Our survey is by no means complete. Many systems are regularly proposed. The majority of them do not survive the market forces. Those who do frequently are acquired by the larger players and their initial business focus gets lost.

A good source of information for electronic payment systems is Dr. Phillip M. Hallam-Baker's Web page on electronic payment schemes (Hallam-Baker, 2004) on the W3 Consortium Web site. This page categorizes electronic payment schemes along two dimensions—the level of abstraction for the payment scheme (namely *policy*, the semantics of the payment scheme; *data flow*, the requirements for storage of data and communication between parties; and *mechanism*, the security methods used) and the payment model for the protocol (namely cash, check, or card). The Web page contains a comprehensive list of Internet payment schemes and protocols. The author makes an earnest effort to keep the list as up-to-date as possible; however, this may not be the case always. The CAFÉ project of the European Community's ESPRIT program (European Community's ESPRIT Program, 1995) and the SEMPER project (European Commission's ACTS Program, 2000) of the European Commission's ACTS program are two important European projects that provide valuable information on electronic payment systems. The list (SIRENE, 2004) maintained by the SIRENE group is also a valuable resource for electronic payment systems. Leo van Hove's database on e-purse (van Hove, 2004) provides a collection of links and references on electronic purses (and related issues). The e-money mini-FAQ page (Miller, 2004), written by Jim Miller and maintained by Roy Davies, provides answers to some frequently asked questions about electronic money and digital cash. Roy Davies also maintains a comprehensive information resource for electronic money and digital cash (Davies, 2004). The Financial Services Technology Consortium (FSTC) has several projects (both past and present) aimed at developing technologies that facilitate electronic payment systems. Information about these projects can be found from the FSTC Projects Web page at <http://www.fstc.org/projects/>. Finally, some useful reference book for electronic commerce and electronic payment systems are the books by Hossein Bidgoli (2002), Gary Schneider and James Perry (2001), and Craig van Slyke and France Belanger (2003).

GLOSSARY

Acquirer The entity or entities that hold(s) deposit accounts for card acceptors (merchants) and to which the card acceptor transmits the data relating to the transaction; the acquirer is responsible for the collection of transaction information and settlement with acceptors.

Audit Trail A sequential record of events that have occurred in a system.

Automated Clearing House (ACH) An electronic rendezvous for financial institutions where payment

orders are exchanged among the financial institutions primarily via magnetic media or communications network.

Automated Teller Machine (ATM) An electromechanical device that permits authorized users to use machine readable plastic cards to withdraw cash from their accounts at a particular financial institution and/or access other services, such as account balance enquiries, transfer funds between accounts, or deposit money into accounts.

Batch Processing The transmission or processing of a group of payment orders as a set at discrete intervals of time.

Card A general term used to describe several types of payment systems including ATM card or cash card, check guarantee card, chip card (or smart card), credit card, charge card, debit card, delayed debit card, prepaid card, retailer card, and stored-value card.

Cash Card Card for use only in ATMs or cash dispensers.

Certificate A document (physical or electronic) that evidences the undertakings of an issuer.

Charge Card Card issued by nonbanks indicating that the holder has been granted a line of credit. It enables the holder to make purchases but does not offer extended credit, the full amount of the debt incurred having to be settled at the end of a specified period. Typical issued by the travel and entertainment industry to their customers.

Check A written order from one party (the drawer) to another (the drawee, normally a bank) requiring the drawee to pay a specified sum on demand to the drawer or a third party of the drawer's choosing. Checks may be used for settling debts and withdrawing money from banks.

Check Card A card issued as part of a check guarantee system.

Check Guarantee System A system to guarantee checks, typically up to a specified amount by the issuer of the guarantee card.

Chip Card See smart card.

Clearing/Clearance The process of transmitting, reconciling, and, in some cases, confirming payment orders or security transfer instructions prior to settlement.

Credit Card A card indicating that the holder has been granted a line of credit. It enables the holder to make purchases and/or withdraw cash up to a prearranged ceiling; the credit granted can be settled in full by end of a specified period or can be settled in part, with the balance taken as extended credit.

Credit Card Company A company that owns the trademark of a particular credit card, and may also provide a number of marketing, processing, or other services to its members using the card services.

Debit Card A card that enables the holder to have his/her purchases directly charged to funds available in his/her account at a deposit-taking financial institution.

Delayed Debit Card A card issued by banks indicating that the holder may charge his/her account up to an authorized limit. It enables the holder to make purchases but does not offer extended credit; the full amount of

the debt incurred needs to be settled at the end of the specified period.

Electronic Fund Transfer System A formal arrangement based on private contract or statute law with multiple membership, common rules, and standardized arrangements, for the electronic transmission and settlement of monetary obligations.

Electronic Payment System An electronic system consisting of a set of instruments, banking procedures, and typically interbank fund transfer systems that ensure the circulation of money.

Electronic Purse A reloadable multipurpose prepaid card that may be used for small retail or other payments instead of coins.

Electronic Wallet A computer device used in some electronic payment systems to store information needed to undertake a financial transaction.

Magnetic Ink Character Recognition (MICR) A technique using machine readable characters imprinted on a document using an ink with magnetic properties by which information on the document is interpreted by machines for electronic processing.

Payment The process of the payer's transfer of a monetary claim on a party acceptable to the payee.

PIN A numeric code that a cardholder may need to quote for verification of identity. It is often seen as the equivalent of a signature.

Prepaid Card A card on which value is stored and for which the holder has paid the issuer in advance; also known as stored-value card.

Provider The operator who establishes the hardware and software conditions for the conduct of transactions with electronic money without necessarily being the issuer of the electronic money units.

Settlement The act of discharging obligations in respect of fund transfers between two or more parties.

Smart Card A card with a built-in microprocessor and memory capable of performing calculations and storing information.

Stored-Value Card See prepaid card.

INTRODUCTION

An intranet is defined by the use of Internet technologies (HTTP, TCP/IP, FTP, SMTP) within an organization. By contrast, the Internet is a global network of networks connecting myriad organizations. The line becomes blurred when an internal system is opened to remote access, and parts of the system are made available to customers and suppliers. This extension of an intranet to selected outsiders is often called an extranet. Many of the applications accessed over intranets are run on ERP systems such as Oracle, Peoplesoft, and SAP that also service external users.

As wired and wireless connectivity continue to develop, distinctions among types of systems will become increasingly artificial and contrived, just as the once clear distinctions among hardware such as personal computers, servers, and minicomputers have lost meaning. When reading this chapter, concentrate on how the issues described may affect Internet technology-based systems within your organization, rather than on the specific definition of any one system.

Because they are based on open Internet standards, intranets are easy to implement technologically. This can be a blessing and a curse. Although they can offer robust functionality with little investment, they are often rolled out with little forethought and therefore may fail to make a significant contribution to the organization or may present security vulnerabilities.

Much of the research and background information applicable to intranets is now being published in other areas. The technological issues overlap with the broader Internet, and many of the internal applications offered on intranets are now encompassed by enterprise applications and knowledge management. Some authors even refer

to business-to-employee (B2E) applications (Hansen & Deimler, 2001), emphasizing the importance of focusing on the access to systems by those within the organization. This chapter draws on these and other literatures to offer a broad perspective on intranets and their application. The chapter outlines what intranets are, how they are used, the technologies for constructing and running them, and how to manage them securely and efficiently.

FEATURES OF AN INTRANET

Few organizations question the value of having an intranet in some form. Indeed, over 90% of major U.S. corporations have intranets (Baker, 2000). The benefits can range from a reduction of paper and headcount, always having the current version of any data or document available, to a central interface, or portal, and repository for all corporate systems and data. Intranets may encompass many different types of content and features. Other benefits include the use of Internet-standard network protocols that facilitate connections to the broader Internet.

Portal

A door or gate; hence, a way of entrance or exit, especially one that is grand and imposing.

—*Webster's Revised Unabridged Dictionary*, 1913

Intranets are often designed to be “portals,” serving as the central point of access to all information resources within an organization. The implication of grandiosity is deliberate and helpful, as good design can be a crucial determining factor in the success of an intranet. A portal also needs to be available regularly to a wide community, with access to multiple sources of data, both

internal and external, with a useful search mechanism. The term portal often evokes third-party commercial portals such as Yahoo.com (<http://www.yahoo.com>) and vertical portals, also called vortals, such as plasticsnet (<http://www.plasticsnet.com>). These portals have struggled to establish successful business models, especially after the dot-com collapse. Portals inside organizations, in contrast, have thrived, often with the support of the information systems (IS) department and the business users.

One of the greatest frustrations for information technology users inside organizations is the necessity of multiple systems with varied interfaces, including command-line-based interfaces. With a portal, users have the ability to go to a single location; use a common, intuitive, and well-established graphical interface; and find their information. Such ease of use makes it more likely the systems will be used to their full potential, generating the efficiencies envisioned when they were designed. Types of information and services found on intranets are outlined in the following sections.

Human Resource Management

Human resource materials are an obvious and common type of content for intranets. Manuals on policies and procedures and frequently asked questions (FAQs) can be kept online, providing employees easy access, facilitating updates, and saving paper.

Benefits management is a significant cost for organizations; tax withholding, health care election choices in the United States, and retirement and pension accounting all involve substantial processing costs. These processing costs include printing, distributing, completing, collecting, and entering data from paper forms; providing support to fill out the forms; and managing subsequent changes. With a well-designed intranet, employees can process their own benefits, saving substantial overhead and time and reducing the need for HR staff. The forms tend to be highly structured, with well-defined fields, and the application can be scaled to all employees, reducing the cost of development per employee. These forms can also change regularly. Changing the online versions is much less expensive, and eliminates the possibility of employees filling out the wrong version of a form.

Human resources is also an excellent choice for intranet applications, particularly early in an intranet rollout, because every employee uses its services. Beginning with a common set of applications with which all or most employees interact may lead users to become familiar with other services located on the intranet as well. Self-service benefits also allow the human resource department to train less computer literate employees on an application that human resources knows intimately and that all employees must use (Meuse, 1999). This makes it an excellent introduction to the intranet. Unfortunately, most users only need to visit the employee benefits site once or twice a year, so it cannot be counted on to drive traffic throughout the year. However, newsletters can be published on the intranet, with notifications sent out via e-mail that may bring some traffic regularly.

Purchasing

For many organizations, especially larger ones, purchasing is a major cost that can be difficult to control. Managing the purchasing function and its information requirements is an inconvenience, and much of the cost is incurred in the overhead of processing purchases. The story of Ford's and Mazda's accounts payable departments has been retold many times and is famously cited by Hammer as an example of reengineering. Ford, with 500 people working in accounts payable, decided to compare itself to Mazda as a benchmark for its efficiency. Ford found that Mazda had only five people working in a similar department (Hammer & Champy, 1993). Although Mazda's efforts predated the Web, information processing was a crucial part of their efforts. This underscores the complexity and overhead often involved in purchasing. Intranets can greatly reduce purchasing overhead by simplifying the process and centralizing the collection of order data. Approval processes can be automated or at least facilitated, reducing paperwork and related clerical work.

Many office and maintenance, repair, and operations suppliers offer customizable versions of their product catalogs to be put onto client company intranets. This customization, which automates the process of billing and shipping, allows employees to order products directly without intervention from corporate purchasing departments. The order data are captured once, at the point of origin, stored in the appropriate database, and reused as needed without reentry, reducing mistakes and clerical staffing needs.

Operations

The intranet can be at the center of all operations for the company, serving in essence as an interface to all enterprise systems. This can include logistics, inventory, project management, and operational systems. With the increasing focus on customer responsiveness, time to market, and value chain integration, such operational transparency is becoming increasingly valued. These systems provide crucial links to extranets. For more on extranets, see chapter 15.

Directories

One simple, useful application is an electronic directory of employees. The directory can easily be kept current, and is regularly used by most employees, particularly if paper directories are no longer published.

Menus

Something as simple as cafeteria menus and catering information can be a useful tool to drive traffic to the site.

Calendar Systems

Centralized calendar systems are an excellent intranet application for many reasons. First, it is an extremely valuable service to all users who schedule meetings or other appointments. It is also something most people are likely to use on a daily basis. Benefits include the reduction of time spent in arranging meetings or other events, the

elimination of “double booking,” and the increased efficiency of all involved staff.

The system may be used to schedule meetings and conference rooms and to coordinate individual schedules. Such technologies can also synchronize personal digital assistants (PDAs), allowing employees to keep their calendars with them and also have them stored centrally. Organizations may also enable the PDAs to access the intranet remotely via wireless technologies including WiFi and Bluetooth. Convergence of standards, advances in security, and decreasing hardware cost make such wireless access relatively inexpensive and viable.

Intranets may also include time clocks. As organizations move closer to activity-based costing, they require additional data on employee productivity. In particular, as more employees become knowledge workers, time tracking becomes an increasingly valuable tool and intranet applications make the input and analysis of these data easier, with widely accessible, familiar, intuitive graphical interfaces.

Group Collaboration

An increasing amount of work in organizations is being done by multiple people working collaboratively in disparate geographic locations, often at different times. Many intranet- and Internet-based applications are available to support such work. These systems include those for group authoring, document management, change control, moderated and threaded message boards, shared whiteboards, and workflow management software. Benefits of these applications can be realized by employees working on-site and remotely, making the intranet a necessary component of any organization’s attempts to expand remote work arrangements such as telecommuting, hoteling, and accommodating those employees who are frequently on the road.

Hewlett-Packard found that such traditional group collaboration tools were not sufficient because they lacked the “causal proximity” necessary for productive group work. They implemented passive cameras to indicate whether someone was at or near their desk, and included an intercom-enabled telephone system and instant messaging, to foster regular, brief conversations (Sieloff, 1999). Such richer media helped emulate the benefits of working in the same physical location.

Syndicated Data

Many organizations make regular use of purchased external data feeds for strategic and operational work. Stock prices, weather, and news streams may all be purchased and made available through the intranet, customized for users based on their needs. Coordinating these streams requires careful management to balance easy access to current data with security.

Knowledge Management

Knowledge management has received a great deal of attention in the business and popular press. As organizations move away from manufacturing toward services, more knowledge is in the minds of workers than

embedded in physical systems, or even documentation. This increases the cost of employee turnover and can impede growth.

Part of the challenge of knowledge management is uncovering, storing, and retrieving tacit knowledge. Although many organizations struggle with simply managing explicit knowledge that can be readily articulated and documented, the greatest benefits often come from capturing tacit knowledge. The regular use of an intranet may encourage employees to store routinely information and knowledge and make explicit previously tacit knowledge.

Given the volume of information created in organizations, not only is indexing and retrieval important, but forgetting is also crucial. Archiving functions can move information out of the main databases to improve the relevancy of searches.

Implementing an intranet can fundamentally change the nature of the organization by reorganizing its business processes. By doing so, intranets can be a powerful lever of control (Simons, 1995), serving as a catalyst for change. General Motors credits its intranet, which links GM’s 14 engineering centers with computer-aided design software and 3-D simulators, with an increase in creativity and even now recruits from the motion picture industry rather than just fine arts and automotive design programs (Rifkin, 2002) to take advantage of the Web-based skills. Such intranet-driven changes are so common that Pitt et al. have developed I-CAT, an instrument for measuring the effectiveness of an intranet as a catalyst for change (Pitt, Murgolog-Poore, & Dix, 2001).

TECHNOLOGY

The technology for intranets is straightforward and similar to any other Web-based system. With nearly all corporate networks running on TCP/IP, starting an intranet site is as simple as placing a machine on the network, or finding one already connected, and installing or enabling a Web server. Current versions of Microsoft Windows desktop and server software come with Web servers installed and can be easily configured by anyone comfortable with personal computers. Once the server is up and running, the server may operate in the background on an employee’s ordinary PC workstation. Other employees may access the server by entering the IP address of the machine. Obviously, most users would prefer to type in a text domain name rather than a series of numbers. Such a text name would require either registration on the company’s domain name server, which maps IP addresses to text names, or the use of Windows Internet Name Service (WINS), which serves the same purpose as DNS, but on Windows networks.

Content may be added to the Intranet in the form of HTML pages, which may be coded by hand, saved as HTML from word processors such as Microsoft Word, or written in HTML editors such as FrontPage and DreamWeaver. Simple programs for generating content in response to requests on the intranet may also be written in such languages as Cold Fusion, UltraDev, JSP, ASP, and Perl. HTML editors can generate simple scripts automatically for novice users. Such dynamic Web pages allow greater flexibility in the design of intranet Web pages.

Establishing the corporate portal/intranet as the access point for all information services is an appealing architecture for the IS department. Assuming the workstations are Windows-based, then all that needs to be installed on each machine is Microsoft Office with the Internet Explorer Web browser. This simplicity is one overarching benefit of an intranet over legacy network systems, since the need for individual computing support is significantly reduced by the common hardware and software, and user access is enabled through graphical, largely intuitive, interfaces.

All major software vendors have addressed the intranet market. Microsoft is working aggressively to integrate its desktop productivity software in Office with Web-based intranet tools, including video, Exchange server, SharePoint services, and Microsoft Project (Microsoft, 2004). Microsoft even ships wizards for the creation of intranets. Server software vendors such as Sun, IBM, and open-source Apache all offer intranet configuration suggestions and options for network and systems administrators familiar with those companies' products.

Enterprise system vendors have also focused heavily on Web-based access in the past several years. In that time, SAP, PeopleSoft, Baan, Oracle, and JD Edwards have all launched enterprise portal products to integrate their systems with a Web interface and other corporate intranet applications. Customer relationship management products such as Applix and Siebel have also launched portal interfaces in response to demands from the corporate market. The intranet/Web browser has become a common and accepted interface for corporate applications.

Extensible markup language (XML) is rapidly gaining support as a standard for Web documents. This is good news for intranets for several reasons. First, XML, with its focus on metadata, supports the complex, structured documents that populate most intranets. Second, as XML becomes a standard format for word processors, saving files to the intranet will become even easier. This approach has gained attention since Microsoft announced it intends to base its Office applications on XML. Finally, XML documents can be readily stored in databases and searched and retrieved quickly and easily, improving performance for large intranets.

Dot-coms were a major market for many of the software vendors who also compete in the intranet software market. With the collapse of the dot-coms, prices for Internet, and therefore intranet, software have dropped considerably. In addition, open-source software is becoming more robust, offering much less expensive alternatives to the major software vendors. Many companies use the open-source Apache suite to develop and manage their corporate intranets, and most major software vendors have started to support interface with Apache and other common open-source products.

As intranets grow, and increasing amounts of data are available, there must be a way to find information effectively. Information anxiety (Wurtman, 1989) is an inevitable challenge for intranets, given the volume of data likely to proliferate. Hewlett-Packard, for instance, found that within two years of launching its intranet, there were over two million documents stored on thousands of servers throughout the organization, and fewer

than 5% of them were traditional official communications (Sieloff, 1999). Such volumes make information architecture (Rosenfeld & Morville, 2002) essential. Information architecture is a crucial component of successful intranets, and the hierarchical structure and navigation themes must be well thought out and implemented. An efficient and effective search engine available for the entire intranet is also required. Many organizations license third-party search engines to reduce the problems inherent in searching the wide variety and amount of information stored in an intranet.

Unless entries are key worded with metadata, users' searches are reduced to full-text searches, which are likely to return massive numbers of hits even with the best search engines. Proper metadata coding requires an appropriate taxonomy. Such a taxonomy may be available within the industry, or extant in the organization. If not, a thorough metadata taxonomy must be developed and implemented. Without a pre-hoc taxonomy, it is unlikely the metadata will be very useful. One survey found that only 31% of companies with enterprise portals had implemented a taxonomy (Answerthink, 2002), emphasizing the need for corporate information metadata management.

Establishing a taxonomy is only the first step; it must be used correctly and consistently to be effective. This requires all of those entrusted with entering data to use the taxonomy properly. This can be accomplished by simplifying the taxonomy so that there is no ambiguity in the interpretation, and there must be documentation and/or training to ensure consistency of the taxonomy's application at all data entry points. It is also likely that the taxonomy will need to evolve over time, requiring a plan for maintenance and continued training.

It may be possible to post much of the content on the intranet with limited metadata coding because most users would find the content via browsing, or the search engine would likely find it and rate it as highly relevant.

Personalization

For users, having the most applicable material readily accessible can be extremely powerful and empowering. Customization strategies for intranet access can be individualized or group based. For example, a different interface can be developed for selective categories of employees, offering some customization at low cost, or personalization software can be installed to generate pages based on an individual's expressed or inferred preferences or behaviors. Most Web servers, including Microsoft IIS, iPlanet, and Apache, now come with basic personalization functionality.

However, Web developers have found that personalization is not a silver bullet. Indeed, Yahoo!, one of the largest personalizable sites on the Web, learned that most users, if given the choice, do not customize their interfaces (Manber, 2000). This makes designing the default pages and customizations more important than extensive customization options. Yahoo! also discovered that any customizations applied in one section of the site should apply to all areas, or users will become frustrated because they expect to need to set up customization

only once. Yahoo! did find that a cadre of power users customized their interfaces beyond all expectations of the developers. Lessons learned from these power users can be applied to other users through redesign of the default or group-customized pages, underscoring the power of an information architecture steering group with input from all user groups.

Content Management

The Yankee Group outlines a three-stage content delivery cycle: creation, management, and presentation (Perry, 2001). Content management systems such as Vignette and Interwoven's TeamSite manage all three of these stages by storing all Web site data in a database. They facilitate content management by accepting external and internal automated data streams through syndicated, operational, and financial data and receive input from publishers throughout the organization in word-processing, spreadsheet, presentation, XML, and HTML formats. These systems manage the data with change control, security, and workflow tools. Content management systems handle presentation by working with application servers such as BEA's WebLogic and IBM's WebSphere to create pages based on templates created by designers.

For large intranets, content management can be a worthwhile solution. Much of the data on the intranet change regularly, and updating a database is more efficient than making changes to all Web pages that contain it. Content management systems facilitate the distribution of intranet content over multiple channels, including multiple Web sites, possibly including externally accessible sites, high- and low-bandwidth versions, wireless/mobile, syndication, and even hard copy. Document management systems such as Documentum and Hummingbird and even document imaging software serve a similar purpose. In general, all of these products are evolving toward enterprise content management.

Ease of Use

The importance of usability is well established for all Web sites. In addition, usability has been linked to effective knowledge management (Begbie & Chudry, 2002). For intranets to be effective, they need a wide array of users across the organization. Providing extensive training and technical support to all users is not likely to be possible for reasons of cost and logistics. As employee turnover rises, reducing the learning curve for using the intranet becomes more important. Therefore the intranet must be well designed and simple to use.

BUILDING AND MAINTAINING SECURE INTRANETS

Although intranets may be developed easily within departments with little support from IS, if the intranet is to scale and to function well, there are several areas the IS department must address. As more crucial data are stored and accessed on the intranet, security becomes increasingly important. In addition, intranets are likely to fundamentally change the nature of systems analysis and design,

as users become more intimately involved in the process (Perry, 1998).

Standards versus Flexibility

The question of how much to constrain users in the interest of promoting standards for efficiency has plagued information systems professionals for decades. With intranets, the implications are substantially greater as many people in the organization become, essentially, systems developers.

Controlling the use of spreadsheets and other personal productivity software was hard enough, but at least those systems were only accessed by one user, or perhaps disseminated over an informal "sneaker net." With intranet data, potentially the entire organization has access to what is developed, and the developers have no formal training in systems analysis, design, or security. Substantial duplication may arise, adding to costs and confusion. Poorly designed applications or content may lead to user rejection of the intranet, despite realizing other benefits, and data may be left unprotected from unauthorized access and without audit trails.

The power of such distributed systems lies in the empowerment of employees with access to the data, and the ability to enter and manipulate it online. This empowerment is consistent with the principles of reengineering, "just in time," customer relationship management, supply chain management, and other management trends of the past several decades: enter data only once, at the source.

Intranet standards can be set for data storage, color schemes, templates, navigation, file naming, graphics formats, file formats, file sizes, and narrative voice. Content management systems can automate much of this standardization, and also establish approval processes for implementation.

Intranets have the benefit of limited or no access by those outside the organization, and this insulation offers many a false sense of security about the lack of need to protect it. It is likely that much of the data on the intranet will make its way to suppliers and customers, whether indirectly or directly, because a successful intranet will be the primary source of information throughout the organization.

Training and Support

As applications and services are moved onto the intranet, and traditional physical channels are closed down, there will be a significant need for training and support. Often the systems are brought live by departments without thought of the need for training personnel, but the support demands are made to the IS department. A training program can obviate many of the support calls, but requires a coordinated effort and a willingness on the part of departments to support in principle, if not financially, such training programs. Given the expense of lost productivity, such programs are often politically unpopular, but necessary for a successful implementation of any internal system.

Support for the systems is also a challenge because these applications may change frequently and the IS department may not have been involved in their

construction. It is unrealistic, however, to believe that the call center, or its equivalent in smaller companies, will not be the main source of intranet support, whether de facto or de jure. Successful, sustainable intranets involve the IS department, especially for support.

Access and Control

If a Sun employee attaches a modem inside our network without going through the firewall, he's fired.

—Geoffrey Baebr, Sun Microsystems chief network officer, *Information Week*, 1997

Intranet security is similar to security for any Web-based system, but potentially more complex because of the larger number of people with authorized access. When the Navy began implementing its Navy/Marine Corps Intranet (NMCI), it quickly found that the U.S. Department of Defense Information Technology Security Certification and Accreditation Process (DITSCAP) was difficult to apply. The Department of Defense needed to adapt the process to fit the needs of intranet development (Gerstmar, 2002).

Given that the vast majority of security lapses are from authorized users within the organization, intranets create numerous potential breaches. Access controls for data and process may be set at the operating system, directory, application server, and Web server levels. Authorization can be done through passwords, or even biometrics, depending on the value of the information.

Firewalls can be established not only at the border with the Internet to keep those outside the organization out, but also inside the organization to limit access to authorized employees. For more on firewalls, see chapters “Antivirus Technology” and “Biometric Basics and Biometric Authentication.”

Access controls are more likely to be successful if the organization has implemented a single sign-on process, where users have only one username and password and are authorized through a centralized system. This allows centralized control of access levels and facilitates terminated access when employees leave the organization.

For the intranet to achieve its potential, it must displace other channels such as paper, phone, in person, and even e-mail. As these other channels are shut down, many employees who did not previously need access to a computer now need it to manage their benefits, enter a request for a repair with physical plant, look up a phone number, etc. This means providing access to all employees, many of whom have never needed computers previously. Custodial staff, warehouse employees, and others may not need individual workstations, but do need convenient access to a computer connected to the intranet. This may mean extending the network to areas of buildings previously left unwired. Although modern construction and wireless technologies make this less of an issue than previously, there may still be significant expense and effort to ensure intranet access to all. Access must also be established to legacy software systems that may not be Web-enabled.

Network Availability and Security

Intranets are easier to secure and keep reliable than the external Internet because companies have control over the

network and servers on which they run. This greater control should not be used to excuse lower vigilance. Intranet access may substantially increase the need for bandwidth on the network. Bandwidth demands can easily grow exponentially when an intranet is introduced, especially as the cost of multimedia hardware continues to drop. Although the cost of bandwidth is also dropping, the complexity of network management increases substantially as more bandwidth is used. Also, as demand for the services increases, the need for network reliability also rises. Good networks are more than bandwidth. As more work is intranet-based and dependent on the corporate network, availability, reliability, service, support, and scalability of the network all become crucial.

With most companies distributed geographically, thought should also be given to the security of intranet transmissions. Even if access controls are well implemented, unauthorized access could be achieved by intercepting packets. Secure socket layer (SSL) can be easily enabled for any intranet pages that contain sensitive information. With increasingly powerful client machines and servers, the overhead involved in the encryption is no longer prohibitive. Many organizations should consider using SSL as the default on all intranet pages, relaxing security only when the content does not need to be protected.

Once an intranet site is established, IS will be held responsible for ensuring that the site is available whenever needed. This may mean 24/7 in some instances. For a traditional system, with a limited number of professional developers operating in a staged development environment with source control on systems running in a data center, this is a well-solved problem, depending on resource constraints. However, for systems often hosted within departments outside IS control, and developed by untrained personnel, keeping the systems running can be a challenge. One poorly constructed script can bring a system to its knees and make diagnosis difficult. These systems are often not backed up, and nearly all lack any form of source control. However, such carelessness is not inevitable, and traditional IS methodologies may be applied to ensure the reliability of intranets.

Implementation

It is well established that top management support is a crucial factor in the success of all information systems implementations. However, it is not always sufficient. Many intranets are small, bootstrapped applications implemented with little fanfare. For an intranet to be successful, the goals for the initiative must be articulated. This involves determining the audiences for the system, the services to be offered, and the extent to which they are to be used. Once the goals are known, then metrics can be established for measuring success. With metrics in place, a plan for implementing the system can be created. This is another reason to have a corporate information systems architecture that covers the development, implementation, and maintenance of all intranets.

Importance of Pilot Studies

Because intranet systems are Web-based, prototypes are easy and generally inexpensive to build. This makes pilot

testing an effective tool for determining the relevance of this technology in relation to a company's needs. However, it is important to keep in mind the goal of the pilot study. Many people incorrectly view pilot studies as always determining definitively whether a given system will work within the target community. Rather, most initial pilot studies should be tests for proof of concept, and should be repeated several times in different areas of the organization to ensure the generalizability of the concept test.

If the pilot is testing for proof of concept, then the population chosen for the test should be the one likely to adopt it. The initial pilot will be closely watched by many in the organization, and a failure could set the project back significantly. Participation in the pilot study is also an opportunity for potential users of the production system to invest psychologically in it. Potential users may be coopted into adopting the technology by being brought into the development process as well as testing. IS research has shown that involvement in the design process makes people more likely to support and use the intranet system when implemented, and with intranet technologies, these people can be involved not only in the abstract design but in the actual construction, increasing their actual and perceived investment in the system, and therefore the likelihood of their support.

Successful intranets require momentum to achieve critical mass. Gladwell (2000) refers to a tipping point, where phenomena, including technology adoptions, either succeed or fail. Gladwell notes three factors that determine the tipping point of a technology: the law of the few, stickiness, and context.

The law of the few reflects the fact that not all users or decision-makers are equally influential. Gladwell identifies three types of people that are particularly influential: connectors, who know and interact with a large number of people; mavens, who are considered experts in a given area; and salespeople, who will advocate for a position in which they believe. When implementing an intranet, identifying and engaging people from each of these groups is crucial to the project's success.

Stickiness reflects the extent to which something is memorable. The term stickiness is often used in reference to Web pages to describe how long visitors stay. Time spent by visitors is an easily gathered measure of user interest in a page or site.

Finally, context refers to the way in which information about the innovation or technology is disseminated. For instance, something advocated by members of the business units is likely to be more successful than something promoted by an e-mail from the IS department.

When the concept has been firmly established as viable, and there is support within the organization, then a representative group that will be more likely to predict success in the organization as a whole may be chosen.

Once the system is implemented, it is essential to eliminate other sources of the same information or service. This can be done drastically or gradually. For instance, callers to the help desk or human resources could be asked whether the employee has gone through the Web site. If she/he has not accessed the intranet before calling for support, IS or HR staff could offer to guide the caller through the site for resolution before providing an answer directly.

Maintenance and Management

A major component of a successful intranet is a plan for its control. The first obvious question is who should control it. Four common configurations have emerged: IS, corporate, human resources, and distributed. Any one of the models may work, depending on the goals of the intranet and the structure of the organization.

With the IS department in control of the intranet, the technology is likely to be well aligned with the existing systems and architecture, making it more reliable. It is also likely to have the most robust security. However, in terms of prioritization, the IS department is likely to be the worst choice for deciding what needs to be updated first. At a minimum, putting IS in charge adds an additional layer of control beyond the creators of the content. Technologies such as content management can make it more viable for business units to control the system.

In a corporate structure, there is a decision-maker within the organization who oversees the business units involved in the intranet. This person makes strategic decisions about the intranet. Tactical decisions may be delegated farther down the organization. The systems themselves may be built by the business units or the IS department, and secured by IS.

Although human resources applications are among the most common and heavily used functions of intranets, as more operational information is added, most human resource departments are ill equipped to manage the systems.

The distributed model is appealing because the subject matter experts can be put in control of the data. With content management systems supported by the IS department, this model can be viable as the business users are relieved of responsibility for design and security, but retain control of content.

A plan for maintenance of the system is crucial. At a minimum, such a plan should address how often the information should be updated, who is responsible for removing out-of-date information, how information will be archived, and how often the design should be revisited. Redesigns should have a formal structure and budget process (Fichter, 2001). Regular updates should also be made to access lists.

There should also be a disaster recovery plan commensurate with the importance of the intranet. Depending on the organizational value of the intranet, the plan for business continuity in the event of a disaster may range from periodic backups with a restoration plan, to off-site mirrored servers.

An acceptable use policy is an integral part of any intranet plan. Such a plan makes clear what is appropriate for the intranet, and may also include guidelines for Internet access as well. Although filters can be helpful in reducing inappropriate content, they are not a substitute for a well-articulated policy. For guidelines on creating an acceptable use policy, see Lichtenstein and Swatman (1997).

Cost/Benefit Calculations

Calculating the value of information technology has been the subject of extensive research over the past decade. The term productivity paradox is often used to describe the argument that despite rapid increases in spending on

information technology, there is not a concurrent increase in productivity.

Measuring the return on intranet investments poses the same complexities as other information systems: calculating all of the costs involved is difficult and attributing benefits to them is even more challenging. However, such calculations are feasible, and there is reason to believe that a well-planned intranet can be profitable (Healey, 2001).

Among the obvious and easily calculated costs of an intranet are the hardware and software required for the servers, including any support contracts, and development software purchased. The costs of development may be relatively easy to measure for IS personnel involved in the system construction if they are contracted, or if the internal IS shop tracks costs on a project basis. However, much of the construction will involve the time of those outside IS, and there may be no extant tools for tracking their time, nor easy access to data on the cost of their time. Network costs for running the intranet may not be easy to track, because both utilization and marginal cost would need to be calculated. A methodological change in how such costs are calculated could make the difference in positive or negative ROI. Training costs must be included, both for the trainers' time in development and delivery and for lost productivity for trainees.

Application service providers can provide all of the infrastructure and functionality of an intranet for an organization with only an Internet connection. Infostreet.com (<http://www.infostreet.com>), Intranets.com (<http://www.intranets.com>), and others offer a broad array of cost-effective intranet services to companies of all sizes.

The decision to outsource intranet development is much like the "make or buy" decision for types of information technology. Organizations must decide what, if any, aspects of the intranet should be produced or maintained outside the organization.

Whereas cost calculation is difficult, benefit calculation is even more difficult. Benefit calculation should include obvious direct cost reductions such as headcount, paper, and software licenses. One commonly used metric for efficiency is to credit the system for the prorated salary saved by using the intranet rather than the previous methods. However, this makes the assumption that all of the difference is saved. In many cases, the previous methods were not a complete loss; for instance, workers were doing other work while on the phone, or filled out forms during their commute. Not all of the recovered time will be used productively. Potentially more important than such bottom-line cost reductions are top-line enhancements in revenue. However, such improvements are harder to measure. Specifically, has the intranet contributed to better service, higher quality products, or improved time to market? If so, how much is that worth to the organization?

One excellent source of metrics for evaluating an intranet is the server access logs. All page accesses are automatically logged, along with the time and date of access, IP address of the user, which can be mapped to the specific intranet user, and the referring page, if any. These data may be analyzed to determine how employees are using the intranet and to identify potential enhancements. Estimates of the most and least popular pages, typical paths through the site, most used search terms, performance data, and other metrics are easily generated with simple analysis tools. This can be supplemented with direct surveys of users, online and through other channels.

Many surveys show intranet initiative failure rates of over 50%. Of course, it is important to keep this number in perspective, as surveys show similar percentages of all IS projects fail. These rates of failure may reflect unrealistic goals in some organizations, but often there are fundamental causes for failure. Table 1 outlines common

Table 1 Why Intranets Fail

Reasons for Failure	Measures to Ensure Success
Other channels are not shut down Electronic systems only save paper if the paper versions are eliminated. If an employee handbook is still printed, then the intranet version is simply an added cost, and confusion arises about which version is correct.	Commit to eliminating paper when intranet functionality is launched.
Intranet is not used Many intranet systems languish after expensive and extensive construction.	Monitor usage and identify issues early in the process.
Lack of maintenance Many intranets fall victim to good intentions. Intranets are often implemented, but are not made anyone's primary responsibility. There is often an initial burst of energy, but then no information is updated.	Make someone responsible for intranet content and management.
Poor planning Inadequate content Poor performance	Specify hardware to meet peak demand and optimize databases when appropriate.
Poor interface design	Involve people with formal training in systems design throughout intranet development.

reasons for failures of intranets and ways to prevent such failures.

Privacy

Intranets may contain a great deal of sensitive personal and organizational data. These clearly need to be protected. The fact that intranets are for internal use only offers some a false sense of security. This laxity can lead to greater risks if there is any exposure to external access.

Because the intranet is company property and all of the users are employees, companies have the right to gather and use any information they choose. Although this absolves companies of any legal obligation to reveal privacy policies, it is still advisable to publish a privacy statement modeled on those standard for externally accessible sites. For more on privacy policies, see chapter "Privacy Law and the Internet".

CONCLUSION

Intranets can be useful for organizations of any size to improve communication and information dissemination, and to lower costs. Powerful tools can be installed and configured quickly with relatively low investment. The technologies have standardized and are reliable and reasonably priced. Qualified, experienced personnel are readily available to build and maintain intranets. Success in intranet development and management simply requires the application of traditional business and information systems skills for establishing goals, planning, employing the proper architecture and technologies in response to business needs, and measuring outcomes.

GLOSSARY

Acceptable Use Policies How users may employ a system.

Content Management Systems Systems that use databases to store text, graphics, and other material to be displayed on a Web site, and then dynamically build pages based on previously designed templates.

Extensible Markup Language (XML) A language for describing the content and format of documents containing structured information.

Extranets Corporate systems containing sensitive data made accessible over the Internet to selected customers, suppliers, and business partners.

Hoteling An office configuration that allocates space temporarily on a first-come, first-served basis, similar to a hotel stay rather than assigning permanent space to workers who may not spend all of their time in the office.

Information Architecture The modeling of the structure of a Web site, including functionality and data, based on articulated goals.

Intranets Systems that use Web technologies such as HTTP, TCP/IP, FTP, and SMTP within organizations to facilitate communication and the distribution of information.

Knowledge Management The process of making explicit and codifying the knowledge in an organization.

Metadata The structure and content of data to facilitate future use of the data, particularly for searching.

Portals Web pages or sites that aggregate access to information and to other systems, serving as a starting point for users.

Reengineering The process of redesigning business processes to achieve radical improvements.

Self-Service Benefits The online management by employees of their human resource benefits administration without intervention by support staff.

Scripting Languages Programming tools for handling simple processing needs, two popular Web ones being Perl and JavaScript.

Syndicated Data Feeds that may be purchased to provide consistent or streaming updates such as weather, news, and stock prices.

INTRODUCTION

The Internet is a wide-area network that consists of thousands of organizational networks worldwide. The Internet became popular in the 1990s with the advent of the "World Wide Web." The Web provides information stored on servers connected to the Internet. Web browsers, such as Netscape Navigator and Microsoft's Internet Explorer, provide interfaces to interpret and display the Web pages. Documents accessible on the Web contain hyperlinks to move from one document to another. The benefits of the Internet include the ability to discover information more quickly and in larger volumes as well as increased opportunities for communication with individuals and groups. It is hard to imagine an organization today that does not have access to the Internet or does not maintain its own organizational Web site. In the early days of the Internet, an organizational presence on the Web provided a competitive advantage. Today, an organization's presence on the Web is an essential part of doing business.

The benefits of Internet technology and Web browsing led to the creation of organizational networks that provide restricted access for internal employees. The internal networks became known as "intranets," private enterprise networks that use the Internet and Web technologies for information gathering and distribution within the organization. By converting old applications or writing new applications for use on an intranet, organizations can eliminate dependence on a particular operating system/platform. The intranet has also become an effective communication vehicle for sharing information within the organization. The intranet provides easy access to internal information that can be published by departments within the organization. Other applications supported by the intranet include employee access to legacy systems, Web sites for human resources, payroll information, and even training programs. Intranets support collaborative processes between departments, such as scheduling, messaging, and discussion groups (Lloyd & Boyle, 1998). Intranets can also empower customer support center staff

with intranet knowledge management systems that result in improved customer satisfaction (Phaltankar, 2000). Through the use of intranets, organizations have reduced costs while also increasing employee productivity.

The intranet is typically protected from the public Internet by a firewall, a device that acts as a gatekeeper between the organizational intranet and the outside Internet. The firewall permits internal employees to access the public Internet, but it prevents outside users (the public) from accessing the internal resources of the organization.

A natural extension of the intranet would allow selected external entities to access internal organizational resources. An "extranet" provides a collaborative network that uses Internet technologies to extend intranet applications and services to selected external organizations, thereby creating a community of interest beyond the walls of the organization. In addition, providing remote access to the intranet permits employees who are off-site to access intranet services; for example, employees working from home could access intranet resources through the deployment of an extranet. The extranet is typically not available to the general public but rather it is limited to "strategic partners." These strategic partners may include suppliers, vendors, customers, or other organizations involved in collaborative research and development. Bringing suppliers, partners, and even customers into the information loop is critical to developing a company's quick response and strategic movement as it adapts to an evolving market environment (Baker, 2000). Figure 1 depicts an organizational extranet.

STRATEGIC USES OF EXTRANETS

The role and importance of extranets appear to be increasing. In a 1999 study by Forrester Research of 50 large manufacturers who had implemented extranets, 80% of the interviewees said they expected to extend extranet access to all of their business partners within two years (Orlov, 1999). Whereas over two-thirds of those surveyed were

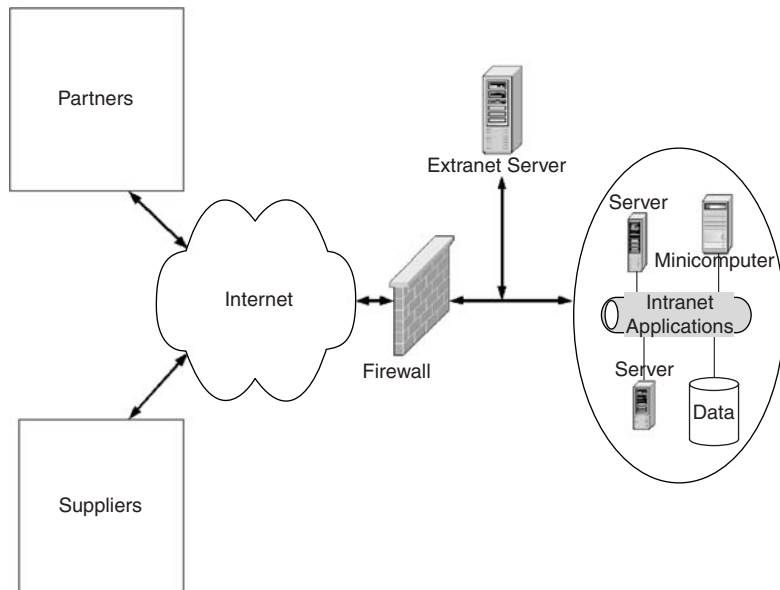

Figure 1: Organizational extranet.

already providing marketing and product specifications through their extranets, virtually all of the executives interviewed expected to expand their extranets to include online sales and sharing of inventory information. The manufacturers also anticipated a 32% reduction in support costs and a 17% increase in sales from their extranet applications.

Extranets provide several strategic advantages for organizations to extend their intranet applications to their business partners: business-to-business e-commerce, collaboration for research and development, and internal efficiency. Throughout the following section, several examples of extranets will be described to illustrate the application of extranets. The illustrations are intentionally drawn from a variety of industries to demonstrate the ubiquity of extranet deployment in business.

Business-to-Business E-Commerce

Business-to-business (B2B) e-commerce has taken off in recent years through the maturity of the Internet and the Web. Extranets provide a means for sharing existing intranet content for real-time communication between business partners. The extranet also provides external organizations with access to internal databases and legacy systems without necessarily connecting to the full intranet of the organization. Among the advantages of e-commerce, the extranet can be an effective tool in customer relationship management, supply chain management, and the electronic exchange of business transactions.

Customer Relationship Management (CRM)

Customer relationship management (CRM) involves integrating the customer service processes with a business, such as sales, marketing, customer service, and support. The idea behind CRM is to adapt business processes to a "customer-centric" business strategy. The deployment of an extranet achieves CRM strategies by providing customers with 24-hours-a-day, seven-days-a-week access to

internal information without the involvement of business personnel. For example, extranets can support business-to-business transactions, such as sales, while also providing information resources for products and services. Several customer service components of an organization could potentially be deployed through an extranet. Through improved customer relations, organizations can increase customer loyalty, improve their image, and even increase customer recognition for improved service (Ling & Yen, 2001).

In the health care industry, Humana has developed an extranet application for physicians, consumers, employers, and brokers that may well transform the company and establish it as a technology leader in health care (Lewis, 2001). The extranet site, Emphesys.com, provides a customer-centric approach toward delivering information in real time for various organizational constituencies. The extranet offers Web portals for doctors, patients, and others to share real-time data as well as to access information from a medical database. The extranet includes links for doctors to access the National Institutes of Health and other research resources. In addition, physician offices will have online access to patient data ranging from claims status to prescription histories. For health care plan members, the extranet application provides information regarding Humana's various health plans and allows individuals to review their medical records and prescription data. The extranet application will permit members to enroll in the health care plan of their choice and provide expedited plan authorization. Efficiencies are gained through the extranet, which will provide a member's enrollment eligibility information to doctors within four hours, compared to two or more weeks that had been necessary before the extranet.

Supply Chain Management

Supply chain management involves the integration of business processes and technology to optimize information and product flows among the business partners

within the supply chain, from suppliers to internal logistics, distribution, and customers. By providing suppliers with access to organization inventory systems through an extranet, the organization can implement “just-in-time” inventory replenishment policies. This provides a cost savings since the inventory is not maintained by the organization, but rather by the supplier. Extranets also provide the possibility of outsourcing the function of inventory management to suppliers.

Cisco Systems, a networking equipment maker, has deployed an extranet that links their component suppliers, distributors, and manufacturers to form a virtual, just-in-time supply chain (Koch, 2000). When a customer order arrives, typically through Cisco’s Web site, a series of electronic messages are sent through the extranet to their business partners to produce the requested equipment. Contract manufacturers are able to access the supply chain process through Cisco’s extranet that links to their manufacturing execution systems. On the other hand, Cisco has access to the contractor’s assembly line and, when the equipment is ready, a connection is established for Cisco to complete product testing through their automated testing software. When testing is completed satisfactorily, Cisco releases the customer name and shipping address so the contractor can complete distribution to the customer. Through this innovative use of extranet applications, Cisco reduces or eliminates entirely the need for inventory space and paper invoices.

Electronic Data Interchange (EDI)

Extranets provide an economical method for the exchange of business transactions between organizations. To gain efficiencies in business-to-business transactions, large organizations adopted strategies for electronic data interchange to conduct business transactions through private, long-distance networks. Electronic data interchange is a computer-to-computer exchange of business information in a standard electronic format between business partners. These networks, however, required propriety protocols and were expensive to implement. The high cost of investing in private networks and the hardware and software for EDI was prohibitive for smaller organizations that could not realize the benefits of this technology.

Unlike traditional EDI systems that required private networking solutions, the extranet uses the public Internet to exchange transactional data. By eliminating the costs of private networking technologies, an extranet provides an economical alternative for medium and smaller companies to exchange transactional data with other businesses (Pfaffenberger, 1998; Salamone, 2000). Because the extranet uses the public Internet and TCP/IP protocols, it provides an open platform that is not limited to only participants who use the same protocols, Internet service providers, or operating systems.

Collaboration with Business Partners

Communication up and down the supply chain with business partners is typically handled by telephone, fax, or e-mail. The extranet, however, provides the ability to get all parts of the business community working together and communicating in a way that is more timely and

effective (Meyer, 2000). By putting employees, customers, and strategic partners in closer contact, extranets promote real-time collaborative efforts and expedite the time to market for products. Because everyone involved in a project can see proposed changes in real time, the extranet can also support many more iterations of the design process than that possible with traditional techniques (Pfaffenberger, 1998).

The McCann Worldgroup is a marketing communications agency that uses collaboration software for internal and external communications to provide employees and clients with more effective ways to share work in progress (Maddox, 2001). The portal product, McWisdom, is both an intranet for internal communications and an extranet for client collaboration. By logging onto the secure area of the McCann Web site, employees as well as clients can review media plans, status reports on ad campaigns, and reports on campaign performance. The portal also provides clients with personalized views of projects in development.

Internal Efficiencies

The use of an extranet can simplify workflow and create internal efficiencies. By allowing authorized employees to access supplier extranets, for example, organizations can simplify processes for ordering supplies and products (Ling & Yen, 2001).

The implementation of an extranet for the Brunswick Corporation Boat Group, called Compass, has dramatically changed the way vendors, suppliers, and partners communicate. The extranet has reduced the time it takes to process boat warranty documents from 90 days to as little as 7 days (Chen, 2003). Moreover, the extranet facilitates processing warranty claims online, which can also reduce costs and enhance customer service. Prior to the extranet, processing warranty claims at Brunswick would take several weeks. With Compass, the processing time has been reduced to fewer than 10 days.

The Ketchum extranet speeds up interoffice communications and provides an efficient method for helping employees learn about new client businesses (Clark, 2001). Ketchum, a public relations firm, introduced MyKGN in March 2000, which allows employees to do research and work with customers online. In the past, research was done on a piecemeal basis. With the extranet, employees are able to research subject databases quickly and efficiently, while also working with clients in real time on such things as press releases and company logos. Ketchum has deployed over 400 collaborative client sites that are using MyKGN and estimates that its extranet application saves 90 minutes a week per employee. By 2003, Ketchum was to realize up to \$5.6 million in cash flow and productivity benefits (Clark, 2001).

Organizations can realize internal efficiencies by enabling customers or suppliers to search internal business databases to find and order products, check pricing and availability, and find product documentation without the intervention of employees within the organization. Beyond the benefits of providing faster access to information for customers, extranet applications relieve some of the demands on customer support service personnel

(Pfaffenberger, 1998). SunLife Financial, for example, recently deployed an extranet to attract insurance brokers to do business with them rather than their competitors. They hope the extranet will provide a competitive advantage while also holding down costs by allowing insurance brokers to obtain information without having to contact SunLife's call center. By making information available through the extranet, SunLife expects to be able to expand their business without having to increase call center resources (Messmer, 2000).

PLANNING AND IMPLEMENTING AN ORGANIZATIONAL EXTRANET

Planning and implementing an extranet require careful coordination between the organization and its business partners to identify the best business opportunities for an extranet, as well as an assessment of the potential risks to the organization once an extranet is implemented (Szuprowicz, 1998). Important issues to consider in building an extranet include defining the purpose and intended audience of the extranet and developing a content management approach, information privacy policies, and security strategies. Of these issues, clearly security of internal information that will be shared over the public Internet is a critical concern. However, defining the purpose and applications for the extranet is also critical if the extranet is to provide the organization with a competitive advantage. In addition, outsourcing the development of the extranet is a possibility for those organizations that do not have the time or expertise to invest in design, implementation, and management of an extranet.

Defining the Purpose for an Extranet

Developing an extranet involves a shift in management philosophy since traditionally internal corporate information was intended to remain internal. Changing the management philosophy will likely meet with cultural barriers among employees who may not be eager to share internal data with outside organizations (Harreld, 2000). People who controlled information in the past may feel threatened by an extranet approach that eliminates information silos and potentially the power bases of some individuals. It is a management imperative to anticipate and resolve internal opposition in order for the development and implementation of an extranet to be successful; in fact, failing to recognize and address resistance is one reason for extranet failure (Pfaffenberger, 1998; Szuprowicz, 1998).

In deciding to implement an extranet, the organization must have a clear purpose in mind, which in part requires a determination of the target audience. With extranet applications, the target audience is typically an established business partner with whom the organization is looking to make doing business easier, faster, and more economical. Without a clear understanding of the purpose and audience for the extranet, content developers will be unable to create a satisfactory site.

Although extranet design will be specific to the organization and its business opportunities, extranets tend to fall into three general categories: publishing, collaboration,

and transactional (Pfaffenberger, 1998; Szuprowicz, 1998). Publishing extranets are intended to make internal documents available to external users. These documents might include technical documentation, training materials, specifications, and research data. Publishing extranets rely on servers and scripts to database applications for document retrieval. The primary focus of a publishing extranet is cost reduction by eliminating paper, mailing and faxing expenses, and even reducing customer service center expenses (Szuprowicz, 1998).

The easiest to implement, publishing extranets do not typically demand extensive privacy or security considerations. In many cases, the organization controls the content of what is published on the extranet and can therefore consider the issue of privacy of information when posting content. The security of the extranet can be as simple as a login procedure where authorization to view content is controlled by the identification of the user.

Collaboration extranets are designed to provide interaction between internal employees and external partners. The focus of collaboration extranets is to reduce the time to market of products by accelerating the product design cycle. The extranet examples cited earlier from the McCann Worldgroup and Ketchum facilitate communication between employees and clients in planning, designing, and reviewing marketing strategies in real time (Clark, 2001; Maddox, 2001). These extranets are more complex than publishing extranets since they must enable two-way interaction with outside users in addition to document sharing.

Issues of security and privacy become more complicated with collaboration extranets. From a privacy standpoint, the organization must ensure through privacy policies the ownership and protection of intellectual property. In addition, added efforts must be taken in extranet development to ensure that outside clients and partners can only access what the organization intends. Beyond standard security and password access for authorization, the content of the extranet should be partitioned to avoid outside access to sensitive information (White, 2003).

The most advanced extranets are transactional in nature and facilitate electronic commerce. These extranets are designed to support online transaction processing (for example, sales) and typically provide EDI services through the public Internet. Transactional extranets are complex to design and implement and require more extensive security, as discussed later in this chapter.

Inasmuch as the design of an extranet includes both an analysis of the business processes and the technical logistics, individuals who possess an understanding of the business as well as technical experts will need to work together to define the extranet applications, who will be invited to participate from the outside, and how the extranet will be deployed. Failure of extranet projects is often attributed to insufficient involvement of both business and technical people working together on the extranet project design (Covill, 1998).

Content Management Strategy

Once the purpose for an extranet is established, developing and managing content on the extranet become

priorities. Unlike intranets where content is often developed in a distributed fashion for internal use, content on an extranet is shared with strategic partners and customers outside of the organization. In fact, simply providing access to the intranet, although expedient for implementation, may be inappropriate for extranet content and client access (White, 2003). A successful extranet will require a clear corporate identity, look, and feel (Baker, 2000). Because of this outside access, the content must be presented in a useable form, and links to resources must be operable. If information on an extranet site is incomplete, outdated, or missing, the organization's credibility and possibly sales will be lost (Reimers, 2001).

The importance of content management cannot be overemphasized. Failures of extranet sites can often be traced to insufficient content management and extranet site development. Successful extranets ensure that their sites offer valuable content and functionality so the users can find what they are looking for quickly. In addition, the extranet site must be fast and reliable.

Selecting products and services for developing and managing the content of an extranet site is a real challenge because of the evolving state of technology. Software tools, such as those for database integration, auditing, and performance evaluation, will be required for Web authoring and content management of the extranet site. Forrester Research, in their rankings of content management vendors in March 2001, suggested three key players should be identified when selecting content management software (Wilkoff, 2001). First, the dominant content source should be identified since this source will require high integration with the content management application. Second, content managers should be determined. Identifying the right content management software will depend on whether the content is going to be managed by a centralized information technology department or delegated to nontechnical business users. Finally, the audience of the content should be identified. If the target audience consists of consumers, then they will require greater performance than typical extranet users will. If the target audience of the extranet is buyers, on the other hand, then they will likely require personalization of content.

In developing extranet applications, consideration should be given to how much of the intranet content will be mirrored on the extranet site. Duplication of extensive databases and applications on an extranet can create problems with synchronizing the data stored on the intranet behind the firewall with the data provided on the extranet. For this reason, organizations may consider providing trusted partners with direct access to selected intranet servers, although this is more often the exception than the rule because of obvious security concerns.

From a security and privacy of information perspective, careful attention must be given to the types of information that will be provided to strategic partners. Related to privacy concerns, the organization must assess how its information will be used and by whom. Agreements with external partners should carefully outline the acceptable uses of extranet information and privacy of use expectations (Hallawell, 2001).

Beyond privacy policies, extranet developers must take care to ensure that sensitive information cannot be

inadvertently accessed from documents freely provided through the extranet. An inadvertent hyperlink in a public document, for example, might provide outside clients with sensitive information not intended for distribution (White, 2003). To avoid these possibilities, intranet content may need to be rewritten for publication on the extranet. From a security perspective, developers may consider maintaining extranet content on a separate server that prohibits access to intranet documents and applications.

Outsourcing the Extranet

For organizations that do not have the internal expertise, the time, or the interest to develop and manage an extranet application, extranet service providers may provide a solution (Harreld, 2000). Outsourcing the extranet design, implementation, and management provides the organization with the expertise needed to deploy an extranet while freeing the organization to focus on content management concerns.

Several organizations provide outsourcing resources and technology for deployment of organizational extranets (see, for example, Szuprowicz, 1998). These services typically include extranet development, integration of existing intranets, facilities management, and security. Larger Internet service providers now provide extranet hosting services.

In evaluating outsourcing vendors, management should give serious consideration to security provisions and capabilities utilized by the application service provider. These precautions not only include security of data, but also security precautions to prevent other organizations who utilize these extranet services from accessing organizational resources (Pipping, 2002). Organizations considering outsourcing to extranet service providers would be well advised to ensure that all organizational data maintained by the service provider are proprietary and confidential to the organization. In addition to evaluating security precautions, organizations should also review and evaluate the corporate privacy policy of the potential service provider (Hallawell, 2001).

SECURITY AND INFORMATION PRIVACY

Security of the extranet and use of information are critical aspects of extranet development, which extends to both the organization and its partners (Phaltankar, 2000). Security issues must be considered through the design, implementation, and management of any extranet applications.

Developing a security plan for an extranet application should begin with a risk assessment to identify the potential sources of threat to the network, how likely these threats are to occur, and the investment (cost) in security that will be required. The level of security investment will vary depending on the nature of the extranet application, the threats of intrusion, and the sensitivity of the information content that will be shared through the extranet application.

Risk Assessment

The deployment of an extranet, as described earlier, can provide organizations with competitive and strategic advantages through business-to-business e-commerce, collaboration for research and development, and internal efficiencies. However, extending internal resources beyond the intranet walls introduces risk to information assets. Organizations must consider the risks associated with extending internal information to external business partners. Stated simply, additional levels of risk or network vulnerability will be introduced by extending access to corporate partners via an extranet application (Maier, 2000; Marcinkowski, 2001). As part of the risk assessment, the organization should consider the levels of security already in place for internal systems. Whereas intranets are typically protected behind firewalls, extranet applications will expose intranet applications to the public Internet. Therefore, internal security policies will most likely require some updating to extend authorized access for outside partners to the organizational intranet.

Through risk assessment, the organization must weigh the potential costs it is willing to accept in terms of economic loss of revenues, loss of reputation with customers, or even the costs of criminal prosecution from the compromise of information protected by federal privacy laws (Marcinkowski, 2001). As the value of the information asset rises, the level of risk aversion will increase, which will increase the level and cost of information security.

Another trade-off in risk assessment is security precautions versus performance of the extranet application. As a general rule of thumb, as security requirements are increased, the level of extranet performance will be decreased. Thus, risk aversion and performance issues will become trade-offs in designing security policies and procedures (Campbell, Calvert, & Boswell, 2004). Maier (2000) suggests that organizations consider the value of data and their location within the network, the method of data transmission that will define the degree of exposure between the organization and the external sites (for example, Internet, private network, wireless transmission, virtual private networks), along with the number of users and growth rate of the extranet that will provide guidance for performance expectations.

In considering risk assessment, the organization must also consider the partners for whom the extranet will be provided. Beyond the security of using the public Internet for business transactions, establishing business partnerships involves careful planning as well. Information technology professionals can design security systems to protect intranet resources from hackers on the public Internet. However, with extranets, the greater security threat may well be from within—disgruntled employees or business partners who have access to internal information (Marcinkowski, 2001). An organization's extranet partners may come and go, and therefore consideration must be given to guarding against potential misuse of internal information. Moreover, the security of the extranet may be compromised by insufficient security at the partner's site; that is, a security breach at a partner's site also exposes the organization's internal resources made available on the extranet (Schwartz, 2000). Weiler (2001) suggests several steps to safeguarding internal resources:

- Verify the security of internal systems before exposing them to extranet partners;
- Develop contracts between business partners that address expectations, process, hiring background checks, and security administration;
- Develop human resources notification systems for events such as employee termination;
- Examine security administration systems;
- Increase funding for security-awareness programs that will also be shared with business partners; and
- Plan strategies based on risk management and emerging business requirements rather than on technology.

Information Use and Privacy

In addition to the protection of information assets, organizations considering extranet partnerships must be concerned with how partners will use corporate information accessed through the extranet. Corporate partnerships can be dynamic and will likely change over time. Moreover, there is little control that can be exercised over the flow of information from one partner to another. Organizations need to consider the type of information that will be shared with partners, and these partnerships should be defined carefully. It seems reasonable, for example, that different partners might receive different information through extranet applications based on the type and value of the partnership. Stated another way, the organization should grant information that is important and necessary for the success of the partnership, but nothing more.

Extranet planners should also incorporate organizational privacy policies. Hallawell (2001) suggests that corporate privacy policies should be defined more broadly to describe how corporate information will be used and gathered within the extranet framework. Questions that should be addressed include how much data should be shared with corporate partners and how competitive and proprietary data that an organization does not want to share can be separated from information necessary for the partnership systems to operate. Security policies and procedures should include provisions for the protection of content and information provided through the extranet applications. Such policies and procedures should be endorsed by corporate partners as a necessary condition for access to extranet applications.

Goals of an Extranet Security Plan

The goals of a security plan will include access control, authentication, confidentiality, and data integrity (Meyer, 2000; Pfaffenberger, 1998). These goals, such as access control and authentication, become critically important for extranet deployment where access to the extranet is absolutely limited to specific individuals and/or organizations; thus, security procedures must eliminate the anonymous nature of the Internet. Moreover, extranet security steps must limit outside users to just that portion of the intranet that is necessary to conduct business over the extranet. The following sections discuss the goals of a security plan.

Access Control

Access control provides or denies access to the network and is usually implemented through deployment of a firewall. A firewall alone, however, is not a sufficient security strategy. Providing confidentiality of information while it is in transit over the public Internet can occur through encryption strategies. User authentication can take place in part at the firewall, but it is usually handled by the application service. User control, however, is almost always handled by the application service (Meyer, 2000).

Authentication

Authentication defines the external population that is permitted to access the extranet and ensures that the external interaction with the extranet is coming from an authorized course. The protection of extranet resources can be described by the model of authentication, authorization, and accounting (AAA). This model first and foremost requires the positive identification of the outside client or partner (authentication). Through authentication, the individual is granted access to resources (authorization), which is then monitored through an accounting process that records activity of the individual for later review if necessary. Although all three steps in the model are important, clearly the model will break down if authentication is not handled correctly. Authentication requires sufficient safeguards proportionate to the information assets that the organization seeks to protect (Campbell et al., 2004).

Assigning account names and passwords to extranet users is the typical method for implementing authentication. The identity of an extranet user is then confirmed when she presents both the account name and password to the host application. Some extranet applications have incorporated a single sign-on option that allows users, once authenticated, to move from one application to another without requiring additional usernames and passwords. Eliminating multiple usernames and passwords for different applications can reduce the potential security risk of users writing down their passwords as well as the potential for users to forget passwords.

Static passwords are not only the simplest way to control access, but also the least secure (Covill, 1998; Szuprowicz, 1998). Moreover, the password if transmitted over the Internet in text (versus encrypted) can be compromised by a password "sniffing" application. A security policy can resolve this potential security breach by using one-time-only passwords that expire once a user has been authenticated or encrypting the password before transmission over the Internet (Phaltankar, 2000).

The challenge handshake authentication protocol (CHAP) provides added security by encrypting the logon information. It has the added benefits of first establishing a trusted relationship between the authenticating server and the peer through a challenge-and-response sequence. Moreover, once the connection is successfully established, the authenticating server will continue to send new challenges to the peer at random intervals to ensure that it is still communicating with the same trusted peer (Campbell et al., 2004).

Additional options for authentication are available depending on the level of security required for the extranet.

Source address authentication, for example, would authenticate an extranet user based on the IP address of their Internet connection (Maier, 2000; Phaltankar, 2000; Wack, Cutler, & Pole, 2001). This technique is typically used on intranets to restrict access based on those IP addresses that are internal to an organization. This method of authentication could be sufficient for small-scale extranets with few external organizations where the static IP addresses are known. This technique would not be ideal for global access to an extranet where the IP address of the user is unknown in advance.

Other forms of authentication include tokens, digital signatures, and smartcards to establish the identity of users (Pfaffenberger, 1998; Phaltankar, 2000). Token authentication schemes typically involve two levels of authentication. The first requirement is a personal identification number (PIN), whereas the second form of authentication is a number displayed on the token card. For example, the SecurID card from Security Dynamics displays a unique number every 60 seconds, which in combination with the user's PIN forms a unique password. The advantage of using tokens or other authentication schemes is that authentication requires two pieces of information: something from the card and something from the user. Without both the card and the valid PIN, authentication will not occur. Of course these additional techniques require additional investments in hardware and software to manage user accounts and for password synchronization between the extranet server and the user's token card (Phaltankar, 2000).

Confidentiality

The security goal of confidentiality requires strategies to protect information from unauthorized disclosure to third parties. Corporate privacy policies, discussed earlier, provide one means of ensuring that partners are aware of their obligation to protect information maintained on the extranet. However, from a networking standpoint, extranet developers must also consider the protection of data in transit over the public Internet.

Privacy of communication with the extranet and exchange of data are typically implemented through an encryption technique. Encryption is the process of scrambling data before transmission over the public Internet. Several techniques, such as the public and private-key cryptography systems developed by RSA (see <http://www.rsasecurity.com>), are available.

Exchanging information over the public Internet encounters the risk of alteration during transmission. Although encryption is an effective strategy for protecting the confidentiality of information during transmission, it does not prevent interception and alteration or guarantee that the data packets are received intact.

Data Integrity

Data integrity provides the assurance that the data transmitted over the public Internet are not modified in any way. Data integrity can be implemented by cryptographic checksums and hashing (Phaltankar, 2000). Hash functions create a fixed-size hash value that is a compressed, nonreadable form of a variable-length data message. One-way hash functions are preferred because the hash value

cannot be reversed to reconstruct the original message (Covill, 1998). If the same hash value is not generated by the receiver when the data are received, the integrity of the data packet becomes questionable.

For most applications requiring privacy, encryption techniques such as a secure sockets layer (SSL) connection will provide sufficient data privacy and integrity. Virtually all Web browsers recognize the SSL protocol, among others, for data encryption. An organization can provide its business partners with access to an internal application via SSL and password authentication, similar to the way e-commerce Web sites currently interact with consumers (Wilson, 2001).

For sensitive applications or the exchange of strategic data, organizations may require additional security precautions, such as the creation of virtual private networks.

Virtual Private Networks (VPNs)

A virtual private network is a technique of implementing secure connections over the public Internet through encryption and authentication schemes. VPNs can also be used to provide secure access to organizational networks for employees who are remote from the organization or perhaps telecommuting. The creation of private networks is also possible through leased lines, X.25 packet-oriented public data networks, or other private IP networks available from major service providers. The use of VPNs is becoming increasingly popular because of the cost savings over implementing private networks or remote access facilities, such as modem pools (Pfaffenberger, 1998; Salamone, 2000).

VPNs require firewalls that support VPN technologies. The VPN adds additional protection for the confidentiality and integrity of data transmitted over the Internet by using additional protocols and encryption. The VPN creates a "tunnel" through the Internet that establishes a secured connection from the user site to the extranet (see Figure 2). Different protocols are available for implementing a VPN. One popular set of protocols is known as IPSec, the Internet security protocol (Wack et al., 2001). Other current VPN protocols include point-to-point tunneling

protocol, which is a Microsoft standard, and the layer 2 tunneling protocol.

The state of VPN technology and standards for communication protocols are still evolving. The disadvantage of implementing a VPN solution is that it almost always requires the same vendor hardware and software product on both ends of the connection, from the organization hosting the extranet and its business partners. It may not be possible, therefore, to require an organization's partners to use one particular vendor's VPN application (Wilson, 2001).

Protocols such as IPSec and point-to-point tunneling VPNs present some problems in managing network access translation (NAT) traversals, access control for traffic within the secured tunnel, and client management (Fratto, 2003). Although site-to-site networking has been effectively implemented through IPSec VPNs, the same degree of success has not been achieved when deploying remote access VPNs to support end-user access. One potential solution is to deploy SSL VPNs since the SSL encryption protocol is available today within virtually all Web browsers. Thus, users can connect to the extranet with their Web browser as the client. The SSL VPN provides connectivity to a growing mobile workforce and may prove more cost-effective in terms of managing remote access authentication (Piscitello and Phifer, 2003).

Demilitarized Zones (DMZs)

In addition to these security mechanisms, the placement of the extranet within the organizational network can affect security. Early implementations of extranets provided direct access to intranet servers to select outside parties. More recently, a "middle ground" between the public Internet and the internal intranet has become the home of the extranet. This middle ground, called the demilitarized zone (DMZ), is a physical space between the public Internet and the firewall of the intranet (Wack et al., 2001). By placing the extranet in the DMZ, the intranet is protected from potential security breaches by outside parties, from both business partners and potential hackers. Figure 3 depicts an organizational extranet within the DMZ. The DMZ is also used for public access servers, and

Figure 2: Virtual private network.

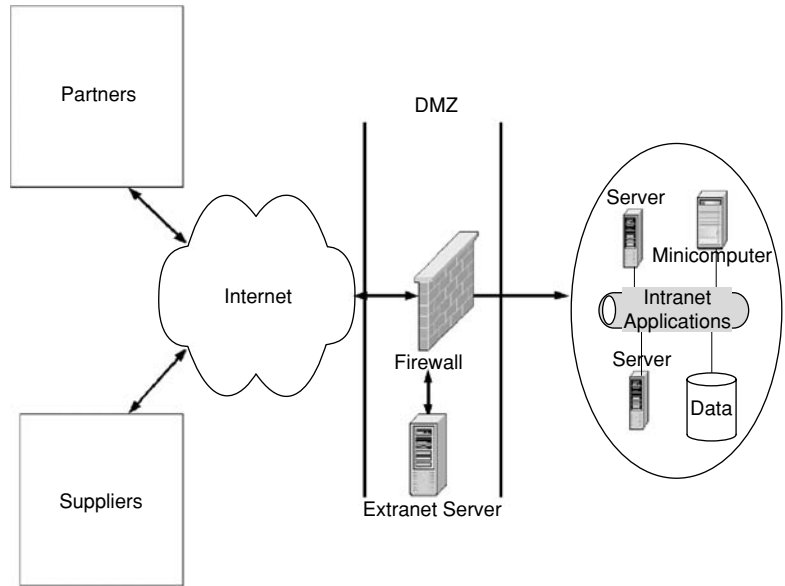

Figure 3: Organizational extranet within DMZ.

again restricts the intranet to internal access. In the single firewall example shown in Figure 3, the firewall provides security protection for both the intranet and the extranet. This configuration will support access from the intranet to update information on the extranet server. In this DMZ design, inbound traffic from the Internet to the extranet is allowed through the firewall and can be rejected if destined for the intranet. Because of the placement of the extranet behind the firewall, two-way traffic is permitted between the intranet and the extranet. This design would allow for updating of a Web server on the extranet, for example, from the internal network.

The dual firewall DMZ design would be better for larger operations that require the capability to offer multiple types of Web access and services to both internal and external networks. Figure 4 depicts a dual firewall organizational extranet within a DMZ. In this design, a true DMZ has been established as a “middle ground” separate from

both the internal and external networks. This design is best used when multiple servers or hosts are required to provide more than one type of service and at multiple levels to internal and external networks, such as e-mail and Web servers.

Compared to the single firewall DMZ, the dual firewall design in Figure 4 requires more hardware and software for implementation, as well as greater effort in configuration and monitoring. However, this design provides the organization with greatest ability to control traffic between the external network, the extranet, and the internal network (Shimonski, et al., 2003).

CONCLUSION

Extranets can fundamentally change how organizations share internal resources and interact with outside suppliers, customers, and strategic business partners.

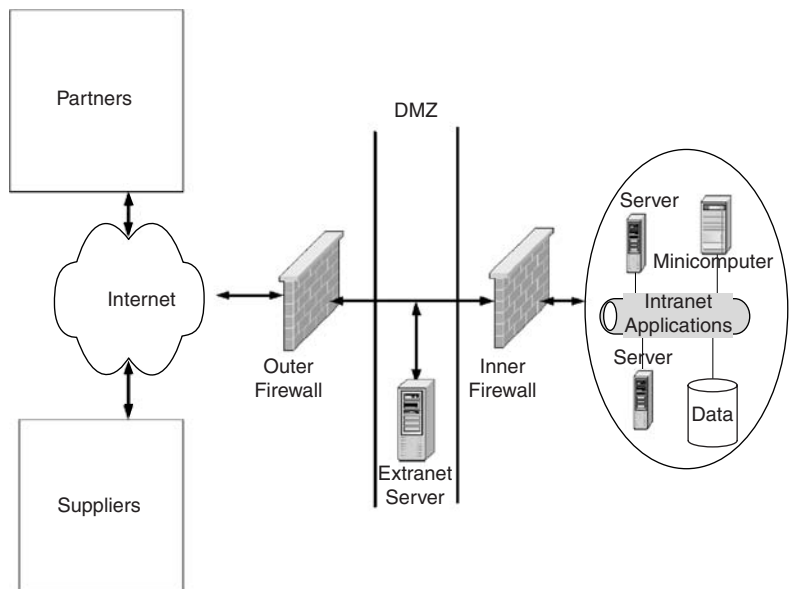

Figure 4: Dual firewall organizational extranet within DMZ.

The implementation of an extranet can be effective in developing tighter linkages in supply chain management and customer relationship management. The current trends suggest an increasing movement toward developing these linkages through extranet applications. Extranets provide a cost-effective means to improve collaboration and decrease the time to market for new products. Moreover, extranets can increase internal efficiencies within the organization. As the extranet examples have shown, applications for extranet deployment are not isolated to one type of industry. Extranets can be effective in seizing a competitive advantage in virtually any type of industry.

The implementation of an extranet solution for any business requires careful planning and a shift in business and management philosophy. Moreover, opening the corporate intranet requires careful assessment of security and privacy precautions, defining the external audiences who should have access, and establishing policies for content management and organizational access.

GLOSSARY

Demilitarized Zone (DMZ) A computer host or small network placed in a “neutral zone” between a public network (such as the Internet) and a company’s private network.

Electronic Data Interchange A computer-to-computer exchange of business information in a standard electronic format between business partners.

Extranet A collaborative network that uses Internet technology to extend intranet application and services to selected entities external to an organization, such as suppliers, customers, or other businesses that share common goals.

Firewall A device that protects internal networks from unauthorized access from external sources, typically the Internet.

Internet A global network of interconnected networks, providing connection for private and public networks in one cohesive unit.

Intranet A private enterprise network that uses the Internet and Web technologies for information gathering and distribution within an organization.

Virtual Private Network A technique of implementing secure connections over the public Internet through encryption and authentication schemes.

INTRODUCTION

The focus of business-to-business e-commerce (e-B2B) is on the coordination and automation of interorganizational processes via electronic means. E-B2B is conducted among business organizations and is a subset of all e-commerce activity including, among others, business-to-consumer (B2C), business-to-government (B2G), and consumer-to-consumer (C2C) activities. Many authors today identify e-commerce as one component of a more general form of electronic business termed e-business. The term e-business is generally used to identify the wider context of process automation that occurs between businesses, including automating provision and exchange of services, support, knowledge transfer, and other aspects of business interaction that do not necessarily result in the execution of a buy or sell transaction. Within this chapter the terms e-commerce and e-business are used interchangeably and refer in either case to the wider context previously defined.

With a reported value of \$873 billion in 2002 and an estimated growth rate of 75% over the preceding years (Schifrin, 2003), e-B2B continues to be an integral component of the Internet economy. Today, organizations are investing heavily in e-B2B initiatives where they account for more than 20% of information technology (IT) budgets (Kearney, 2003). With these sustained rates of growth, e-B2B is likely to remain a significant driving force in the global economy for the foreseeable future. This growth, however, is not without risk. As businesses move to electronic forms of business interaction, cybercriminals are taking advantage of unsophisticated organizations and unsecured machines to perform low-overhead, high-profit crimes (Gartner Group, 2003). The level of activity and pervasiveness of cybercriminal activity is astounding. The Computer Security Institute, an FBI watchdog for computer-related criminal activity, reports that 56% of all U.S. companies surveyed in 2003 experienced some sort of financial loss resulting from cybercriminal

activity. These losses occur across all sectors and sizes of organizations and result from a variety of criminal activities including theft of intellectual property, denial of service attacks, virus attacks, and financial fraud as the most widespread criminal activities (CSI, 2003). Evidence suggests, however, that financial losses are much higher and more widespread than actually reported as organizations are reticent to reveal the true extent of criminal activity, fearing a general loss of confidence in their systems and business processes. Indeed, of those organizations surveyed, fewer than 30% of incidents occurring in 2003 were reported to law enforcement (CSI, 2003).

FOUNDATIONS OF B2B E-COMMERCE

Although commonly regarded as a new business development, electronic commerce has been practiced in one form or another for over a century. The first identifiable forms of electronic commerce used early telecommunication systems, allowing organizations to conduct business deals by telephone, telegraph, and telex (Li, 2003). Achieving current levels of e-business participation, however, required several key developments including innovative application of information technologies, high-speed communication mediums suitable for transmitting e-B2B-related information, business and regulatory environments suitable for sustaining electronic business processes, and last but not least, a set of motivating forces driving organizations to consider forms of e-business as a means of achieving competitive advantage.

Innovations in Technology

The technological foundations of modern e-B2B have been developing over the past 30 years and reflect innovations in telecommunications and computer communications protocols and methods. During the 1970s, electronic funds transfer (EFT) and electronic data interchange (EDI) were communication standards designed to enable

business exchanges over private computer networks. The costs of participating in these initial systems were high. Early EDI systems, for example, required expensive specialized data-processing equipment and dedicated telecommunications facilities, prohibiting participation by all but the largest businesses. Organizations that could afford to adopt these early electronic B2B systems could realize several benefits including greatly reduced labor costs and processing time for recording business transactions as well as vast increases in data quality and accuracy.

Private computer networks requiring dedicated telecommunications facilities, initially the only option for e-business, are still in use today and provide a secure medium for exchanging electronic data. Innovations in telecommunications, information security, and data encryption methods have made other technologies available for organizations, often at a lower cost. Value-added networks (VANs), for example, are semiprivate communication networks usually managed by a third-party provider. VANs enable companies to share business information using commonly agreed-upon data transmission and formatting standards such as EDI. E-business has also been quick to adopt the public Internet as a general purpose communication medium. The Internet provides high data transfer rates and significantly lower operational costs relative to other electronic communication systems, making it an affordable and viable alternative for organizations of all sizes. The Internet, however, is generally considered insecure as data moving over the system can be intercepted and read by anyone with access to it unless the data have been previously encrypted.

Virtual private networks (VPNs) are a form of secure communication using a combination of data encryption and specialized data transmission methods designed to protect proprietary business data as they move between business systems over the public Internet. This protection allows companies to use the public Internet as if it were a secure private communications system, facilitating development of low-cost extended private networks (extranets) that can connect businesses and business partners regardless of their geographic separation.

Adopting the Internet as a communications platform to support e-business processes first requires developing commonly agreed-upon methods for transferring business data between organizations and for managing interoperability of business systems. Today, there are hundreds of protocols and standards governing almost every aspect of using the Internet to transmit and translate business data. Some of these protocols and standards are proprietary and associated with vendor-specific systems whereas others, such as extensible markup language (XML), are designed to be interoperable, allowing them to be understood and processed by a wide variety of heterogeneous computer systems. Some of these new and emerging standards build on earlier protocols such as EFT and EDI. When coupled with system-independent data communication protocols such as the Internet's TCP/IP, these early data translation protocols enable data to literally transcend organizational and technological boundaries. For example, although EDI documents can still be sent over private lines, it is also possible to complete the same transactions using the Internet and XML at a fraction of

the cost of traditional EDI. This provides several benefits for companies. Those companies that invested heavily in early technologies such as EDI can maintain their original investment and are still able to participate in modern e-business initiatives. On the other hand, companies that could not afford such early technologies are now able to engage in intraorganizational data exchange with greatly reduced initial investments in technology.

Innovations in Business Processes

Greenstein, O'Leary, Ray, and Vasarhelyi (2005) identify the recent surge of e-B2B activity as a progression of an evolving process that has been evident throughout the industrial revolution. The authors attribute the rise of e-business as a response to dramatic improvements in both information processing and telecommunications systems that have facilitated revolutionary change in organizational business processes. Centered on the Internet, this latest technological revolution enables businesses to automatically place orders, send quotes, share product designs, communicate sales projections, and collect payment using electronic means, providing the potential for reducing operating costs, shortening time-to-market for new products, and receiving payment faster than ever. Modern computers, able to process thousands of transactions per second, can significantly reduce the time necessary to process business data, allowing organizations to share business information almost instantaneously. Moreover, businesses willing to commit to this digital economy can partner with other similarly focused businesses, creating tightly integrated supply chains and developing networks of loyal customers and trading partners who, research shows, collectively outperform their competitors.

Norris, Hurley, Hartley, Dunleavy, and Balls (2000) identify three stages that established companies go through as they evolve from a traditional organization to a mature e-business. Early e-B2B activities focus on increasing efficiencies of sales and/or purchasing processes while minimizing disruption to existing organizational culture and business processes. The second stage of adoption focuses on using electronic information technologies to integrate supply chain activities and streamline business processes. This stage is often aimed at reducing operating costs and increasing effectiveness of operations beyond sales and purchasing. The last stage involves developing strategic, tightly coupled relationships between companies in order to realize mutual benefits and joint rewards afforded by an optimized supply chain.

E-business strategies are not, however, limited to existing organizations. The Internet has engendered a number of new and innovative businesses dependent on the Internet as a primary means for generating revenue. The dot-com boom of the late 1990s, so visible in the B2C sector with companies such as Pets.Com and WebVan, carried over into the B2B sector. During this time, large numbers of highly innovative, technology-savvy, Internet-focused companies became immersed in all areas of e-B2B activity. These new economy companies relied on digital processes and often purely digital products and services. Online B2B exchanges, for example, emerged as

a multibillion dollar industry virtually overnight, filling a need for increased speed and expediency of interorganizational electronic business transactions. By the year 2000, an estimated 2,500 online B2B exchanges, serving a wide variety of industries such as electronics, health care, chemicals, machinery, food, agriculture, construction, metals, printing, and medical lab equipment, were available (Wichmann, 2002). Like their B2C counterparts, however, many of these B2B dot-com companies failed because of weak business models and misguided, overzealous venture capital. Today, fewer than 150 of these exchanges remain.

Supply chain integration is another area that has engendered significant e-B2B activity. Companies acting as intermediaries provide technology and services necessary to support electronic supply chain management. Manugistics (<http://www.manugistics.com>), for example, successfully adapted its more traditional technologies and services to operate within the emerging e-business environment and now facilitates electronic supply chain operations across a broad array of industries. Elogex (<http://www.elogex.com>), on the other hand, is an example of a brand new, technology-savvy company developing supply chain management technology and services specifically for a narrow industry focus: consumer goods, food and groceries, in this case.

Benefits of B2B Electronic Commerce

Greenstein et al. (2005) identify four specific, measurable benefits directly related to investments in e-B2B systems integration initiatives:

- Improvements in data accuracy;
- Reduced cost per transaction;
- Increased speed of access to important information; and
- Enhanced management decision-making effectiveness.

Additional benefits including reduced risk, better planning and inventory management, strengthened relationships with business partners, and an increased ability to integrate with new business partners in a variety of interesting and innovative ways are also realizable by organizations willing to invest in e-business technologies.

Recent changes in the banking industry provide an example for understanding the potential benefits that can be achieved using electronic automation. The U.S. Federal Reserve along with six other central banks and sixty-six major financial firms implemented the Continuous Link Settlement System. This system automates trading, and settlement of foreign currency exchanges amounts to approximately \$300 trillion each day. Traditionally, as a trade is being conducted, two banks agree on an exchange rate and wire the money to each other, a process that can take two to three days to complete. During the time between a trade being agreed upon and completed, interest is lost and events can change the value of a country's currency, ultimately affecting the final exchange rate. In extreme cases banks have gone bankrupt (Colkin, 2002). Accordingly, the risk associated with transaction latency justifies the \$300 million technology investment made by the banking industry.

Small to mid-sized organizations, in particular, have significantly benefited from the Internet revolution as many of the barriers to participating in e-business have been removed. The financial overhead associated with implementing early e-business systems such as EDI was significant and out of reach of all but the largest corporations. Today, a combination of the Internet and reduced real costs of computer systems and software over the past decade has enabled companies of all sizes to develop e-business strategies. In fact, the inverse relationship between size and agility provides small to mid-sized firms some competitive advantages in e-business.

B2B STRATEGIES

E-business strategies are often classified by the nature of the interaction taking place between business partners. Four strategies that may be identified using this approach are e-selling, e-procurement, e-collaboration, and e-markets. Within each of these strategies we can further identify the vertical or horizontal industry focus of the participation and whether intermediaries are involved. Companies with a vertical focus usually operate within a single industry such as the automotive, chemical, energy, or food-retailing industries. In contrast, companies with horizontal focus provide products and/or services across a wide range of industries. Office supplies and computers are examples of products often regarded as horizontally focused. Intermediaries in e-B2B are most often associated with e-markets and electronic auctions where one company, the intermediary, operates as a broker allowing other companies to buy and sell products and services using technological infrastructure provided by the intermediary.

E-Selling

E-selling is concerned with the direct sale of products and services to other businesses using automated means. The business model is similar to the B2C direct-sale model but differs in that B2B interaction often requires prenegotiation of prices, catalog items, and identification of authorized users.

Two major methods for e-selling are in common use: electronic catalogs and electronic auctions (Turban, King, Lee, Warkentin, & Chung, 2002). Electronic catalogs can be customized in both content and price for specific businesses and can be coupled with customer relationship management software such as SAP's Internet Sales Solution (<http://www.sap.com>) to provide personalized, business-specific content delivery. Dell Computers (<http://www.dell.com>) and Staples (<http://www.staples.com>) are examples of companies providing direct sales to other businesses over the Web, allowing businesses to set up accounts and customize the content available for online purchase. Cisco (<http://www.cisco.com>) is another example of a company that has a very successful direct-sale approach using the Internet. Cisco reportedly receives 98% of their orders online, reducing operating costs by 17.5% and lead times by at least 50% over previous order-handling methods (Turban et al., 2002).

Electronic auctions are sites on the World Wide Web where organizations can quickly and efficiently dispose

of surplus inventory. These auctions allow companies to save time and reduce costs of disposing with surplus inventory, often allowing companies to obtain better prices for items over traditional disposal methods. Ingram Micro, for example, receives 60% of an item's retail cost, on average, by selling surplus inventory through an online auction. This compares to an average 10 to 25% price recovery using traditional liquidation brokers (Schneider, 2002). Some companies create and manage their own auction sites. CompUSA's Auction Site (<http://www.compusauctions.com>), for example, is designed to allow small and mid-sized companies to bid on their surplus inventory. Alternatively, companies can use existing general purpose or industry-specialized auction sites such as eBay (<http://www.ebay.com>) or ChemConnect (<http://www.chemconnect.com>). Both Sun Microsystems and IBM have successfully adopted eBay as an auction site for surplus computer hardware, software, training courses, and refurbished equipment. eBay, in this case, operates as a horizontally aligned intermediary between Sun Microsystems and the companies or individuals bidding on Sun's products. ChemConnect is an example of a specialized third-party auction site designed to manage the selling and buying of chemicals and plastic products using an auction format. Unlike eBay, which is horizontally focused, ChemConnect has vertical focus and concentrates on selling specifically to the chemical industry.

E-Procurement

E-procurement is concerned with automating the purchasing of goods and services from suppliers. These applications facilitate the exchange of electronic information between trading partners by integrating a buyer's purchasing processes with sellers' order entry processes (Davis & Benamati, 2002). E-procurement systems can be either buy- or sell-side applications. Buy-side applications reside on a buyer's system, controlling access to the ordering process, the authorization of orders, and possibly the list of trading partners allowed to receive orders. Sell-side applications reside on a supplier's system and allow authorized buyers to access and place orders directly on the supplier's system. Sell-side systems are often implemented as extranets where access to electronic catalogs and pricing information can be carefully controlled.

Early e-procurement implementations relied on fax, e-mail delivery, EDI, or real-time system processing to transfer data among trading partners. Newer e-procurement systems use Internet technologies to manage ordering processes. Recent surveys indicate that most commercial solutions now use XML and the Internet to share procurement data and provide access to online market places as part of the offering (Aberdeen Group, 2001b).

E-procurement systems can benefit companies in a variety of ways. In 1999 Federal Express identified e-procurement as a key strategy for reducing costs and saving time in the purchase order process. FedEx purchased a B2B e-commerce platform from Ariba Inc. (<http://www.ariba.com>), which was implemented within a month and returned a positive return on investment (ROI) within three months. The new purchasing system

manages approximately 20% of FedEx's 25,000 annual requisitions and reduces purchasing cycle times from 20 to 70%, depending on the type of items purchased. The purchase of new PCs, for example, now takes 2 days rather than the 17 to 19 days it took using a traditional paper-based approach. FedEx also managed to reduce the purchasing department staff by half, allowing these extraneous staff to be reassigned (Aberdeen Group, 2001a). Microsoft reports similar success with MS Market, a desktop e-procurement system designed to run from a Web browser over the company's corporate intranet. MS Market is deployed to 55 Microsoft locations in 48 counties and saves the company an estimated \$7.5 million annually (Microsoft, 2000). In the United States, Microsoft uses MS Market to order almost 100% of the company's requisitions at an average cost of \$5 per requisition.

E-procurement is one of the main areas of e-B2B that is "delivering rapid and quantifiable results" (Aberdeen Group, 2001b). The type of products purchased by e-procurement systems, however, are generally limited and of relatively low value. Strategis (<http://www.strategis.gc.ca>), an online branch of Industry Canada, reports that 42% of e-procurement purchases by businesses in Canada in 2001 were for office supplies, furniture, and office equipment, followed by IT hardware and software (29% of total) and travel services (15% of total). Similarly, Microsoft Corp. reports that 70% of its annual 400,000 procurement purchases are for requisitions less than \$1,000 in value (Microsoft, 2000).

E-Collaboration

E-collaboration is a term broadly used to describe any form of shared e-business activity in which companies collaborate with the common goal of providing a mutually more efficient business environment. E-collaboration can take many forms including supply chain integration, joint design and development of products, joint demand forecasting, and joint planning. General Motors, for example, shares specialized engineering software and data files with its suppliers as a means of reducing product development time. As part of this joint-product design strategy, General Motors partially or fully underwrites the costs of software licenses for some of its suppliers in order to standardize product design platforms across the supply chain. By standardizing and sharing design tools General Motors successfully reduced design-to-production cycles for new products by 50% (Slater, 2002).

Collaborative planning forecasting and replenishment (CPFR) is another form of collaboration allowing suppliers and sellers to jointly forecast demand for products in an attempt to better coordinate value chain processes such as restocking, managing exceptions, and monitoring effectiveness. The motivation underlying CPFR is that better forecasting between trading partners results in improved business processes, which in turn reduces costs while improving customer service and inventories. Wal-Mart's RetailLink is an example of a CPFR system operating over the Internet using EDI documents to share information. RetailLink enables Wal-Mart's suppliers to receive detailed information about store sales, inventory, effects of markdowns, and other operational information.

Access to this information allows Wal-Mart's suppliers to manage their inventory more effectively at each individual Wal-Mart store.

Collaborative approaches such as CPFR and supply chain integration can result in numerous benefits for companies. Following a recent study involving 81 companies, Deloitte and Touche report that companies that "collaborate extensively" with their supply chain partners while focusing heavily on customer loyalty and retention are almost twice as profitable as companies that are "below average" in the areas of supply chain collaboration (Rich, 2001).

E-Markets

E-markets provide third-party integration services by supplying online applications, allowing organizations to exchange goods and services using a common technology platform. In essence these electronic marketplaces bring suppliers and buyers together in a common forum with a common technology platform. E-markets are often vertically aligned, serving specific industries such as the energy or automotive industries. However, horizontally aligned e-markets servicing broad industries such as office supplies and information technology also are available.

Many e-markets are independent exchanges managed by intermediaries that are neither buyers nor sellers in the marketplace but, instead, provide specialized third-party services, enabling other businesses to collaborate through them. Alternatively, e-markets can be created and managed by a company or consortia of companies that are leaders in the industry being served. Covisint (<http://www.covisint.com>) is an example of a global marketplace sponsored by a consortium of industry leaders including DaimlerChrysler, Ford, and General Motors among others. Covisint was jointly funded in 2000 to provide a global solution for the automotive industry with the mandate to "improve the effectiveness of mission critical processes such as collaborative product development, procurement and supply chain management...through implementation and use of a secure and comprehensive online marketplace" (Covisint, 2002). Covisint's mission is to "connect the automotive industry in a virtual environment to bring speed to decision making, eliminate waste and reduce costs while supporting common business processes between manufacturers and their supply chain." This mission is achieved through a number of collaborative processes including online auctions and direct sales via online catalogs.

The total value of transactions managed by Covisint is very large, reportedly exceeding \$129 billion in 2001. During 2001, General Motors purchased \$96 billion worth of raw materials and parts through the exchange. The largest online bidding event to date was also recorded by Covisint in 2001 as DaimlerChrysler used the exchange to procure \$3 billion worth of automobile parts. The exchange also helps reduce costs of purchases and transactions. Ford Motor Co. reported \$70 million in savings in 2001, exceeding its \$50 million initial investment in the exchange in a single year (Konicki, 2001). Recent research, however, has questioned the validity of savings claims made by e-exchanges in general as they often reflect maximum

theoretical savings that could be achieved at the close of auctions, whereas actual savings are likely to be less (Emiliani & Stec, 2002).

METHODS FOR IMPLEMENTING B2B

Integrating business processes in one company with business processes in another requires that both companies provide a technology framework that enables the flow of electronic business information between their respective information systems. This integration could be as simple as establishing a system for sharing electronic information and files via e-mail, magnetic tape, or other digital media. More sophisticated integration techniques involve providing business partners access to real-time information stores such as database systems or applications performing supply chain management, procurement, and enterprise resource planning activities.

Point-to-Point Transfer Methods

By the 1950s companies had started to use computers to manage business transactions. At this time, paper forms were used to move business information between companies that had to be re-entered into recipient computer systems using manual methods: a process that was unreliable, expensive, and redundant (Schneider, 2002). In the 1960s, magnetic tape and punch cards replaced paper forms for recording and transferring business information. These encoded tapes or card decks could be transferred to a recipient computer system and automatically processed using card or tape readers, negating the need for expensive and error-prone redigitizing processes (Figure 1).

Tape and card decks have since been replaced by network-based file-transfer applications such as Tymnet, UUCP, and Kermit and more recently by applications implementing the Internet's file transfer protocol (FTP). File transfer applications allow one computer system to export business data from an application to an electronic data file. The file is then transferred to a recipient computer system in digital form over a phone line, computer network, or the Internet where it is subsequently loaded into the recipient application using specialized software.

These point-to-point file transfer methods are perhaps the simplest integration approaches to design and implement as the only factors in common between collaborating systems are a prenegotiated file format and common communication method. Such methods work well in situations where there is little change over time in the applications at either end of the process and where there is a high degree of collaboration between the business entities. Several disadvantages of the point-to-point approach, however, can be identified. With respect to the format of the data being shared, the sending and receiving applications must agree on a fixed file format, export and import logic is often restricted by the applications, and lastly the overall system is brittle and can fail if either system changes the data format. From a data management perspective: data transfer is conducted in batch mode rather than real time, which introduces latency into the system; there are also no methods for data recovery or guaranteed delivery of

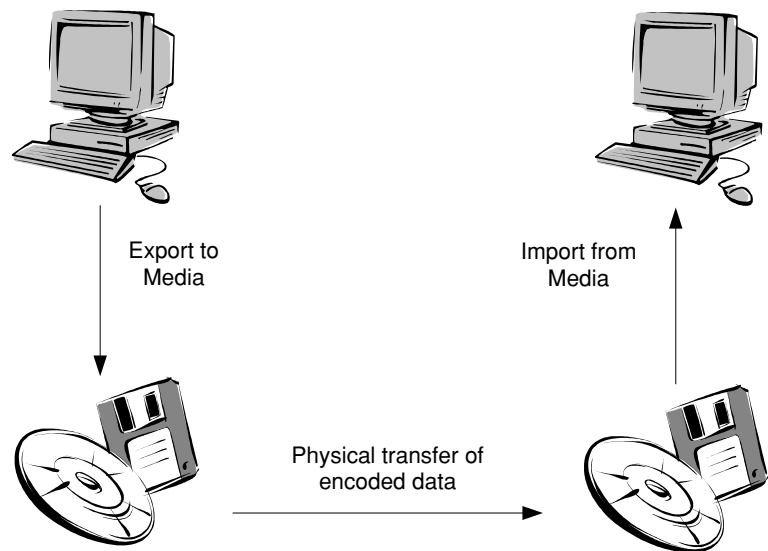

Figure 1: Point-to-point data transfer.

the data (Yee & Apte, 2001). Moreover, sharing data with multiple business partners becomes difficult to manage as the impact of these disadvantages becomes multiplied as each additional business partner is added.

Database Integration Methods

Allowing a business partner direct access to business information stored in a database can overcome many of the technical issues associated with point-to-point integration methods. Providing direct access to data stores can be relatively straightforward to implement using modern relational database management systems (RDBMSs) and given the correct set of business and technical conditions.

Relational database management systems such as Oracle's Enterprise Database, Microsoft's SQL Server, and IBM's DB2 can be thought of as layered applications consisting of many individual procedures that together provide a complete data management system. The lowest layer consists of actual data storage facilities and procedures that efficiently organize stored data on a host computer system. The top layer consists of a user interface providing capabilities for generating reports and managing stored data. Between the data and user interface layers are a suite of applications implementing the data management and query capabilities of the database system. This application layer typically uses a specialized computer language called structured query language (SQL) to manage all aspects of the database and to provide an interface between users and stored data (Figure 2).

In an e-business context, it is more likely that a business partner's application or software agent will initiate a data interaction than an actual person. When applications access a database they often use database connectivity middleware such as JDBC, ODBC, or ADO and bypass a database's user interface layers. Database connectivity middleware enables programmatic access to the data management and query services of a database by generating SQL commands directly from a remote application,

enabling systems designers to create points of integration between business systems over a telecommunications system such as the Internet. Database connectivity middleware provides an abstraction layer for applications, shielding them from actual data storage mechanisms. This approach allows systems designers to overcome differences in storage formats and storage methods that can occur between disparate databases and computer systems. Applications sharing business information through a database need only understand how data are organized in a partner's database and have the ability and necessary permissions to access the database resources over a computer network.

Newer business systems tend to separate application logic from actual data storage methods and often use

Figure 2: Database management system components.

commercial RDBMSs to manage and protect stored business data. This “two-tier system” design facilitates data integration between business partners, as business data stored in one database can, in theory, be accessed directly by any number of remote systems. Older business systems, however, tend to tightly couple business logic and business data, often using proprietary data storage formats. This approach makes integration at the data level problematic. Linthicum (2001) suggests that integration with these older closed systems is best managed at an application level as it is often impossible to deal with the database without also dealing with the application logic.

Many companies today deploy a number of databases within their organization, often of different vendor types. In these cases, database integration approaches can be more complicated as business partners might need to share data from two or more database systems simultaneously. Federated databases, also called database gateways, are middleware technologies that can be used to overcome these types of integration issues where there are multiple data sources. Database gateways are middleware providing proxy services. The database proxy accepts incoming requests for data from client systems, translating each

client request into a form that can be executed against one or more underlying connected databases, then formats and returns the results (Figure 3). In essence, database gateway middleware systems create virtual databases for client applications by conjoining selected elements of underlying physical databases and managing interactions between the virtual and physical systems. IBM’s Distributed Relational Database Architecture (DRDA) is an example of a database gateway delivered as part of IBM’s DB2 enterprise database systems facilitating interoperation of multiple databases within heterogeneous computing environments.

Although proficient at providing read-only access to business data for remote applications, database gateways have limitations for e-business systems. Database gateways tend to be inefficient as queries against the virtual database must be recast to query underlying physical data sources and results from queries merged by the middleware to form reports that can be returned to client applications. The database approach to integration also bypasses any business rules that might be implemented in an application, resulting in redundant business logic that must be both developed and maintained at some cost (Yee & Apte, 2001).

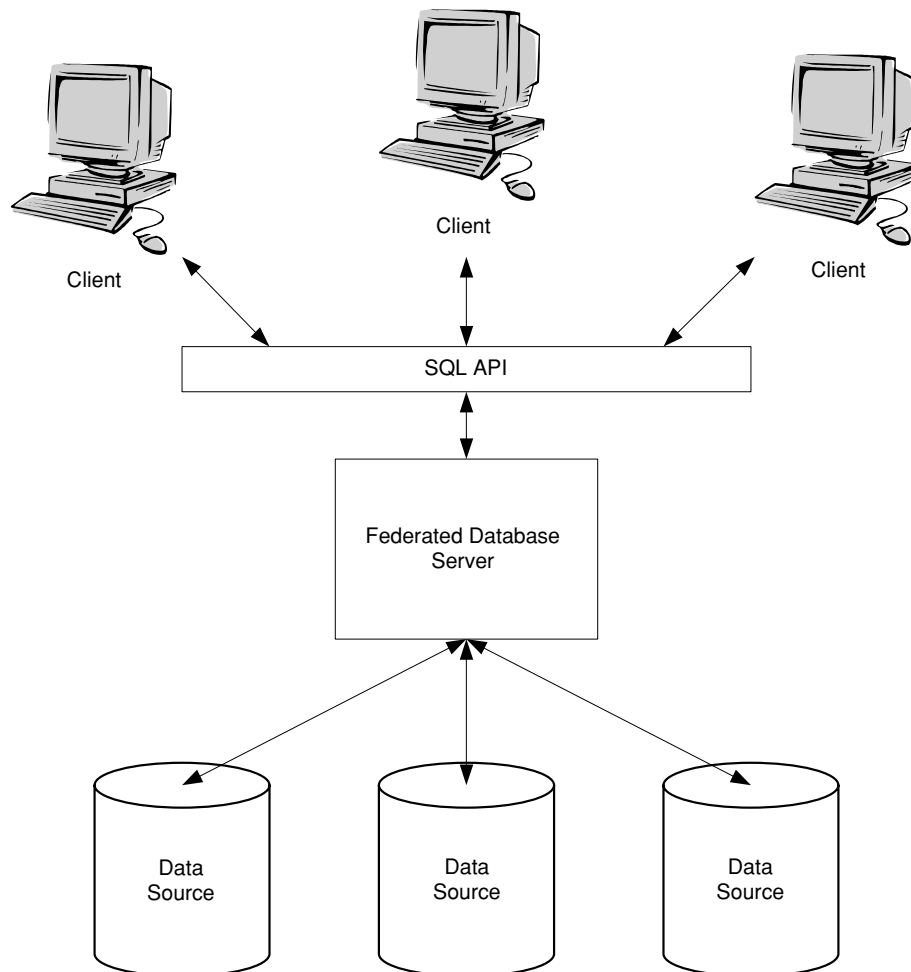

Figure 3: Database gateways.

Figure 4: Data integration via application programming interfaces.

API Integration

An alternative to integrating business applications through direct access to business data is to enable applications to share information directly. This can be achieved by developing programmatic interfaces that are built into an application and specifically designed to be accessed by other applications. Application programming interfaces (APIs) allow external applications (clients) to share data and business logic with host applications (servers) over a computer network (Figure 4). Using this approach, applications can share computer data composed of text and numbers and even complex structured data objects representing atomic information components such as customers or purchase orders. Some APIs allow client systems to execute business logic on a server such as removing an element of data or performing some business interaction.

B2B integration via APIs is often more difficult in a heterogeneous computing environment as differences in computer systems affect how data and business logic can be accessed, how client systems can be authenticated, and how data components such as strings, numbers, dates, and complex higher-order objects are represented. These well-known system compatibility issues can often be overcome by middleware applications designed to broker the flow of information between different systems. Remote procedure calls (RPCs), initially developed for UNIX systems, are one such middleware technology providing a framework for translating system-specific data to and from a common data format. Once business data have been encoded into a common format, they can be transferred without loss of representation between client and server systems over a computer network. RPC frameworks are available for most computer systems used by busi-

nesses today and use a computer language called interface definition language (IDL) to represent business data in a system-independent form suitable for transmission between systems over a computer network. Other API middleware technologies are in common use. Microsoft (<http://www.microsoft.com>) have extended their component object model (COM) to allow computers to share data and methods between systems running different versions of Windows software over a network. This distributed COM (DCOM), also known as COM+, is available on all second-generation Microsoft Server products. The common object request broker architecture (CORBA) provides a processing model similar to Microsoft's DCOM and was developed as an open specification by the Object Management Group (<http://www.omg.org>), consisting of over 800 independent software developers. The initial CORBA specification was developed in 1991 and is still in use today, especially in the banking industry, which has adopted it as their standard method of systems integration.

Message-oriented middleware (MOM) addresses some of the issues associated with tightly coupled API solutions such as RPCs and DCOM. MOM applications transfer data between systems in the form of application-defined units of data called messages. Most message-driven applications use an asynchronous processing model rather than the synchronous model used by most tightly coupled systems. Unlike RPCs, which deliver data from a client to a server immediately, messages sent from one application to another using MOM are usually placed into a specialized piece of middleware responsible for storing and querying messages called a message queue (Figure 5). When a recipient application is ready to process messages it accesses the message queue and extracts those messages that have been sent to it by one or more client applications. This

Figure 5: Message-oriented middleware.

processing model allows a system to send messages to possibly several recipient systems at the same time without having to wait for each recipient application to process the data, thereby allowing different systems to process data at different speeds. Newer MOM implementations guarantee message delivery even though a recipient application might not be available at the time a message was sent. Today, messaging middleware is a standard component of several systems development platforms including Microsoft's DCOM (MSMQ), Microsoft's .NET platform, and the Enterprise Java platform (JMS).

Java is a computer language developed by Sun Microsystems in the 1990s specifically for use on the Internet. Unlike traditional computer languages, Java uses a data format common to all Java implementations that is independent of any specific hardware/software environment, thereby allowing Java applications to be executed on any platform for which Java is available. This "write-once-run-anywhere" approach negates the need for intermediate data format languages such as IDL to represent data transmitted between applications over a computer network, greatly decreasing system development and maintenance costs for networks applications. The Java language has continued to grow from its initial form in the 1990s to meet the evolving needs of business communities. Today, versions of the Java language are available to meet the specific needs and challenges of enterprise and mobile applications. Java 2 Enterprise Edition (J2EE) provides a programmatic framework for developing robust distributed applications using specialized software platforms called application servers. J2EE application servers, such as BEA Systems Web Logic (<http://www.bea.com>), IBM's Web Sphere (<http://www.ibm.com>), and JBoss's open-source application server (<http://www.jboss.org>) provide all the middleware technology necessary for efficiently accessing remote databases, managing distributed transactions, creating message-driven applications, and developing Web-based user and application interfaces. In contrast, Java 2 Mobile Edition (J2ME) is a restricted version of the Java language specifically designed and optimized for use on mobile devices such as personal digital assistants and in-vehicle systems.

The recent adoption and proliferation of XML and XML-oriented middleware provides an alternative means for sharing data between systems and forms the basis of a new generation of interapplication data-sharing methods called Web services. Web services are similar to RPCs in

that middleware responsible for formatting and transferring business data between systems exists on both client and server systems. Web services typically use a XML document format based on the simple object access protocol (SOAP) specification, developed jointly by Microsoft, IBM, and others to share data using commonly available Internet network protocols such as HTTP and TCP/IP for communication. Web services implement a service-oriented architecture (SOA), facilitating dynamic discovery and centralized service registries. These features allow client applications to automatically locate server applications provided by a business partner on the Internet and simultaneously discover all system interfaces and data formats necessary to enable a client application to couple to and interact with those services. This SOA model significantly reduces the complexity, cost, and time necessary to integrate disparate business systems.

Process-Oriented Integration

Process-oriented integration focuses on the logical sequencing of events and the processing of business information as it moves within and between business organizations. This form of e-B2B integration relies on business processes rather than technological foundations to increase competitive advantage. Process-oriented integration tends to be more strategic than tactical as results are often hard to measure in terms of traditional investments as they often involve developing trust relationships with business partners and involve sharing private and often confidential information in order to realize intangible benefits such as better products, increased customer satisfaction, and supply chain efficiencies. Sharing production forecasts and schedules with suppliers, for example, allows business partners to better plan their own production activities, which in turn can lead to lower costs overall as the guess work involved in anticipating demand can be removed and the likelihood of stock-outs diminished. Changes in production schedules can similarly be communicated, allowing suppliers to automatically adjust their own production schedules to match, thereby reducing waste and uncertainty and lowering inventories.

In its simplest form process-oriented integration can be implemented between a group of business partners by agreeing on a common technology platform to use for their internal systems and then deciding which processes they are willing to externalize as integration points. Establishing a common technology platform for business systems also establishes a common framework for sharing business information as data moving between businesses are guaranteed to be compatible and interchangeable. Many enterprise resource planning (ERP) systems such as SAP/R3 (<http://www.sap.com>) and Oracle's E-Business Applications Suite (<http://www.oracle.com>) are specifically engineered to facilitate this type of interoperability and provide integration points as part of the solution.

Evaluating and Selecting Integration Approaches

The wide variety of methods available for B2B system integration provides organizations in the planning phase of

a B2B initiative with a number of alternatives. There are, however, several key issues that should be considered, including the level of effort necessary to integrate with new business partners and issues associated with security and privacy of both business systems and business information.

One of the key decisions to be made is determining the level of effort necessary for trading partners to couple and decouple from the trading environment. Facilitating integration by standardizing on internal systems such as SAP/R3, which requires specialized hardware, software, and connectivity environments, can be expensive and difficult to implement. Hershey Foods, for example, spent three years and \$115 million implementing a software system from SAP. The new system was designed to replace a number of older systems and tie into supply chain management software from Manugistics and customer relationship management products from Siebel. Glitches in the ordering and shipping systems, however, resulted in a 12.4% drop in sales during the company's busiest quarter (Osterland, 2000).

A new generation of Internet-centric ERP software specifically designed to address implementation issues associated with sharing information across a supply chain is now available. ERP II enables companies that have already invested in ERP systems to leverage their existing investments and implement collaborative planning by upgrading their existing ERP systems (Bond et al., 2002). Other lightweight technologies like XML/SOAP-based Web services have been specifically engineered to provide points of integration between business systems and facilitate the flow of business information between organizations with relatively low costs of entry. A possible disbenefit of this relatively low cost of entry and ease-of-implementation is that trading partners can also couple to competitor systems with relative ease, thereby undermining trust relationships that might exist between companies.

When selecting technologies organizations should consider both the security of data as they move between their systems and those of their business partners, as well as the security of their own information systems. Organizations that expose internal systems to others over a computer network typically experience types of risk that do not affect more traditional organizations (Etteridge & Richardson, 2001), including theft of data and intellectual property, unauthorized access, and compromised customer privacy.

B2B E-COMMERCE CHALLENGES

Several types of challenges exist for companies planning an e-B2B strategy, including managing and valuing e-B2B projects and working within the many regulatory environments controlling e-B2B, as well as technical challenges associated with selecting, implementing, managing, and securing e-B2B technologies.

Management Challenges

Several significant management challenges that do not affect more traditional firms are associated with creating a

successful and sustainable e-business. These challenges include accounting challenges associated with measuring true economic benefits of e-B2B activity, managing elevated levels of trust necessary between business partners, managing critical information technology infrastructures, and providing realistic expectations with respect to the benefits and costs of e-business implementations.

Measuring the tangible and intangible benefits of e-B2B investments is difficult for organizations and regulating bodies as many of the benefits arising from e-B2B activities are hard to isolate and quantify using purely economic measures but can affect how an investment is perceived by a company and its shareholders. Tangible benefits arising from e-B2B activities such as increased sales, decreased production time, and reduced waste can be estimated fairly accurately using traditional accounting methods. Other benefits such as increased customer satisfaction, heightened brand visibility, and stronger relationships with business partners, for example, are intangible benefits that are highly sought but difficult to measure. Similarly, benefits arising from increased global visibility through an electronic presence on the Internet might provide better hiring opportunities or more favorable investment opportunities for a company. Again, such benefits are extremely difficult to quantify but can significantly affect how a company is perceived and valued.

Coupling business processes through technological frameworks requires that participants trust each other with valuable and often confidential business information such as new product specifications, purchasing patterns, and production forecasts. As businesses move towards a pattern of sharing information in real time, a bond of trust must be established and proactively managed to ensure continued and mutual benefits for all companies involved. These trust relationships involve guaranteeing the security and confidentiality of data being shared, as well as guaranteeing and maintaining predefined levels of system performance and systems stability. Also important are agreements to apportion responsibility, establish procedures to manage routine maintenance, and upgrade cycles and determine minimum system availability.

IT groups in traditional companies are responsible for managing internal processes and providing support for other business functions within the organizations. These IT groups are often treated as overhead and run as cost centers, thereby reinforcing their supporting role with organizations. In contrast, IT organizations in successful e-businesses are often revenue generators and should be treated as competitive assets, allowing innovation within IT organizations to derive competitive advantage and help reduce costs. Information technology infrastructures within an e-business are foundations of business success and should be carefully managed to support the business goals of a company. The Hurwitz Report (Hurwitz Group, 2001) identifies several ways by which management solutions can maximize e-business success:

- Measuring the business impact of the infrastructure;
- Managing the infrastructure proactively;
- Ensuring availability and reliability of data;

- Securing transactions and data; and
- Deploying applications and services rapidly and reliably.

As e-businesses increasingly rely on electronic processes, potential consequences to a company and its business partners resulting from loss of service can be devastating. A survey of companies in 2001, for example, reports that 46% of companies surveyed would experience losses of up to \$50,000 per hour, 28% would incur a loss of up to \$250,000 per hour, and 26% would lose up to or over \$1 million per hour through loss of e-business services (Contingency Planning Research, 2001).

Managing expectations of an e-business and effectively communicating potential benefits to business partners is another key factor in e-business success. After more than \$1 billion had already been invested by the Boards of Grocery Manufacturers of America and Food Marketing Institute Trading Partners Alliance (TPA) in a variety of exchanges and electronic collaboration platforms, A.T. Kearney (2002) recommended several factors necessary to proactively encourage trading partners to join the alliance. Among these recommendations were:

- A need for better communication among partners to address common concerns over data synchronization;
- Education about the benefits of collaboration and implementing best practices; and
- Regular feedback through surveys and progress-tracking initiatives.

The need for individual companies, especially market leaders, to proactively encourage trading partners to join the trading partnership through training and sharing of best practices was also identified as a key success factor.

Monitoring and Regulation Challenges

Monitoring and regulating online businesses provides many challenges. These challenges associated with taxation, security, and privacy of e-business are more difficult to manage when applied in a global context where laws and ethics governing business are often conflicting rather than complementary. Standardizing accounting mechanisms for digital businesses and processes presents additional issues as traditional accounting principles must adapt to a digital business environment. Lastly, the global nature of the Internet creates issues for prosecuting those who attempt to disrupt or steal digital information, providing significant challenges for national and international legal organizations.

FASB, the U.S. Federal Accounting Standards Board, identifies several challenges to the accounting industry associated with the transition from a traditional paper-driven economy to one where business is transacted using digital documents. From an accounting perspective, there is no standard measure for determining the short- or long-term value of technology, knowledge capital, and intellectual property associated with implementing and managing e-business infrastructure. Companies, however, are investing huge amounts of resources in these activities that must be accounted for fairly. Valuing these intangible

assets requires the accounting profession extend its province to nonfinancial areas of business operations and generate standard frameworks and metrics for reporting and tracking nonfinancial information (FASB, 2001).

E-B2B poses an even more complicated set of issues for those organizations charged with monitoring and regulating international business. The Internet compresses the natural geographic separation of businesses and related movement of products and money between these businesses, allowing business operations to easily span geopolitical borders. The Internet, however, is largely uncontrolled and business on the Internet follows suit. Governments of individual countries participating in online activities are responsible for regulating e-businesses within their borders and determining the degree of regulation, identifying legal bodies responsible for regulation, and determining the level to which they should accommodate rules and regulations established by other countries. There are, however, opposing forces at work within any country. Governments attempt to regulate the Internet in a way that stimulates their economies and encourages adoption and use. At the same time governments are responsible for protecting the rights of their citizens and existing businesses. It is not surprising that few Internet regulatory laws have been passed to date, even though e-B2B has been in place for many years. To further complicate the regulatory issue, the ubiquity of the Internet has resulted in a rapid expansion of businesses interoperating across international borders. Traditionally only large, well-financed companies could perform international commerce; today there are no limits to how small a multinational company can be.

As businesses and industries in general move toward higher degrees of digital collaboration issues with security and privacy of digital information being collected, stored, and transmitted as part of normal e-business operations become increasingly more important. Many of the regulatory laws that do exist are designed to protect personal and confidential business data. The United States has enacted legislation designed to protect personal finances and health care records from accidental or malicious exposure. The Health Insurance Portability and Accountability Act (HIPAA, 1996), for example, is an attempt to regulate movement, storage, and access to health care-related personal information through enforcement of privacy standards. HIPAA is a direct regulatory response within the United States to several well-publicized breaches of doctor-patient trust. Similarly, the Gramm-Leach-Bailey Act, promulgated by the Securities and Exchange Commission and Federal Trade Commission, outlines responsibilities of financial institutions for protecting the privacy of consumers' information and assessing liability for negligence (Personick & Patterson, 2003).

Regulating criminal activity associated with the Internet and e-business systems provides several problems for organizations and regulatory bodies. Different countries treat different types of computer attacks in different ways with little consensus as to the degree of criminality and severity of punishment. Turban et al. (2001) provide a comparison of computer crime legislation in several countries and note that attempting to hack a system, although

legal in the United States, is illegal in the United Kingdom. However, successfully hacking a system and causing financial loss is criminal in both countries but punished far more severely in the United States where the crime carries a maximum penalty of 20 years in prison. With its global accessibility, the Internet presents a significant challenge to regulating hacking and other cybercrimes, as attacks levied against systems can be launched from countries with less-stringent regulations and lower rates of enforcement. In general, governmental intervention is primarily limited to identifying cybercriminals after an attack and attempting to prosecute perpetrators if they are in a country that has extradition treaties. The United States, for example, has caused international concern by successfully detaining and convicting foreign nationals accused of crimes against systems in the United States when the attacks were known to be launched from non-U.S.-based systems (U.S. Department of Justice, 2002). Not all cyberattacks, however, are malicious. So-called “white-hat” hackers often attack business systems as a means to draw public attention to issues of vulnerability with the intent of eliciting a general hardening of systems by the systems developers (Hulme, 2002).

Technological Challenges

Some of the most extreme information technology requirements found in the commercial business world are associated with designing and implementing large-scale e-business systems. Issues with the design and deployment of such systems include localizing applications for international users, managing quality of service, and protecting access to data and applications.

E-B2B is increasingly multinational, and differences in language and culture affect the usability and accuracy of these systems. Information shared across national and cultural borders must be both syntactically correct and unambiguous for all systems involved. Of particular importance to cross-cultural e-business systems is designing data storage and data processing systems that can accommodate locale-specific data and translate data between supported locales when necessary. Business data containing names, dates and times, addresses, telephone numbers, and currency present particular issues across locales as there are a large number of conventions and translations that might need to be accommodated. Microsoft's latest Windows platform, for example, supports over 130 separate locales (Microsoft, 2003).

Information services supporting e-B2B need to provide sufficient system functionality, capacity, and availability to meet planned demand. System demand translates loosely into estimating the number of transactions that will be processed by an information system in a given time period. Estimating this number requires understanding the demand on a system during normal operations and determining how demand might vary over the course of a single day, a week, a month, or year. System designers also need to plan sufficient capacity to accommodate special events, which can cause short-term increases in system use. Lastly, when designing e-B2B systems, system designers should understand how e-B2B interactions will

translate into workload against other information systems in an organization. Internal ERP systems, for example, can be affected by increased activity resulting from external e-B2B systems. IT organizations should plan to match the capacity of internal systems with that of external e-B2B systems being designed so that the internal systems do not become the weak link in the processing chain.

Potentially sensitive information shared between businesses is at risk not only during transmission of information from one system to another, but also as it is stored on file servers and in databases accessible through computer networks. The general trend toward open systems poses transmission security issues as open systems often rely on text-based data formats such as EDI and XML. If intercepted, these documents can be read and understood by a variety of software publicly available on the Internet. Standards for encrypting XML documents are being developed but have yet to be universally adopted. Encryption technologies for securing data moving over the Internet between business partners, such as VPNs, are commonly available but rely on coordinating privacy schemes among businesses, including sharing encryption keys and developing effective implementation policies. To remain effective, such policies must be constantly revised and tuned to adapt to changing events.

Security and Privacy Challenges

There are many types of criminal activity associated with the Internet, ranging from petty acts of vandalism and copyright violations to organized systematic attacks with malicious intent to cause damage, financial loss, or in extreme cases, wholesale disruption of critical infrastructure. Additional threats to e-businesses arise internally from employees and ex-employees with access to systems containing proprietary and/or sensitive information and potential loss of critical systems due to hardware and software failures or widespread infrastructure failure such as a catastrophic loss of telecommunications systems or electrical grid. The first line of defense for any online organization must then be a well-planned and executed security policy that considers internal and external security threats as well as protection against exogenous events with potential to cause data loss and service disruption.

E-business security concerns generally fall into four main categories: loss of data integrity, loss of data privacy, loss of service, and loss of control (Otuteye, 2001). Creating an effective information security policy requires addressing these concerns through a number of major objectives: managing privacy and confidentiality, ensuring data integrity, maintaining systems availability, and non-repudiation (Proctor & Byrnes, 2002). Achieving the first objective requires identifying information within an organization that should be protected and, secondly, identifying those people or systems requiring access to it. As e-business often involves transferring proprietary information between business partners and/or customers, maintaining privacy and confidentiality of information necessitates providing protection for information as it is stored on computer systems and archive devices and also

as the information is transferred between computer systems over a network.

Ensuring data integrity provides assurances that critical information is never damaged or changed in an inappropriate way. Managing this objective requires organizations protect access to information from unauthorized users and systems as well as protecting access to internal and external systems that could be used to change or corrupt data. Effectively achieving this objective requires organizations also consider broader issues of data recovery and disaster planning to prevent loss or corruption of information through human error, systems failure, or massive loss of critical infrastructure.

Managing systems availability requires ensuring that all systems and information are available to those who need it when it is needed. Achieving this objective requires planning against common causes of loss of availability such as denial of service (DoS) attacks and computer viruses that can affect the reliability and responsiveness of systems. Following the tragic events of 9/11/2001 in New York City, organizations are now considering holistic approaches to protecting access to business operations by also protecting access to critical applications such as e-mail and telecommunication systems, which their businesses and those of their business partners depend on (Garvy & McGee, 2002).

The last major objective, nonrepudiation, is a new approach to security management that can be used to verify claims and apportion responsibility in the case of liability (Otuteye, 2001). This objective is necessary to ensure that both parties in a business transaction are confident that they are dealing with the appropriate other party. Achieving nonrepudiation requires enabling an originator or recipient of a transaction to prove to a third party that their counterpart did take an action in question. For example, if one party orders a product from another party then later decides it was not needed and attempts to claim that the product was not, indeed, ordered by them, nonrepudiation would allow the claim to be validated or disapproved in a court of law. Today, nonrepudiation can be obtained through the use of digital signatures, confirmation services issuing digital receipts and timestamps, which can be used to prove that a document existed at a certain time (webopedia.com, 2003).

It is generally agreed that managing security of information for e-businesses requires proactively engaging in security practices rather than attempting to engineer security measures after systems have already been deployed. When designing appropriate security policies, e-business should consider several key factors:

- Security is expensive;
- Security is only as strong as its weakest link;
- Security can often get in the way of doing business;
- Security needs change as organizations and their systems evolve; and
- Security must be always on.

Further, as new technologies such as wireless wide- and local-area networks, Web services, and instant messaging enter the mainstream of enterprise information

systems, new security threats arise that must be dealt with, requiring that organizations constantly re-evaluate their security needs.

B2B E-COMMERCE IN PERSPECTIVE

It is generally agreed that current rates of adoption and continuing pervasiveness of e-B2B activity across all business sectors and all types of industry indicate that e-B2B is and will remain a major driving force within the global economy. At the same time, however, e-B2B should be regarded as a nascent activity that is rapidly emerging and consequently exhibiting growing pains. Based on a survey of 134 companies around the world, the Cutter Consortium provides some interesting insight into e-B2B implementation experience to date (Cutter Consortium, 2000):

- Asked to rank the obstacles to e-business, respondents chose "benefits not demonstrated" as the number one obstacle, followed by financial cost and technological immaturity.
- Success with electronic supply chain management is mixed with half of those using it enjoying success rates of 76 to 100% and about a third experiencing success rates of 0 to 10%.

Similarly, Deloitte and Touche examining data from 300 U.S.- and U.K.-based companies in a wide variety of industries identifies a highly conservative trend toward e-business. Less than half the companies examined expect their e-business strategy to involve transforming business processes while the majority of companies expect their e-business strategy to be limited to simple Internet-based buying and selling. More telling is that only 28% of companies had developed a formal e-business strategy, the majority being in some stage of investigation (Rich, 2001).

E-business success stories, however, are highly compelling. Examples from General Motors, Federal Express, and Cisco clearly demonstrate the types of returns possible when e-business is implemented successfully. The bottom line is that performing business electronically is cheaper, more efficient, and more accurate than traditional means, providing a compelling set of factors for businesses to consider. These benefits, however, should be measured against the risks associated with increasing reliance on information technology and exposure of critical systems to unregulated telecommunication networks such as the Internet. Loss of access to business systems through systematic attacks such the DoS attacks experienced by several major Internet firms in February 2000, or simple system failures such as those experienced by eBay in June 1999, can result in interruptions of service and lead to significant short-term loss of revenues as well as long-term loss of investor confidence, which has shown not to reverse over time (Etteridge & Richardson, 2001).

Clearly, implementing an e-business strategy is highly technical, involving many facets of information technology new to most companies and indeed new to the information technology industry. Lack of knowledge about e-B2B technologies and its risks and rewards combine to make businesses cautious as they plan ahead for a

connected future. These issues, however, can be overcome with time as the global corporate knowledge base grows, as more case studies illustrating successful and profitable implementations are available, and as e-enabling technology frameworks mature. A prerequisite for sustaining e-business, however, requires transforming the Internet into a system capable of promoting safe communication through regulation, monitoring, and prosecution of those who choose to maliciously interrupt the flow of e-business information. This goal must be planned and implemented in a global forum as the Internet and e-business necessarily exist in a global economy. The ultimate responsibility for information security, however, must start within each connected organization as effective security should be regarded as a competitive advantage with potentially significant fiscal and legal liabilities resulting from negligent and ineffective security practices.

ACKNOWLEDGMENTS

An earlier version of this chapter appears in *The Internet Encyclopedia* edited by Dr. Hossein Bigdoli and published by Wiley and Sons. The author is grateful for the comments and suggestions provided by the editor and reviewers on this and the earlier paper.

GLOSSARY

- ActiveX Data Objects (ADO)** Middleware developed by Microsoft Corp. for accessing local and remote databases from computers running a Windows-based operating system.
- Application Programming Interface (API)** Components of an application that allow other applications to connect to and interact with its data and services. APIs are usually published by the application developer as a formal library of functions.
- Digital Signature** A digital code that can be attached to an electronically transmitted message that can be used to uniquely identify the sender.
- Dot-Com** Companies that emerged during the Internet boom of the late 1990s with a focus on building applications for or selling products on the World Wide Web. Dot-coms were usually funded by large amounts of venture and private equity capital.
- E-Business** All types of business activity performed using electronic means; has a wider context than e-commerce and includes business exchanges that involve interorganizational support, knowledge sharing, and collaboration at all levels.
- E-Commerce** A form of e-business that results in a business transaction being performed using electronic means such as a buy or sell event.
- Electronic Data Interchange (EDI)** One of the first forms of e-business used to pass transactions in the form of electronic documents between computer systems often over private telecommunication lines or value-added networks; still used by many businesses today.
- Electronic Funds Transfer (EFT)** An early form of e-commerce used to transfer money electronically between banks.
- Enterprise Resource Planning (ERP)** A collection of applications designed to manage all aspects of a business. ERP systems are designed to integrate sales, manufacturing, human resources, logistics, accounting, and other enterprise functions within an organization.
- Intermediary** A company that adds value or assists other companies in performing supply chain activities such as connecting suppliers with buyers.
- Java Database Connectivity (JDBC)** Middleware used for accessing remote databases from an application written using the Java programming language.
- Message-Oriented Middleware (MOM)** Middleware used to integrate applications using a system of messages and message queues; allows systems to share data using an asynchronous processing model.
- Middleware** Software that enables the access and transport of business data between different information systems often over a computer network.
- Open Database Connectivity (ODBC)** Middleware originally designed by Microsoft Corp. to access remote databases from Windows platforms using a standard API. ODBC has since been ported to other platforms including UNIX and Linux.
- Protocol** A standard for the format and content of data passed between computers over a computer network. Protocols are often maintained by independent organizations such as the World Wide Web Consortium.
- Remote Procedure Call (RPC)** Middleware technology originally developed for UNIX systems for sharing data and methods between applications over a network.
- Structured Query Language (SQL)** A computer language developed by IBM in the 1970s for manipulating data stored in relational database systems; became the standard language of databases in the 1980s.
- Supply Chain** The end-to-end movement of goods and services from one company to another during a manufacturing process.
- Transaction** A record of a business exchange such as a sell or a buy event.
- Transmission Control Protocol/Internet Protocol (TCP/IP)** Communication protocols originally developed as part of ARPAnet that today form the basic communication protocols of the Internet.
- Tymnet** An early value-added network developed by Tymshare Inc. used by companies for transferring computer files between computer systems; the largest commercial computer network in the United States, but was later sold to MCI.
- UNIX-to-UNIX-Copy (UUCP)** A utility and protocol available on UNIX systems allowing two computers to share files using a serial connection or telephone network.
- Value-Added Network (VAN)** A form of computer network connection often between two companies to perform e-business managed by a third party; initially used to transfer EDI documents; modern VANs operate over the Internet.
- Virtual Private Network (VPN)** A form of network connection between two sites over the public Internet that uses encrypted data transmission to provide a private exchange of data.

INTRODUCTION

Despite the early fascination with dot-com companies, there is a growing recognition that the Internet is unlikely to displace traditional channels anytime soon, at least in the world of business-to-consumer (B2C) commerce. Rather, many traditional enterprises have moved to integrate e-commerce into their channel mix, using the Internet to supplement existing brick-and-mortar retail channels (Steinfield, Bouwman, & Adelaar, 2002). Electronic commerce researchers now consider the combination of physical and Web channels to be a distinct electronic commerce business model, most commonly referring to it as a “click-and-brick” or “click-and-mortar” approach (Laudon & Traver, 2004).

In this chapter, a broad overview of the click-and-brick approach to e-commerce is provided, with some attention to the information security implications of this form of e-commerce. The focus is on the use of the click-and-brick approach by firms selling consumer products and services via a combination of physical and Internet retail channels, given the relative prevalence of this situation in the e-commerce arena. Much of the discussion is also relevant to other types of organizations that rely on both Internet and physical channels, such as those involved in education and health care. In the first section, a brief look at the current e-commerce situation highlights the overall importance of taking an integrated brick-and-click approach to e-commerce development. In the second section, a detailed examination of the sources of synergy between traditional and Internet-based channels is provided. The third section introduces the dangers of product and channel conflict and points out possible management strategies to improve channel integration. The fourth section highlights the potential benefits that firms

may reap when pursuing a more integrated approach to e-commerce. The fifth section introduces four brief cases that give concrete examples of click-and-brick strategies. The sixth section discusses several critical factors that may inhibit firms’ attempts to more tightly integrate physical and Internet sales channels and introduces some recent evidence that illustrates the degree to which many retailers find it difficult to do so. The seventh section discusses information security issues in the click-and-brick model. Finally, the chapter closes with several conclusions regarding the importance of the click-and-brick approach in electronic commerce research and practice.

CLICK-AND-BRICK E-COMMERCE OVERVIEW

Many types of companies can be considered click-and-brick firms, including retailers of tangible products, sellers of financial and other services, health care providers, and educational organizations extending learning services via the Internet. Even nonprofit organizations have employed a click-and-brick approach as they seek new ways of reaching and extending service to their constituents. Essentially, all click-and-brick firms have both Internet and physical outlets and seek synergies between them to reduce costs, differentiate products and services, and find new sources of revenue. In the B2C area, electronic commerce can be considered a marketing channel, which can be defined as a means to interact with end consumers. Many firms rely on a mix of different channels such as physical stores, catalog sales, and e-commerce. Firms pursuing channel integration attempt to tightly coordinate the use of channels, even within a single sales activity, to improve their profitability (Friedman

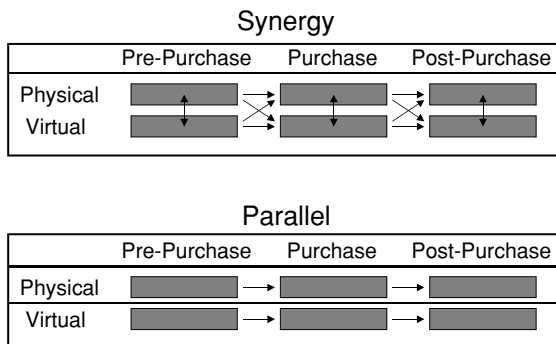

Figure 1: Contrasting Synergy with Parallel Approaches with Click-and-Brick E-Commerce.

& Furey, 1999). It is therefore helpful to distinguish the truly integrated click-and-brick approaches from those that treat electronic commerce more as a separate and parallel channel. The difference is illustrated in Figure 1. In the parallel case, customers are not able to move easily between electronic commerce and traditional channels. For example, many firms require that goods ordered online be returned directly to the e-commerce subsidiary, rather than through physical retail outlets. In the integrated, or synergy approach, customers are able to move seamlessly between channels as they interact with a firm. For example, a customer may do product research and initiate an order online but pick up the merchandise and obtain after-sales service in a physical outlet.

In the early years of electronic commerce, many in the industry felt that pure Internet firms (the dot-coms) had significant economic advantages over traditional firms. As a result, many traditional firms chose a parallel approach to the Internet in an attempt to avoid saddling e-commerce divisions with the burdens of higher costs and reduced innovativeness that they felt characterized their traditional physical channels. The widespread failure of dot-com firms, however, forced traditional retailers to rethink this approach and seek out synergies. Laudon and Traver (2004) noted that traditional retailers are replacing all but the most established dot-coms (e.g., Amazon) on the lists of top e-commerce sites. The electronic commerce activities of traditional retailers have helped to maintain a steady growth in online sales during the period in which large numbers of dot-com enterprises have failed. The U.S. Commerce Department estimated that the number of people who had purchased a product or engaged in banking online more than doubled between 2000 and 2001, growing from 13.3% of the U.S. population in August 2000 to more than 29% in September 2001 (National Telecommunications and Information Administration [NTIA], 2002). Additionally, the NTIA (2002) reported that more than a third of Americans, and fully two-thirds of the Internet users, now use the Internet to obtain product information. Meanwhile, the U.S. Census Bureau continues to measure strong growth in online sales relative to total retail sales, based on a panel of more than 11,000 retailers (U.S. Census Bureau, 2004). Online purchases for the first quarter of 2004 grew by over 28% from the first quarter of 2003, compared to 8.8% for total retail sales. Although still only about 2% of total retail sales in the

United States, the proportion has increased steadily since measurement began in 1999. It is important to note as well that these figures underestimate total consumer-oriented e-commerce activity, because the census does not include online travel, financial services, and ticket agencies in their retail sample. Figures in other developed parts of the world such as Europe reveal similar growth of e-commerce activity (see, for example, the eBusiness Watch web site at <http://www.ebusiness-watch.org>). In essence, the steady growth of online sales suggests that e-commerce has become a mainstream activity, with an increasing number of major retailers now integrating it into their channel mix to supplement brick-and-mortar assets (Otto & Chung, 2000; Rosen & Howard, 2000; Steinfield, Adelaar, & Lai, 2002). Clearly all retailers should be carefully assessing their e-commerce strategy. Surprisingly, the evidence described in the later section “Click-and-Brick E-Commerce in Practice” suggests that a majority of retailers, however, are still reluctant to do so.

SOURCES OF SYNERGY BETWEEN TRADITIONAL AND E-COMMERCE CHANNELS

Click-and-brick firms have many potential sources of synergy not necessarily available to pure Internet firms or traditional firms without an e-commerce channel. Borrowing from classic competitive advantage theory (see Porter, 1985), such sources of synergy include common infrastructures, common operations, common marketing, common customers, and other complementary assets that can be shared between e-commerce and physical outlets.

Common Infrastructures

E-commerce channels can make use of a variety of existing infrastructures such as logistics or information technology (IT) systems to reduce costs or offer capabilities that would be difficult for dot-com firms to match. An example of the use of a common logistics infrastructure would be when a firm relies on the same warehouses and trucks for handling the distribution of goods for e-commerce activities as it does for delivery to its own retail outlets. Likewise, if a firm has a capable IT infrastructure, including product and customer databases, inventory systems, and a high-speed Internet protocol network with high bandwidth connections to the Internet, the adoption and use of Internet-based commerce can be enhanced. Firms can even use their Internet access to offer e-commerce services to customers who are actually in a store or branch—for example, via kiosks.

Common Operations

Existing retail operations can also be put to good use in support of e-commerce, permitting integrated applications to emerge. For example, an order processing system shared between e-commerce and physical channels may enable improved tracking of customers' movements between channels, in addition to potential cost savings.

Common Marketing

E-commerce and physical channels may also share common marketing and sales assets, such as a common product catalog, a sales force that understands the products and customer needs and directs potential buyers to each channel, or advertisements and promotions that draw attention to both channels.

Common Buyers

Instead of competing with each other, or pursuing different target markets, e-commerce channels and physical outlets in click-and-brick firms often target the same potential buyers. This enables a click-and-brick firm to be able to meet customers' needs for both convenience and immediacy, enhancing customer service and improving retention.

Other Complementary Assets

There are many other types of complementary assets that click-and-brick firms possess that purely Internet firms may not. The management literature, for example, notes such additional complementary assets as existing supplier and distributor relationships and experience in the market. As with the other sources of synergy, to the extent firms are able to share these assets across channels, they will be better able to take advantage of an innovation such as e-commerce (Afuah & Tucci, 2001; Teece, 1986).

Of course, click-and-brick firms also obtain many of the same benefits from the use of the Internet channel as other Internet companies. Certainly the Internet channel affords the possibility for 24-hours-a-day, seven-days-a-week customer access; lower cost access to many new markets; the opportunity to develop and maintain a community of customers; and an efficient communication channel for customer input.

MANAGING CHANNEL CONFLICT IN MULTICHANNEL FIRMS

The integration of e-commerce with existing physical channels is a challenging undertaking that can create problems for management. More specifically, firms with multiple channels may fall prey to a variety of channel conflicts. Channel conflicts can occur when the alternative means of reaching customers (e.g., a Web-based store) implicitly or explicitly competes with or bypasses existing physical channels and are nothing new to e-commerce (Stern, El-Ansary, & Coughlan, 1996). One danger is that these conflicts result in one channel simply cannibalizing sales from the other. This is particularly a problem when there are clear cost, convenience, or other advantages for customers using e-commerce, causing them to substitute Internet channels for traditional ones. Such cannibalization of sales becomes a strong threat to company viability if it is difficult to capture larger revenues online. Media companies such as newspaper companies, although not exactly brick-and-mortar firms in a traditional sense, have experienced such product-channel conflicts. This is exacerbated by customers' unwillingness to pay for online information or entertainment, necessitating free online

versions that steal subscriptions from physically distributed media products. Some of the loss is made up by increased advertising revenue from online channels, but it has become increasingly clear that such business models are not sustainable in the current environment (Laudon & Traver, 2004). Additional, and potentially even more damaging, problems for the content industries that sell music and other nonperishable content (i.e., not news) arise from piracy and the massive and unlawful distribution of copyrighted content among Internet users. The rise of online music stores such as Apple's iTunes Music Store demonstrates that the Internet can be a powerful distribution channel for digitized content, threatening established physical channels. Clearly, the product-channel conflicts experienced by companies in the content industry represent a significant challenge. The review in this chapter focuses on a narrower definition of click-and-brick firms, however, in which actual click-and-brick outlets exist to support transactions with customers. Hence, this chapter does not deal directly with issues of copyright and piracy.

Cannibalization of sales is not only a problem for content firms. Price conflicts may arise for any click-and-brick firm when pressures to offer lower prices online surface and impact the attractiveness of goods in the traditional retail outlets (Turban, King, Lee, & Viehland, 2004). Perceived threats caused by competition and conflict across channels can have other harmful effects, including limited cooperation across the channels caused by staff conflicts, brand confusion caused by conflicting advertising and promotion strategies, problems when customers attempt to engage in transactions using the two uncoordinated channels, and even sabotage of one channel by the other (Friedman & Furey, 1999; Turban et al., 2004). Management must act to diffuse conflicts and ensure the necessary alignment of goals, coordination and control, and development of capabilities to achieve synergy benefits (Steinfeld et al., 2002).

Goal Alignment

One of the first tasks for managers of click-and-brick firms is to ensure that all employees agree that an e-commerce channel is needed and that they will support it. This represents a process of goal alignment. Aligning goals across physical and virtual channels implies that all employees involved realize that the parent firm benefits from sales originating in either channel. One problem faced by click-and-brick firms is that the contributions made by the Internet channel may be intangible and difficult to measure. Managers must be open to such intangible benefits and not, for example, evaluate e-commerce divisions purely on the basis of online-only sales and profitability. For example, the improved communication with customers offered by Internet channels may enable firms to better understand customer satisfaction and needs, yielding better products and services and long-run customer retention. Such benefits may not show up in pure Internet sales figures, however. Moreover, there must be agreement as to what types of customers (e.g., existing versus new) are to be targeted by the new e-commerce channel. In essence, to avoid channel conflict, management must be proactive

in obtaining the support of all employees, building consensus about the goals, methods of evaluating success, and targets for e-commerce. If management simply puts an e-commerce division into place without this goal alignment step, existing employees may feel threatened and may be uncooperative.

Coordination and Control Measures

In addition to obtaining consensus on goals, explicit coordination and control mechanisms are needed to move a click-and-brick firm more in the direction of integrated, rather than parallel channels. First, it is important for click-and-brick firms to design for interoperability across channels, so that customers may move freely between online and physical retail outlets. For example, customers may want to search a particular store's inventory from their own home computer to see whether a specific item is in stock. They may want the store to hold the item for them to pick up on their way home, rather than have it delivered. This implies that the online system connects and interoperates with the store system.

Another example of explicit coordination is the use of each channel to promote the other. For example, an online visitor may be informed about various in-store special sales, just as an in-store customer may be told about particular complementary services found on the click-and-brick firm's Web site. The use of kiosks in stores, for example, can directly enable customers on premises to access additional information, services, or promotions at precisely the moment they are considering a specific purchase. Cross-promotions enhance the perception that all the arms of the click-and-brick business are working together to add value for customers. They also create payoffs from e-commerce that can reduce resistance, such as when online promotions generate greater in-store traffic.

One of the most critical management issues for click-and-brick firms is to provide real incentives to employees to encourage cross-channel cooperation. Imagine a situation where store managers know that any time a customer buys something online instead of in the store, it represents lost revenue and lower compensation. Store personnel will invariably encourage customers to buy in the store, because this provides employees with real income. E-commerce sales may help improve customer relations, but no rational salesperson will knowingly direct customers to a sales channel that only ends up reducing his or her income. In many successful click-and-brick firms, efforts have been made to allocate online sales to particular establishments, so that e-commerce does not succeed at the expense of physical outlets. This often is possible when customers have accounts tied to a particular establishment, and online sales from specific accounts are credited to the home establishment. Another way of allocating online sales to a physical outlet is to use the address of the customer.

Finally, click-and-brick firms often find that they are able to capitalize on the unique strengths of each sales channel, affording the possibility for some degree of channel specialization (Steinfeld et al., 2002). For example, costs for certain types of transactions may indeed be

less in an online environment, suggesting that companies should encourage customers to use more efficient channels when possible. Banks, for example, have long attempted to persuade customers to use ATMs for routine cash transactions, rather than coming to a branch and occupying the services of a teller. On the other hand, many financial transactions require expert advice and counseling and are best done in-person at a branch. Hence, click-and-brick banks following a channel specialization strategy might offer customers incentives such as better interest rates or lower fees in return for the use of more efficient online channels for routine transactions like money transfers or bill payments. When more "advice-sensitive" transactions are sought, customers would be directed to their local physical bank branch (Steinfeld et al., 2002).

When there is potential for severe product-channel conflicts, such as when customers decide to forego a newspaper or magazine subscription to read free content online, a channel specialization strategy may offer a viable alternative. For example, some newspaper and magazine companies derive additional revenue from their online versions using the unique search and archive advantages of the Web-based channel. A specific niche segment of their market may willingly pay for the ability to research back issues and articles on certain topics. This approach to adding value to an online version to encourage payment has been tried by such publications as the *Wall Street Journal* (Laudon & Traver, 2004).

Capability Development

In many situations, traditional firms may lack important competencies needed to achieve synergy benefits with e-commerce. For example, traditional firms may lack Web development skills or logistics skills needed to serve distant markets. Indeed, the ability to serve remote customers is an important prerequisite to successful Web-based commerce, which explains why catalog companies such as Lands' End have experienced so much success with e-commerce. It fits well with their existing capabilities and adds value in the form of enhanced transaction efficiencies and lower costs. When lacking such capabilities, alliances may be more useful than attempting to develop a virtual channel in-house. Managers must recognize whether the requisite competencies are present in the existing traditional company and, if a partner is needed, must carefully construct an alliance that ensures that their e-commerce partner is not simply siphoning business from physical retail outlets.

POTENTIAL BENEFITS OF AN INTEGRATED CHANNEL APPROACH

Once click-and-brick companies recognize the various sources of synergy across channels and develop management strategies to avoid conflicts and encourage cooperation across channels, numerous benefits may result. Four broad areas of benefit include (a) lower costs, (b) increased differentiation through value-added services, (c) improved trust, and (d) geographic and product market extension. The potential benefits from physical and virtual integration are discussed in this section.

Lower Costs

Cost savings may occur in a number of areas, including labor, inventory, marketing and promotion, and distribution. Labor savings result when costs are switched to consumers for such activities as looking up product information, filling out forms, and relying on online technical assistance for after-sales service. Inventory savings arise when firms find that they can avoid having to stock infrequently purchased goods at local outlets, while still offering the full range of choices to consumers via the Internet. Marketing and promotion efficiencies are garnered when each channel is used to inform consumers about services and products available in the other. Delivery savings may result from using the physical outlet as the pickup location for online purchases or as the initiation point for local deliveries.

Differentiation through Value-Added Services

Physical and virtual channel synergies can be exploited at various stages in a transaction to help differentiate products and add value. Examples of prepurchase services include various online information aids to help assess needs and select appropriate targets, or, conversely, opportunities in the physical environment to test products. Examples of purchase services include ordering, customization, and reservation services, as well as easy access to complementary products and services. Post-purchase services include online account management, social community support, loyalty programs, and various after-sales activities that may be provided either online or in the physical store. Typical opportunities are in the areas of installation, repair, service reminders, and training. Although many of these value-added services are potentially available to single-channel vendors, combined deployment of such services (e.g., online purchase of computer with in-store repair or training) can enhance differentiation and lock-in effects (Shapiro & Varian, 1999).

Across all transaction stages, the improved communications from the Internet channel (assuming a well-developed and fully functional site) can yield better insights into customer needs and wants. Such customer relationship management can ultimately add value for both parties over the lifetime of a customer's interaction with a click-and-brick firm, offering benefits in excess of the actual online sales by enhancing loyalty and retention.

Improved Trust

Three reasons for improved trust, relative to pure Internet firms, derive from the physical presence of click-and-brick firms, including reduced consumer risk, affiliation with and embeddedness in recognized local social and business networks, and the ability to leverage brand awareness. Lower perceived risk results from the fact that there is an accessible location to which goods can be returned or complaints can be registered. Affiliation and embeddedness in a variety of social networks may facilitate the substitution of social and reputational governance for expensive contracts or legal fees (Granovetter, 1985). For example, an online customer may be more prone to trust

the Web site of a business when the store manager is a member of his or her church or when the customer's business and the online vendor are both members of the same chamber of commerce. Such ties are more likely to exist between geographically proximate buyers and sellers, suggesting that there may indeed be a preference for doing business with firms already physically present in the local market. Finally, marketing theorists have long recognized the power of branding as a means of building consumer confidence and trust in a product (Kotler, 1999). Established firms are able to leverage their familiar name to make it easier for consumers to find and trust their affiliated online services.

Geographic and Product Market Extension

Adding a virtual channel can help extend the reach of a firm beyond its traditional physical outlets, addressing new geographic markets, new product markets, and new types of buyers. Those in other geographic markets may be new or former customers who have moved away. Virtual channels can also extend the product scope and product depth of physical channels by enabling firms to offer new products that they do not have to stock locally. Moreover, firms may add new revenue-generating information services online that would not be feasible to offer in physical outlets. Finally, the Internet may help reach customers within an existing market who may not have visited the physical outlet but are otherwise attracted to the virtual channel due to its special characteristics.

SUMMARY OF THE CLICK-AND-BRICK FRAMEWORK

The click-and-brick framework elements can be assembled into the summary framework portrayed in Figure 2. The framework directs our attention to the sources of synergy, the need for management strategies to capitalize on click-and-brick applications, and the potential benefits that can result.

EXPLORING THE FRAMEWORK WITH SEVERAL CLICK-AND-BRICK CASES

The framework is best illustrated by describing several cases of click-and-brick firms. These examples were selected and adapted from a series of click-and-brick cases developed by Steinfield et al. (2002). Among their cases (the actual firm names were not reported based on the wishes of the interviewed companies) were a specialty retailer, a business-to-business (B2B) building materials supplier, an automobile manufacturer selling through dealerships, and a financial services firm. Each represents a different basic business arrangement—a multichannel retailer operating in the B2C arena, a B2B wholesaler, a manufacturer promoting sales to consumers through an affiliated, but independently owned, network of dealerships, and a firm selling information and services rather than tangible products. They nicely illustrate the robustness of the click-and-brick approach.

Figure 2: A Comprehensive Click-and-Brick Model (Adapted from Steinfield, Adelaar, & Lai, 2002).

An Electronics Retailer

This company is one of the largest specialty retailers of consumer electronics, personal computers, entertainment software, and appliances with more than 400 stores. The firm recently rolled out a new e-commerce site that featured both a deeper selection of products and a tighter integration with its traditional physical stores. The click-and-brick design strategy enables the firm to benefit from a range of synergies between their virtual and physical channels. The goal is to be “channel agnostic,” letting customers choose whichever channel or combination of channels best suits their needs.

A number of sources of synergy are available to the firm. One key source is the firm’s exploitation of a common IT infrastructure between their e-commerce and store channels. It accomplished this by tightly integrating the Internet operations with existing databases and other legacy systems. The firm also consciously capitalized on common operations, especially in terms of purchasing, inventory management, and order processing. That common marketing and common buyers were a source of synergy is evident in their emphasis on replicating and leveraging the store brand in their online services.

One of the services enabled by the tight IT integration allows online customers to check out the inventory of individual stores, so that they might order merchandise for immediate pickup in the nearest store. To achieve this value-added service and derive the differentiation benefit from it, the service had to be supported by a change in business processes that ensured interoperability across the two channels. For example, if only one or two items that an online purchaser desires are in stock, in-store customers might claim them by the time the Web customer arrives for pickup. To avoid this situation, store personnel must be notified that an online customer has requested an item for pickup. Then employees remove the item from the shelf and send an e-mail confirmation to the online customer. To ensure that stores cooperated with this new capability, management incentives were also considered to avoid or diffuse potential channel conflicts. In particular, the company included performance in fulfilling online

orders as one of the parameters influencing store manager compensation.

This seemingly simple service thus reflects the main components of the framework. Several sources of synergy come into play. First, the firm built the service by tying the Internet to a common, integrated IT infrastructure. Second, it supports the service by using existing store inventory that was warehoused and delivered using common logistics infrastructure. Third, the shoppers can provide payment that is credited to the store, using existing operational systems such as credit card verification and approval systems already in place. Finally, the service targets common buyers, that is, people living near existing physical stores.

Management initiatives to achieve synergy and avoid conflict are also evident in this simple example. The online service depended on the cooperation of store personnel, reflecting a need for goal alignment. This was achieved by developing a service that brought traffic into the store, rather than simply bypassing it altogether. Moreover, management recognized that the Internet could assist in prepurchase activities, even if the eventual sale was consummated in the store. It did not require the e-commerce channel to generate its own profits. Additionally, it attended to the need for explicit coordination and control by developing a business process that ensured cross-channel interoperability. Finally, it created an incentive system that rewarded store personnel for their cooperation with the e-commerce channel.

Finally, the benefits of this one service are also captured well by the framework. Consider the cost savings in labor that stores accrue when customers search for products online, conduct research, order the product, and even make payment ahead of time, all without needing the assistance of a single employee. In terms of differentiation, this represents a prepurchase and purchase service that would be difficult for a non-click-and-brick firm to offer. It caters to the different needs and wants of store and online customers, improving satisfaction. Because of the tie-in to the local store, which is also part of a well-known national chain, customers perceive much lower risk than

they would if ordering from a less familiar, nonlocal Internet business.

The tight integration between the e-commerce and existing retail infrastructure offers this firm many other advantages derived from the same sources of synergy and enabled by many of the same management strategies. For example, because of their integrated approach, customers who order products online with home delivery are able to return products to their local store, enhancing trust and reducing perceived risk. Moreover, the integration of IT systems enabled store employees to access customer and order data to improve customer assistance, such as finding complementary goods.

Channel cooperation extends in both directions. In-store customers who are unable to find a product on the shelf can search the firm's online site through kiosks available in the store. Because of the integrated approach to marketing, the firm is also able to undertake promotional campaigns, such as sales and contests that customers can access in the store and on the Web. In addition, the Web channel also enabled value-added services geared toward improving customer relationship management. In particular, the Web site allowed customers to store items under consideration in a "Think About" folder. This provides useful marketing information to the firm, because it can provide more targeted promotions related to desired products.

A Building Material Supplier

The building materials supply company has a double-pronged approach to e-commerce. First, it maintains its own Web site, offering rich information services to its primary customer base—the professional builder. Second, it has an alliance with a building supply portal that allows it to offer e-commerce transactions to its existing client base as well as to new customer segments.

Professional builders are provided with an account that allows them to use the e-commerce site. They can log in directly from the builder supply firm's home page. A local lumberyard where the builder has an account fulfills the orders. Essentially, each lumberyard caters to the market located within a radius of 100 miles. Prices are individualized, encouraging builders to consolidate their purchases for volume discounts.

The building supply portal works with other suppliers but is tightly coupled with the case study firm because both firms have the same principal stockholder. In addition to providing online supply ordering services to builders, it also enables the firm to offer value-added services, extend into the consumer home improvement market, and provide customers goods that the local lumberyard does not carry. Among the value-added services are a variety of accounting and management options that builders can use. These include maintaining an online ledger for a project—for example, a house—that can be used as a template for the next project, saving builders time on order entry. Each builder can have his or her own personal Web page, including a personal product usage and construction plan folder. Builders can also check the status of their orders on a daily basis and order material outside the regular store hours. This is help-

ful because many builders do their administrative tasks at home in the evening. The personal pages include information on activities and promotions occurring at the local branch.

By outsourcing consumer e-commerce transactions to the online portal, the company now has a presence in the growing home-improvement market now dominated by such superstores as Home Depot. Because of the other partners who participate in the portal, the company is able to offer their existing customers one-stop shopping services, even for goods that they do not carry.

Individual stores receive electronically all orders placed on the portal for their products and fulfill them through their normal supply chain and existing fleet of delivery trucks. New professional clients are first encouraged to set up an account at a local branch, where local employees negotiate individual pricing arrangements.

The Web-based service supports standard orders. The company still maintains outside sales representatives (OSRs), however, who visit with builders on job sites to maintain good customer relations. The increased use of online ordering by builders allows OSRs to pay less attention to administrative tasks and to focus on selling value-added services, giving advice, educating the client about the online channels, and strengthening customer relationships.

Through its online partner, the firm also completed a successful mobile service pilot using Palm Pilots. Builders were able to make on-site purchases for critical materials needed immediately. Materials were then brought out to the job by the local delivery truck. One interesting impact of this service is that it encouraged builders to wait until the last minute for some orders and to make orders in smaller quantities than they would through normal channels. This is, of course, less efficient for the supply firm, creating some challenges for their delivery system. It is, however, a new value-added service that strengthens their relationship with core clients.

An Automobile Manufacturer/Dealer Network

All automobile manufacturers realize that car shoppers are able to conduct extensive research online before buying a car. Carmakers have well-developed Web sites providing rich information about their models, but for a variety of reasons they are not able to sell cars directly to end customers through the Web. Hence, they must work with traditional dealers to offer a click-and-brick experience. In one carmaker's e-commerce service, customers can configure their desired car online, obtain a fixed price quote, and choose a local dealer from whom they wish to take delivery. The application locates the matching car from dealer inventories, and if in stock at a different dealer from that chosen by the customer, the dealers will swap cars with each other. The chosen dealer then gets full credit for the sale of the online-configured car, as well as the continuing service relationship to the customer. At the Web site, customers can also research cars and check the inventory of local dealers online. In addition, customers can apply online for credit and insurance, which is also submitted to the local dealer.

This approach helps the manufacturer sell more cars without alienating its existing dealer network. The company realizes that in the car market, because of the logistics of delivery and the need for a physical presence for service and warranty work, bypassing dealers will not work. In fact, in many states, it is illegal for car manufacturers to sell directly to end consumers. To secure support from dealers for the initiative, an e-dealer advisory board was created. The manufacturer has also introduced features such as online scheduling for maintenance and repair and an ownership Web site where customers can find accessories that go with their car and receive maintenance service reminders.

Other electronic services initiatives include the introduction of mobile in-car services for safety, security, and information. They are utilizing the combination of Global Positioning System with wireless technology to deliver emergency roadside assistance, stolen vehicle tracking, navigation aids, and other travel-related services. The selling dealer will activate these in-car wireless services and provide training to customers.

A Financial Services Provider

The final case described here is a large national bank offering a traditional range of banking and financial services. The company focuses on the consumer and small business segment and has more than 8 million households as customers. It took a somewhat different path from the other cases to arrive at a click-and-brick strategy. In fact, this bank, through acquisitions and mergers, had both a typical online banking service available to its account holders and an entirely separate Internet brand that solely targeted new customers over the Web. In the description of this case that follows, the former is referred to as the internal online banking service, whereas the latter is referred to as the Internet pureplay bank.

Their Internet pureplay bank was not successful, largely because of the high costs of customer acquisition and the lack of necessary synergies with the parent bank. One particularly troublesome problem faced by all Internet-only banks results from the difficulties and costs of transferring money into and out of the Internet bank. Because of customers' reluctance to deposit cash or checks in ATMs, Internet-only bank users first must deposit funds in a traditional banking account and then transfer money (e.g., via a check or bank transfer) to their Internet account. This implies that the Internet pureplay bank would always be a supplementary rather than a primary bank. Moreover, in this bank's earlier parallel approach, the Internet pureplay bank had to rely on other banks' ATM networks to allow customers to make cash withdrawals, resulting in relatively high surcharges.

On the other hand, the internal online banking channel service was closely tied to the brick-and-mortar branches, had much lower customer acquisition costs, and offered many customer retention services. Existing account holders were freely offered the opportunity to sign up for online access to their bank accounts and other banking services, allowing online customer acquisition at a fraction of the cost of finding entirely new bank account clients. Customer retention was enhanced by providing such ser-

vices as online bill payment. Services such as this increase retention by raising switching costs, because customers need to reenter extensive billing information if they change to a new bank. Another synergy benefit the bank experienced with its internal online banking channel stemmed from cost savings at brick-and-mortar branches due to the ability to offload routine transactions to the cheaper and more convenient Web channel. In keeping with the channel specialization management strategy described earlier, price incentives were also introduced to stimulate the use of the online services.

The parent bank took advantage of IT infrastructure synergies between its branches and its integrated online banking service by designing financial applications once and implementing them across the virtual and physical channels. For example, an application to speed up the approval of home equity loans was "mirrored" between the Web and the physical branches. The bank effectively developed coordination and control measures to be able to offer seamless customer support, so that customers would not have to repeat any transactions on multiple channels. For example, if customers changed their address using one channel, all systems would be updated at the same time. To achieve this, the bank had to integrate systems so that Web services were integrated into the day-to-day operations of branches.

As a result of these experiences, the formerly separate Internet pureplay bank was reintegrated into the parent bank, tying it more closely to the click-and-brick branches. Networked kiosks in bank branch offices introduced the Internet brand more directly to existing bank clients. The parent bank now supplies many of the core services, including deposits and withdrawals, and its connection to the Internet brand creates the trust that had been lacking. The benefit for customers is that they have the choice of a more differentiated set of banking services, with more differentiated prices that reflect the costs of transactions.

CLICK-AND-BRICK E-COMMERCE IN PRACTICE

Most research on click-and-brick e-commerce has used a case study approach, yielding many of the insights discussed earlier. However, cases do not necessarily reveal trends in the broader population of retailers and cannot tell us whether the kinds of click-and-brick approaches described here are really all that widely used. Therefore, in the spring of 2002, an analysis of the use of the Web by approximately 3100 retailers was conducted (Steinfeld, Adelaar, and Liu, 2005). The sample comprised companies drawn from nine different retail sectors according to the North American Industrial Classification System (NAICS), focusing on retail sectors where e-commerce sales have been reported to be higher. Despite more than a decade of e-commerce via the Internet, only slightly more than half (54%) had a Web presence, with less than a third (31.5%) having sites considered to be working and active. Those with working sites (note that to be working simply meant that the links functioned appropriately—it did not mean that the site supported full online transactions) numbered 979 and were included for further analysis.

Table 1 Summary of Firms Included in the Web Site Content Analysis^a

Retail Sector	NAICS Code	Number of Firms	Avg. Annual Sales (in millions)	Avg. Number of Employees
Motor vehicle and parts dealers	441	200	361.5	593
Furniture and home furnishings	442	138	64.7	495
Electronics and appliances	443	144	359.2	1,715
Building material, garden equipment, and supplies dealers	444	121	737.0	4,186
Health and personal care	446	58	1,114.5	5,937
Clothing and clothing accessories	448	97	833.2	8,465
Sporting goods, hobby, book and music	451	141	120.0	1,135
General merchandise	452	55	6,591.9	47,451
Miscellaneous store retailers	453	29	674.1	4,196

^aAdapted from Steinfield et al. (2005).

Table 1 provides a summary of the companies that were included in the content analysis.

Despite the expectations from the click-and-brick cases, a content analysis of retailer Web sites revealed a surprisingly low incidence of real integration between e-commerce and physical channels. Trained coders analyzed all of the company Web sites for the presence or absence of 16 different characteristics grouped into three categories:

1. features that are universal (i.e., they are found in nearly all firms' Web sites);

2. features that reflect an integrated, click-and-brick emphasis (i.e., they explicitly involve a retail outlet in some way); and
3. other features that reflect some degree of online expertise, but do not necessarily imply a click-and-brick orientation.

As shown in Table 2, nearly all firms included the telephone number (96%) and address of retail outlets (95.5%), and so these were considered universal features. Common click-and-brick features included providing a map or driving directions to retail outlets (71.4%), giving

Table 2 Relative Frequency of Selected Web Site Characteristics in Click-and-Brick Firms^a

Web Site Characteristics	Number (%) of Sites with Feature
Universal features	
Phone number of retail outlets	946 (96%)
Mail address of retail outlets	941 (95.5%)
Features reflecting a click-and-brick orientation	
Map to retail outlets or driving directions	702 (71.4%)
Company background or history	565 (57.4%)
Hours of operation of retail outlets	516 (52.4%)
Information on retail outlet events or specials	443 (45%)
Coupons or gift certificates redeemable in retail outlets	248 (25.2%)
Ability to search the inventory of a retail outlet	189 (19.2%)
Ability to make an appointment or reservation for a service in the retail outlet	148 (15%)
Allow customers to return items purchased online to retail outlets	80 (8.1%)
Links to other businesses in the community where retail outlets are located	69 (7%)
Allow online orders to be picked up at retail outlet	61 (6.2%)
Other features reflecting online expertise, but not necessarily a click-and-brick orientation	
Ability to complete a full transaction online	330 (33.5%)
Allow customers to set up and manage accounts	266 (27%)
Allow checking on the status of an online order	206 (20.9%)
Allow customers to place items in a gift registry	64 (6.5%)

^a Adapted from Steinfield et al. (2005).

historical background on the company (57.4%), listing store hours (52.4%), and providing information about in-store events or specials (45%). These all reflect informational strategies rather than transaction-oriented click-and-brick services or services illustrating interoperability between stores and Web sites. Few sites offered coupons or gift certificates redeemable in stores (25.2%), allowed users to search in-store inventories (19.2%), let customers make appointments (15%), let online buyers return goods to physical stores (8.1%), linked to other local businesses (7%), or allowed online orders to be picked up at a physical store (6.2%). In general, the results demonstrate the relative lack of sophistication of retailers vis-à-vis online sales, let alone click-and-brick integration. Indeed, in only a third of the sampled firms could customers even complete a full transaction online.

These results show that, despite the apparent benefits arising from the integration of online and offline channels, in practice most firms fail to pursue a click-and-brick strategy. Further analysis of the 2002 data show that mainly larger firms, and those selling large products (e.g., cars), are more likely to pursue a click-and-brick strategy. Larger firms have the IT resources to develop a credible e-commerce capability and are more likely to possess an established brand identity from which their e-commerce channel can establish trust. For firms selling large products like cars, the logistical issues involved with product shipping compel retailers such as automobile dealers to use the Web mainly to bring customers to their lots.

Click-and-brick integration may thus be used less widely than expected, mainly because of the need for significant IT and financial resources that smaller retailers lack.

INFORMATION SECURITY AND CLICK-AND-BRICK RETAILERS

In general, click-and-brick retailers face many of the same information security threats and must rely on the same techniques to protect customers as any Internet-based retailer. As in all other e-commerce, click-and-brick e-commerce requires the authentication of both consumers and the online store channel, the preservation of the confidentiality of information related to online transactions, and the guarantee of the integrity of transaction-related information (see chapter "Electronic Commerce", this volume). Click-and-brick customers who buy from the online channel must provide personal and financial information, and can suffer financial loss and fall prey to identity theft. Indeed, since click-and-brick businesses, by definition, have a physical outlet that, by and large, was in existence prior to the Internet, attention to information security issues in the online business is critical. Otherwise, such companies may end up alienating an established customer base should they suffer losses as a result of inadequate attention to information security. Click-and-brick firms must support secure transmissions using encryption techniques such as secure sockets layer (SSL; see chapter "Public Key Cryptography Standards", this volume) and both symmetric and public key encryption systems (see chapters "Internet E-Mail Architecture", "S/MIME (Secure MIME)", and "Secure Shell (SSH)", this volume).

There are, however, a number of important distinctions that can be mentioned when comparing information security issues in a click-and-brick environment with general e-commerce security. One set of distinctions stems from the various ways that the physical outlet can augment customers' perceived security when engaging in transactions with the online channel. As noted earlier in the chapter, click-and-brick firms can benefit from an existing reputation and higher initial trust because they have physical outlets. Research has shown that this factor enhances trust because customers have a sense that there is a place to go to complain if transactions are not satisfactory, and if they want to return products. Moreover, highly integrated click-and-brick stores possess another critical advantage vis-à-vis payment for online purchases. Since they do have a physical outlet, the option of allowing offline payment in the store can help provide an additional layer of perceived security for those customers who fear inputting private financial information onto a Web form. Such customers can defer payment until they pick up purchased items at the store, limiting their online exposure.

On the other hand, the goal of integrating online and offline operations introduces new security challenges for click-and-brick firms. Highly integrated click-and-brick firms will want to allow more access to company information (e.g., store inventory), necessitating more sophisticated authentication and authorization, so that customers cannot access private company data. Moreover, the focus on existing customers who live near physical outlets will further necessitate the establishment of customer accounts, placing pressure on retailers to establish sound practices vis-à-vis computer account management, password management, and the like. Truly creative hybrid stores may also run into problems when their attempts at online and offline integration are developed on an insecure infrastructure. For example, firms that integrate wireless LAN technology into their physical sales infrastructure face challenges raised by the early problems with the security of the transmissions. Early encryption approaches in 802.11b wireless LANs (also known as wireless fidelity or Wi-Fi networks) such as the wireless equivalent privacy (WEP) protocol were quickly compromised by hackers (see chapters "Fault Attacks" and "Physical Security Measures", Volume III, this *Handbook*). In one well-known case, the large electronics retailer Best Buy found that it was possible to intercept transmissions of credit card numbers being sent via wireless LAN in the store to cash registers (Stone, 2002). This illustrates that despite the integration with physical outlets, click-and-brick retailers are not immune to the information and network security threats raised by e-commerce. Finally, as noted earlier, a large number of retailers seem to have difficulty establishing even the most basic online transaction capability. The research suggests that smaller and medium-sized enterprises lack the resources and IT sophistication to build e-commerce channels highly integrated with offline businesses. Hence, it seems likely that such firms would also face challenges in attending to the development of sound information security practices in their computer and network infrastructures. Lack of meaningful information security will thus remain a significant challenge to the growth of click-and-brick electronic commerce.

CONCLUSION

This chapter has provided a broad overview of the click-and-brick business approach, noting both the potential benefits as well as the challenges that firms face because of channel conflicts. A framework to help understand the dynamics of managing a click-and-brick enterprise was introduced. The framework begins by identifying potential sources of synergy available to firms that choose to integrate e-commerce with traditional forms of business. It further emphasizes the many actions that firms can take to minimize channel conflicts and help achieve the benefits of synergy, and it describes four categories of synergy-related benefits from the integration of e-commerce with traditional businesses, including potential cost savings, gains due to enhanced differentiation, improved trust, and potential extensions into new markets. Four case studies were described to provide a concrete illustration of the approaches taken by click-and-brick firms. The chapter acknowledges, however, that despite the potential benefits, truly integrated click-and-brick retailing remains the exception rather than the rule, largely due to a lack of IT and financial resources among retailers. The chapter addresses the theme of the *Handbook* by pointing out that click-and-brick retailers must be as attentive to information security as any e-commerce firm. Although they have some advantages, such as the ability to fall back on in-store payment and pickup for online orders, click-and-brick businesses also have their own unique security challenges. As such firms attempt to gain real synergies through online/offline systems integration, threats from inadequate security increase significantly. Finally, the lack of IT and financial resources does imply that many click-and-brick firms will be unable to support sound computer and network security practices necessary for comprehensive e-commerce information security.

ACKNOWLEDGMENT

I am grateful to the reviewers and editor for the thoughtful comments on an earlier version of this chapter.

GLOSSARY

Channel A means by which a seller interacts with end consumers. Many firms rely on a mix of different channels, such as physical stores, catalog sales, and e-commerce. Firms pursuing channel integration attempt to coordinate the use of channels tightly, even within a single sales activity, to improve their profitability.

Channel Conflict The conflict that occurs when an alternative means of reaching customers (e.g., a Web-based store) implicitly or explicitly competes with or bypasses existing physical channels. Perceived threats caused by competition and conflict across channels can have other harmful effects, including limited cooperation across the channels, confusion when customers attempt to engage in transactions using the two uncoordinated channels, and even sabotage of one channel by the other.

Channel Specialization The directing of customers by click-and-brick firms to the most appropriate channel

(e.g., one that is the lowest cost or one that offers the requisite capabilities). It allows firms to capitalize on the unique strengths of each sales channel.

Complementary Assets Assets possessed by a firm, such as existing supplier and distributor relationships and experience in the market, that help it take advantage of innovations such as e-commerce.

Differentiation A competitive approach used by companies to set themselves apart from competitors through higher quality products and better customer services. Click-and-brick firms hope that they can use their combined channels to differentiate themselves from competitors.

Kiosks Self-service computer stations, often with a touch-screen display, located in malls, stores, and other places where customers can use them to locate products or information and access services electronically. Click-and-brick firms may offer networked kiosks on store premises to allow in-store customers access to the firms' e-commerce channel.

Synergy The combined effect of two actions that is greater than the sum of the individual effects. Click-and-brick firms hope that by combining traditional and online services, they can offer an experience to customers greater than that possible through each channel by itself.

INTRODUCTION

Mobile commerce (m-commerce) is the buying and selling of goods and services, or the exchange of information in the support of commercial activities through wireless handheld devices such as cellular telephones and personal digital assistants (PDAs). Mobile commerce enables users to access the Internet and conduct transactions with monetary value from anywhere, anytime. For mobile commerce to take off, it needs to build on the established habits and practices of the consumers, and on the infrastructure, and then should add specific benefits due to mobility. For instance, the added benefits may include instantaneous access and delivery, flexibility, convenience, personalization, location awareness, and better customer service. In addition, the ease-of-use, convenience, and ensuring of security and privacy should be the salient features of mobile commerce.

The increase in the demand for applications dealing with moving objects can be seen in the past decade. Furthermore, mobile phones and/or wireless PDAs are expected to evolve into wireless terminals that are global positioning system (GPS)-enabled. In addition to wireless computing devices, tracking of other moving objects such as boats, trucks, automobiles, airplanes, and soldiers has become a growing interest. With the great demand on mobile devices, mobile commerce has emerged as a gigantic market opportunity. The mobile customer base has grown to 1.52 billion, among which U.S. mobile users number 140 million (Wireless World Forum, 2004). A Yankee Group survey (Yankee Group Research, 2004.)

suggests that U.S. consumers are not convinced they want or need mobile services and many think it is simply too complicated. This is in contrast to other global markets in Asia and Europe where “going online” means reaching for a mobile handset, but not turning on a PC. In Japan and Korea, for example, reports suggest that one-third of all mobile phone subscribers use their handsets for m-commerce activities (InStat/MDR, 2002).

Worldwide, mobile commerce revenues are expected to exceed \$25 billion by 2006 (NUA Internet Surveys, 2002). According to Juniper Research, it is expected that retailers will make up to \$40 billion in sales from customers who will use mobile phones to spend cash on everything from cinema tickets to hourly car parking (Ambassna-Jones, 2004). This excludes already popular m-commerce products like mobile phone ringtones, Java games, wallpaper, and screen savers. According to an IDC study, mobile entertainment will be worth \$8 billion in Western Europe in 2008. The purchases consumers will make will mainly consist of low-priced items, or what the industry calls micropayments. It is also expected that radio frequency identification (RFID) and infrared technologies will have a major influence on the future development of devices that allow for payments. DoCoMo's i-mode mobile service has attracted over 41 million subscribers since its introduction in February 1999. The revenues from mobile services reached \$2 billion by the end of 2002 and are expected to reach \$18 billion by the end of 2006. These revenues are divided as follows: 31% in Western Europe, 22% in the United States, and 47% in Japan and the rest of the world. As such, the market for location-aware mobile

applications such as mobile shopping, mobile advertising, mobile retailing, mobile entertainment, and mobile online banking is very promising. Figure 1 provides an overview of different mobile commerce components. We will review each of them in this chapter, with the exception of the standards and policies.

MOBILE COMMERCE APPLICATIONS

As content delivery over wireless devices becomes faster, more secure, and scalable, it is believed that mobile commerce may exceed the traditional e-commerce. Mobile commerce applications can be categorized into the following classes: business-to-business (B2B), business-to-consumer (B2C), consumer-to-consumer (C2C), business-to-employee (B2E) (Lehmann & Lehner, 2004), and government-to-citizen (G2C). Whereas security is not important in some information service applications, it is significant in certain transaction-oriented applications. For example, a cellular phone can be used as a personal trusted device (PTD). In such cases, mobile customers may use it to pay for goods and services that may typically include gas, soft drink, or a ticket to a football game, or check their bank balances. In such scenarios, the mobile service calls for confidentiality, integrity, identification, and authentication requirements.

Many aspects of the mobile communications industry, including the importance of mobile communications and mobile applications, and the competitive landscape of a mobile phone market based on competing protocols or standards, airtime carriers, and handset providers have been explored (Kumar, 2004). Table 1 summarizes different types of applications (not an exhaustive list) and their category. We describe these applications in detail in the following.

Mobile Financial Services

These services will encompass:

1. Mobile banking through which customers access their bank accounts and pay their bills using handheld devices, and
2. Mobile brokerage through which customers obtain stock quotes displayed on their handheld devices and conduct trading using these devices.

In both cases, the mobile customer uses his/her PTD to set up a secure session with the bank.

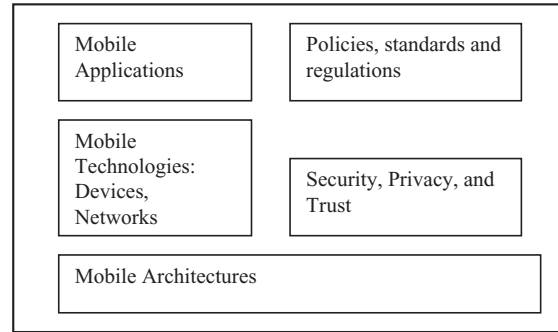

Figure 1: Mobile commerce: the big picture.

Mobile Telecommunications Services

These include services provided by telecommunication companies where a customer uses his/her handheld device for the purposes of service changes, bill payment, and account reviews.

Mobile Information Provisioning

These services include the delivery of financial and sports news and traffic updates to mobile customers. Other information service provisioning applications include integrated information services, such as tourist services, traffic coordination and management, way-finding, weather reports and forecasts, stock quotes, travel itineraries and nearby restaurants, news updates, business and technology news, local town information, telephone directory, restaurant guide, dictionary service, and cooking recipes, among others.

Mobile Security Services

Many public safety and security-related services can be provided through mobile devices as one can track and pinpoint the location of the device. These safety-related services include:

1. Tracking and locating stolen cars as well as automatically notifying the owner;
2. Remotely controlling a car, for example, disabling or starting the car engine, or honking the horn;
3. Tracking groups of vehicles and sending an alert when a vehicle crosses a predefined boundary;
4. Transmitting an alert when a laptop moves beyond a predefined area;

Table 1 Mobile commerce categories and their applications

Category	Application
B2B	Advertising, location-based services (e.g., supply chain management)
B2C	Financial services, telecommunications services, information provisioning, security services, remote shopping, on-site shopping, ticketing, advertising, entertainment, location-based services
C2C	User-to-user applications, wireless video conferencing
B2E	Wireless video conferencing, reporting, claim processing
G2C	Security services

5. Tracking children, people with Alzheimer's disease, or those mentally disabled, as well as pets, and transmitting an automatic notification to their parents or carers;
6. Sending remote control commands via phone or Web to let someone into the house, to turn down the thermostat, or to start an appliance;
7. Transmitting messages via a reverse 911 service to individuals in emergency situations; and
8. Helping to dispatch 911 services, including real-time delivery of information on crime mapping, and providing of access to federal and state databases and mug shots.

Mobile Remote Shopping

The mobile phone user browses in a wireless application protocol (WAP)-enabled shop, selects the desired goods, and pays for them with funds from his bank or credit card account. These include services or retail purchases as consumers are given the ability to place and pay for orders on-the-fly.

Mobile On-Site Shopping

A mobile user may select the desired goods in a retail store and use his/her PTD to pay by logging onto the department store's Bluetooth wireless LAN.

Mobile Ticketing

The user browses a WAP ticketer's site, selecting and purchasing a ticket for a movie, show, or game. All ticket information is stored in the PTD's transaction database. At the venue, the user goes up to one of the wireless access nodes on the premises (similar to an ATM), calls up the ticket information from the PTD's database, and sends it via Bluetooth to this access node, which then prints out the user's ticket.

Mobile Advertising

Mobile advertising includes personalized, location-aware, and context-sensitive advertising, as mobile devices are ideal for marketing channels for impulse buying. For example, mobile users can be pushed with information related to nearby hotels when they are not in their home location, nearby movies during evenings and weekends, or nearby restaurants based on their preferences.

Mobile Entertainment

Mobile entertainment may include location-based games, character download, horoscope and fortune telling, karaoke information, hit songs, downloadable ringtones, club event information, etc.

Wireless Video Conferencing

Wireless video conferencing can be enabled using voice over Internet protocol (VoIP) and full-motion video communication over both wireless fidelity (Wi-Fi) and universal mobile telecommunications system (UMTS)-based networks.

Mobile User-to-User Applications

Mobile user-to-user applications include mobile games, pictures, cartoons, or personal files shared between users and their friends and colleagues via the handset; user-to-user content provision; conversational applications (which provide the means for bidirectional communication with real-time end-to-end information transfer), such as video conferencing; groupware (collaborative work); and messaging applications (which offer user-to-user or user-to-user group communication), such as messaging of photographs and video.

Location-Based Services

The demand for location based services (LBS) can be categorized into the following types (Rao & Minakakis, 2003):

1. *Location and navigation service*: Maps, driving directions, directory and yellow page listings, and business descriptions in a given geographical radius all serve this purpose. These types of LBS have become popular in Japan, whereas they are a more recent phenomenon in the United States. GPS capabilities may allow customers to find their way to their destinations and alert friends and colleagues to their whereabouts. If a person gets relocated, they can use mobile location-based services to familiarize themselves with their new surroundings. Examples also include getting detailed maps and directions, real-time alerts on traffic conditions, and information about highway services like gas, food, and lodging. Although auto manufacturers are investing in making mobile platforms available in cars, currently relatively inexpensive handheld devices are serving this purpose. These include devices like golfing assistants mounted on golf carts that provide everything from course maps to teeing tips, fish finders that combine sonar and GPS capabilities to allow anglers to pinpoint locations of schools of fish, and people locators, which enable parents to locate children in urban areas and shopping environments (Spagat, 2002).
2. *Point-of-need information delivery*: This service is for requesting usable, personalized information to be delivered at the point of need, which can include automatic updates of travel reservations as well as information about new or interesting products and services, promotions, and targeting of customers based on more advanced knowledge of customer profiles and preferences. For example, a wireless shopping site can be designed to present users with targeted content such as clothing items on sale, based on prior knowledge of their preferences and/or knowledge of their current location, such as proximity to a shopping mall (Venkatesh, Ramesh, & Massey, 2003). To deliver such LBS, service providers require access to customers' preference profiles either through a proprietary database or through an arrangement with an LBS provider, who matches customer profiles to vendor offerings. In order to implement such services, customization and personalization based on the location information, customer needs, and vendor offerings are required.

3. *Industrial and corporate applications*: This type of LBS finds its way into a number of applications including tracking material through the supply chain and inventory, and tracking physicians, patients, and equipment in a hospital. This relies on the deployment of RFID technologies, which is becoming inexpensive and will likely be used by a number of retail businesses such as Wal-Mart.

BUSINESS MODELS IN THE M-COMMERCE ENVIRONMENT

A number of business models are being practiced by the vendors of mobile commerce. Notable ones among these include:

1. User fee business model;
2. Shopping business model;
3. Marketing business model;
4. Improved efficiency business model;
5. Advertising business model; and
6. Revenue sharing business model (Sadeh, 2002).

These are described briefly in the following.

User Fee Business Model

Under this model, payment can be based on a subscription fee, or based on usage. This model is best suited for regularly updated content such as customized news, location-sensitive weather, and traffic conditions. In reality, the content provider may rely on the mobile service provider to implement it and collect the appropriate fee. The obvious advantages of adopting a subscription fee-based model over the usage fee model are that it is easier to collect the fees and the income is relatively better predictable. However, the usage fee model would be more attractive to one-time or infrequent users.

Shopping Business Model

Under this model, the traditional Internet companies sell their goods and services through the new mobile medium to reach their customers to offer better services and convenience, and moreover to capture additional customers. Essentially, the traditional Internet companies seek a mobile presence. The payment is done with the mobile device, but typically involves a third party such as a credit card company or a bank.

Improved Efficiency Business Model

Whereas the shopping business model is adopted by traditional Internet companies for expanding their customer base, the improved efficiency business model offers mobile services, such as mobile banking and mobile ticketing, to those companies hoping to reduce their operating costs.

Marketing Business Model

The traditional brick-and-mortar companies push the information about their products and services directly to

customers through mobile channels. However, the customers make payments using traditional methods, not mobile devices.

Advertising Business Model

The advertising business model involves the gathering of profiles and preferences of mobile customers and targeting advertising based on a customer's location, time, and preferences. Typically, the advertiser passes on the information to the content provider, who would deliver the advertisements relevant to the user's queries. The advertiser pays for the content provider by a flat fee, or based on traffic (number of ad impressions) or on performance (number of click-throughs or call-throughs).

Revenue-Sharing Business Model

Under the revenue-sharing business model, the mobile content owner utilizes the services of a mobile content provider, which is suitable in cases where the content provided by a single owner is not sufficient to attract the attention of mobile customers or is not valuable as standalone information. In such cases, the mobile content provider combines the content from different owners and may enhance it with value-added information before delivering it to the mobile customer. For example, local weather reports, local traffic conditions, stock quotes, and news updates can all be combined appropriately by the content provider. Typically the content provider collects the customer's payment and shares it with the content owners.

ENABLING TECHNOLOGIES

Mobile commerce has emerged as a result of the developments in several technologies. In this section, we review the advances in these different technologies that have propelled the growth of mobile commerce.

Mobile Devices

Mobile devices such as smart phones and personal digital assistants have reached new levels of usability, performance, and computing power. Increasingly, these devices are equipped with wireless communications capabilities and location technologies. In order to exploit the m-commerce market potential, a number of industry initiatives to enable secure and reliable mobile commerce transactions have taken place. Handset manufacturers such as Nokia, Ericsson, Motorola, and Qualcomm have been working with carriers such as AT&T Wireless and Sprint to develop WAP-enabled smart phones to transform a mobile phone into a PTD. In addition, IBM and other companies have been developing speech recognition software to ensure security in mobile commerce transactions. Using Bluetooth technology, smart phones offer fax, e-mail, and phone capabilities all in one, paving the way for m-commerce to be accepted by an increasingly mobile workforce. Although, the current speeds are limited, the new generations of wireless networks such as UTMS will provide much faster speeds. In addition, these technologies will provide always-on connectivity.

Wireless Networks

The enabling technologies for m-commerce include wide-area and short-range wireless communication technologies such as Wi-Fi, Bluetooth, and RFID technologies. In the following, we review their evolution over different generations—1G through 4G. Based on the technology use, the market growth in global GSM (global system for mobile communication) users has increased to 1.25 billion, global CDMA (code-division multiple-access) users to 202 million, global TDMA (time-division multiple-access) users to 120 million, and total 3G users to 130 million (<http://www.cellular.co.za/stats/stats-main.htm>). According to Pyramid Research (2004), Wi-Fi users will surpass 3G users, and it is expected that by the year 2008 the number of Wi-Fi users will reach 180 million, whereas that of 3G will be less than 100 million.

1G

The first generation of wireless technologies used analog transmission, which operates in the 800-MHz band and uses 30-kHz channels using frequency division multiple access (FDMA). It was introduced in North America in 1985 (advanced mobile phone service). Because of the limited bandwidth, this soon exhausted the available channels, thereby limiting the number of subscribers. Since digital signals can be compressed, enabling more effective use of the frequency spectrum, it was natural to employ digital technology.

2G

The second-generation systems, which digitized not only the control link but also the voice signal and used TDMA and CDMA, appeared in the early 1990s. Unlike 1G, which primarily supports voice signals, 2G networks are capable of supporting voice, data, paging, and fax services. Moreover, they provide better quality and higher capacity at lower cost to consumers. GSM was the first commercially operated digital cellular system based on TDMA.

2.5G

One of the major enhancements of 2.5G over 2G is the use of packet-switching technology. The general packet radio service (GPRS) is based on packet-switching technology, which sends packets of data over a radio wave (on the GSM network). GPRS was standardized by the European Telecommunications Standards Institute (ETSI), but today is standardized by the Third Generation Partnership Program (3GPP).

With GPRS, a maximum speed of up to 171.2 kbps, which is almost ten times faster than that of the current circuit-switched data services on GSM networks, can be achieved. However, realistically they currently only have a maximum downstream speed of 50 kbps and an upstream speed of 10–28 kbps. Speeds will also depend on which GPRS version an operator uses, as well as how busy the network is at a particular time. In addition to achieving higher transmission speeds, unlike the users served by circuit-switching networks, GPRS users are “always connected.” GPRS data transmission technology is optimized for “bursty” communication services such as wireless Internet/intranet and multimedia services. It is also known as GSM-IP (Internet protocol) because it connects

users directly to Internet service providers, allowing Web browsing, chat, e-mail, telnet and FTP, multimedia services, and instant messaging to be supported over the mobile network. GPRS therefore offers a smooth add-on to integrate into existing networks and supplements today’s circuit-switched data and short message service. Future applications may have the ability to remotely access and control in-house appliances and machines. Voice calls can be made simultaneously over GSM-IP while a data connection is operating—depending on the phone class and type. Although users are always connected and always online, they may still be charged for the amount of data transported.

3G

Telecommunications companies around the world have been working toward the commercialization of third-generation (3G) mobile phone technology. It enables the transmission of high-quality video images in the 2-GHz frequency band and realizes new mobile multimedia communications services. NTT DoCoMo was one of the firsts in the world to begin research and development on W-CDMA, a key foundation for 3G mobile phone technology. The UMTS is a 3G mobile communications technology that provides wideband CDMA radio technology. With data rates up to 2 Mbps, UMTS provides increased capacity and data capability and a far greater range of services. A variation of CDMA, called the time-division synchronous CDMA (TD-SCDMA) was proposed by China Wireless Telecommunication Standards group (CWTS), which uses the time-division duplex (TDD) mode. The CDMA technology offers higher throughput, real-time services, and end-to-end quality of service (QoS), and is capable of delivering pictures, graphics, customized infotainment, streaming video, video messaging to locational services, and other multimedia information as well as voice and data to mobile wireless subscribers. UMTS is standardized by the 3GPP.

4G

The 4G mobile services are the advanced version of the 3G mobile communication services. The 4G mobile communication services are expected to provide broadband, large-capacity, high-speed data transmission, providing users with high-quality interactive multimedia services including teleconferencing, color video images, 3D graphic animation games, and audio services. In addition, 4G networks are expected to offer global mobility, service portability, and scalability at lower cost. They are expected to be based on orthogonal frequency division multiplexing (OFDM), which is capable of having hundreds of parallel channels. The data transmission rates are planned to be up to 20 Mbps. This next-next generation technology is expected to allow seamless merging between different wireless standards, making it possible for one mobile device to move from indoor networks such as wireless LANs and Bluetooth to cellular, radio, and TV broadcasting or to satellite communications. NewLogic claims that by the end of 2007 4G digital IP-based high-speed cellular systems will account for 14% of total mobile wireless data revenues, 50 million subscribers, and \$5.3 billion in 4G infrastructure sales (*Electronic News*, 2003).

Wireless LANs

Similar to the use of 3G as a wide-area mobile networking technology, wireless LANs (WLANs) are also widely used for mobile commerce. IEEE 802.11 or Wi-Fi is a family of networking protocols developed by the working group 11 of IEEE 802. Wi-Fi is a trade term promulgated by the Wireless Ethernet Compatibility Alliance (WECA) and is used in place of 802.11b. Products certified as Wi-Fi by WECA are interoperable with each other even if they are from different manufacturers. A user with a Wi-Fi product can use any brand of access point with any other brand of client hardware built to the Wi-Fi standard. WLANs are cheaper than 3G to install, maintain, and use. Moreover, they are relatively mature technologies compared to the 3G.

The 802.11 family currently includes three separate protocols, 802.11a, 802.11b, and 802.11g. 802.11b was the first widely accepted wireless networking standard, which was later followed by 802.11a and 802.11g (<http://grouper.ieee.org/groups/802/11/>).

802.11b

802.11b has a range of about 50 m and has a maximum throughput of 11 Mbps. 802.11 runs in the 2.4-GHz spectrum and uses carrier sense multiple access with collision avoidance (CSMA/CA) as its media access method. Extensions have been made to the 802.11b protocol to increase speed to 22, 33, and 44 Mbps, but the extensions are proprietary and have not been endorsed by the IEEE.

802.11a

The 802.11a standard uses the 5-GHz band, and operates at a raw speed of 54 Mbps. 802.11a has not seen wide adoption because of the high adoption rate of 802.11b, and because of concerns about range: at 5 GHz, 802.11a cannot reach as far as 802.11b.

802.11g

In June 2003, a third standard, 802.11g, for encoding was ratified. This works in the 2.4-GHz band (like 802.11b), but operates at 54 Mbps raw, or about 24.7 Mbps net, throughput like 802.11a. It is fully backward compatible with 11-Mbps 802.11b. It uses orthogonal frequency division multiplexing (OFDM) technology, and enables streaming media, video downloads, and a greater concentration of users without interference.

802.11n

In January 2004 IEEE announced that it will develop a new standard for wide-area wireless networks. The real speed will be 100 Mbps, so up to four to five times faster than 802.11g, and perhaps fifty times faster than 802.11b. As projected, 802.11n will also offer a better operating distance than current networks. The standardization progress is expected to be completed by the end of 2006.

802.11i

This is an amendment to the 802.11 standard specifying security mechanisms for wireless networks. The draft standard was ratified on 24 June 2004, and supercedes the

previous security specification, wired equivalent privacy (WEP), which was shown to have severe security weaknesses. Wi-Fi protected access (WPA) had previously been introduced by the Wi-Fi Alliance. It implemented a subset of 802.11i and makes use of the advanced encryption standard (AES) block cipher; WEP and WPA use only the RC4 stream cipher. In addition to improved encryption, it includes improvements in key management, user authentication through 802.1x, and data integrity of headers and contents using counter-mode/CBC-Mac protocol (CCMP).

Bluetooth

Other wireless technologies include short-range technologies such as Bluetooth, which can play an important role in some applications such as mobile payments. It is an industrial specification for wireless personal area networks (PANs). Bluetooth provides a way to connect and exchange information between devices like PDAs, mobile phones, laptops, PCs, printers, and digital cameras via a secure, low-cost, globally available short-range radio frequency. Bluetooth lets these devices talk to each other when they come in range, as long as they are within 32 feet of each other. Every device can be configured to constantly announce its presence to nearby devices in order to establish a connection. The protocol operates at 2.45 GHz and can reach speeds of 723.1 kbps. In order to avoid interfering with other protocols that use the 2.45-GHz band, the Bluetooth protocol divides the band into 79 channels and changes channels up to 1600 times per second.

Bluetooth should not be compared to Wi-Fi, which is a faster protocol requiring more expensive hardware that covers greater distances and uses the same frequency range. Whereas Bluetooth is a cable replacement creating personal area networking between different devices, Wi-Fi is a cable replacement for local area network access. The Bluetooth SIG works on versions 1.2 and 2.0. Bluetooth enhanced data rate (EDR), which will have a data rate of 2.1 Mbps, is expected to be finalized in the fourth quarter of 2004.

One of the ways Bluetooth technology may become useful is in VoIP. Bluetooth may be used for communication between a cordless phone and a computer listening for VoIP with an infrared peripheral component interconnect card acting as a base for the cordless phone. Cars can also install hands-free Bluetooth technology, which allows users with Bluetooth-equipped cell phones to make use of some of the phone's features.

RFID

Another emerging wireless technology is the radio frequency identification. RFID is a method of remotely storing and retrieving data using devices called RFID tags. An RFID tag can be either attached to or incorporated into a product. RFID tags can be either active or passive. Passive RFID tags do not have their own power supply, but can respond to incoming radio-frequency signals. The range of passive tags can vary from 10 mm to 5 m. As of 2004, these tags cost from \$0.25. The aim to produce tags for less than \$0.05 may make widespread RFID tagging commercially viable. Active RFID tags have a power source and have longer ranges and contain larger

memory than their passive counterparts. Active tags may have ranges on the order of tens of meters, and a battery life of up to several years.

There are four different kinds of tags commonly in use, their differences being based on the level of their radio frequency: low-frequency tags (between 125 and 134 kHz), high-frequency tags (13.56 MHz), UHF tags (868 to 956 MHz), and microwave tags (2.45 GHz). Low-frequency tags are primarily used for identification and tracking of objects such as children and animals, anti-theft systems, etc. High-frequency RFID tags can be used to track library books, pallets, airline baggage, and retail goods as well as to control building access. UHF tags can be typically used in shipping yards to track pallets and containers as well as trucks and trailers. Microwave tags can be used in long-range access control of vehicles. Some tollbooths use RFID tags for electronic toll collection (e.g., the EZ-Pass system).

Using RFID tags in place of bar-code technology may have a number of advantages. Unlike bar codes, which are the same for the same type of product, RFID codes are unique for each product. As a result, a product may be individually tracked as it moves from location to location, from manufacturers to wholesalers, to retailers, and finally to consumers. This may help companies to combat theft and other forms of product loss, and can be used for point-of-sale automatic checkout with the option of removing the tag at checkout. Moreover, cards embedded with RFID chips are widely used as electronic cash, for example, to pay fares in mass transit systems and/or retails. EPCglobal is working on an international standard for the use of RFID and the electronic product code (EPC) to be used in tracking goods along the supply chain. It includes members from EAN International, Uniform Code Council, Gillette, Procter and Gamble, Wal-Mart, Hewlett-Packard, Johnson and Johnson, and Auto-ID Labs. Futuristic uses include monitoring the expiration dates of the food in the refrigerator, etc. In summary, RFID technology can be used for collecting information from moving objects, and can also be utilized in applications such as supply chain management, advanced product tracking, inventory control, warehouse management, the checking of compliance regulations, recall, enhancement, accountability, and documentation.

However, RFID technology may raise a number of privacy concerns as the tags affixed to products remain functional even after the products have been purchased and taken home, thus, capable of being read from a distance without the knowledge of the purchaser. This

information can be potentially used for surveillance and other purposes not related to the supply chain inventory functions. Another privacy concern is due to RFID's support for anti-collision, in which a reader enumerates all the tags responding to it without them mutually interfering. As a result, all but the last bit of each tag's serial number can be deduced by passively eavesdropping on the RFID reader. Juels, Rivest, and Szydlo (2003) have proposed a selective blocking approach using a blocker tag as a way of protecting consumers from unwanted scanning of RFID tags attached to items they may be carrying or wearing. A blocker tag is a cheap passive RFID device that can simulate many ordinary RFID tags simultaneously and thus block RFID readers from reading the actual RFID tag. It can do so universally by simulating all possible RFID tags. Also a blocker tag can block selectively by simulating only selected subsets of ID codes, such as those of a particular manufacturer, or those in a designated privacy zone. Later, Juels & Brainard (2004) extended the blocker tag approach to enforce flexible privacy policies in which partial or scrubbed data are revealed about private tags, in lieu of the all-or-nothing policy enforced by a blocker tag. Privacy-related guidelines proposed by EPCglobal include the requirement to give consumers clear notice of the presence of EPC and to inform them of the choice that they have to discard, disable, or remove EPC tags (http://www.epcglobalinc.org/public_policy/public_policy_guidelines.html). Table 2 (partially from Umar (2003)) summarizes the bandwidth and range of different wireless technologies.

Other Technologies

Location Technologies

Although location technologies have been around for a number of years, they have evolved rapidly in recent years because of the increasing use of mobile applications. They can be broadly classified into outdoor and indoor technologies. Outdoor technologies include GPS, network-assisted GPS (A-GPS), time of arrival (TOA), uplink time of arrival (UL-TOA), enhanced observed time difference (E-OTD), and cell of origin (COO) (Andersson 2001, Durl 2001). Indoor technologies include Active Badge system developed by Olivetti Research Ltd. (ORL), PARC by Xerox, Shopping Assistant by AT&T Bell Laboratories, and Cyberguide by Georgia Institute of Technology, among others. Because most mobile applications rely on outdoor technologies, indoor technologies have

Table 2 Bandwidths and Ranges of Wireless Technologies

	Data Rate	Range
Bluetooth	1 Mbps	10 m
IEEE 802.11a	Up to 54 Mbps	<50 m
IEEE 802.11b	11 Mbps	100 m
IEEE 802.11g	Up to 54 Mbps	100 m
3G cellular	Up to 2 Mbps	Cell sizes 5 to 10 km
RFID	Up to 2.45 Gbps	Up to 10s of meters
Satellites	64 kbps	Thousands of miles

limited applications such as computerized visitor guides in museums. Wireless networks can provide approximate information about the location of a customer; this information exists as part of the routing information in the wireless network. GPS provides a more accurate location but requires some add-in to the mobile device. This technology is typically used for driver assistance systems and in military applications such as guided missiles. For indoor applications, other technologies such as the smart badge developed by Xerox Labs in the UK are used.

Application Protocols

The emerging technology behind m-commerce is the set of protocols called the wireless application protocols, which provide a functionality similar to that of the traditional Internet protocols such as TCP/IP, secure socket layer (SSL), and hypertext transfer protocol (HTTP). Typically the translation between the two sets of protocols is performed by some middleware at the mobile support station (MSS), which is part of the infrastructure of the wireless provider. (More details on WAP are provided in the next section.) WAP also includes a markup language based on XML, called the wireless markup language (WML). IMode-enabled Web sites utilize cHTML, a subset of the familiar HTML 4.0 (Barnes & Huff, 2003) that has been developed with the restrictions of the wireless infrastructure in mind, such as the limited bandwidth and high latencies of the networks, and small screens and limited functionality of the devices. Essentially, it removes certain features of conventional HTML, such as tables and frames. Mobile services equipped with WAP have been widely accepted, and the mobile devices equipped with Web-ready microbrowsers are much more common in Europe than in the United States. This growth is partly driven by the GPRS, WAP, and Bluetooth technologies and their use in mobile commerce applications.

Semantic Web Technologies

M-commerce is benefiting from emerging technologies such as Web services, .Net technologies, and ontologies. Several new technologies and standards are affecting the design of m-commerce applications. These include semantic Web technologies, such as RDF, DAML, DAML-S, DAML+OIL, and OWL, and service interaction technologies such as the universal description, discovery, and integration (UDDI) specifications. The .NET framework is the programming model for developing, deploying, and running Web services and applications. Web services are units of code that allow programs written in different programming languages and on different platforms to communicate and share data through standard Internet protocols such as XML, SOAP, Web services description language (WSDL), and UDDI. They allow easy building of Web-based applications, including ERP, CRM, e-commerce, messaging and calendaring functionality, workflow services, and the like.

Languages

Another driving force to mobile commerce is the standardization of programming language for mobile devices. Languages such as Java 2 Mobile Edition (J2ME) makes it possible to write powerful applications that can leverage

and integrate the different capabilities of the device including voice, telephony, security, communications, and location capabilities. These standards are geared for devices with small memory, and are therefore suitable for mobile devices.

ARCHITECTURAL COMPONENTS

A mobile communication network protocol should deliver functionalities similar to those provided by the different layers of the OSI model for enabling communication in the mobile Internet. Because destination nodes are mobile, traditional IP protocols are no longer applicable for the mobile communication environment. In the wired network, the convention is that the IP addresses are organized such that nodes in the same location have the same prefixes. This no longer holds well as the nodes themselves are moving and do not have a fixed location. To overcome this problem, the mobile IP uses the concept of a care-of-address, and employs tunneling. Essentially, under the mobile IP, each mobile node sends its location by sending its care-of-address to its home agent. The home agent then tunnels the packets destined to the mobile node by forwarding them to the care-of-address, which are then delivered to the mobile node. Several standards are in place today; however, they differ in the way in which they have adapted the standard transport and the network layer protocols of the TCP/IP. For example, the mobile IP is now part of the 3G standard; however, other standards such as the GPRS support only a simplified version of the mobile IP.

Whereas the IP layers are responsible for delivery of packets to the destination node, the TCP layers are responsible for reliably delivering the packets, assembling the packets in the right order, and finally handing them over to the target application. The TCP protocol is also responsible for congestion control to ensure graceful performance degradation. With respect to the mobile communication version of the TCP protocol, it must address specific problems due to the fact that connections are often lost and transmission errors are more common in the mobile communication environment, and, therefore, roundtrip times are harder to predict.

In addition to adapting the TCP/IP to the mobile communication environment, the mobile Internet needs to take into consideration the limited power, memory, computing capacity, and the screen size of the mobile devices. Moreover, because of the unreliable network connections, even the most common protocols such as HTTP do not work well. Furthermore, the Web languages responsible for displaying the Web content, such as HTML, must be modified.

The wireless application protocol has been proposed as a standard for addressing these challenges. The WAP Forum (<http://www.wapforum.org>) was founded in the summer of 1997 by Ericsson, Nokia, Motorola, and Unwired Planet for the purpose of defining an industry-wide specification for developing applications over wireless communications networks. Forum members represent over 90% of the global handset market, as well as leading infrastructure providers, software developers, and other organizations. The WAP Forum with Open Mobile Architecture

Figure 2: A comparison of WAP and Internet technologies. Source: WAP Forum.

formed, and has now become part of, the Open Mobile Alliance (OMA), which consists of several working groups, one of which is on mobile commerce. A comparison of the Internet and WAP technologies is provided in Figure 2. WAP architecture, as published by the WAP Forum, is shown in Figure 3. More details of the WAP are in the following.

- *WAP*: The wireless application protocol is the de facto standard for information services on wireless terminals. It is an intelligent messaging service for handheld mobile devices such as mobile phones. WAP is an application communication protocol, and is used to access services and information. It is an application environment and a set of communication protocols for wireless devices designed to enable mobile users technology-independent access to the Internet and advanced telephony services. In particular, WAP specifications define a set of protocols in application, session, and transport layers of the communication protocol, as well as provide transactional and security services.
- *WAE*: WAP also defines a wireless application environment (WAE) composed of a microbrowser, scripting facilities, e-mail, Web-to-mobile-handset messaging, and mobile-to-telefax access. It allows digital content to be displayed on special WAP-enabled GSM mobile phones

in a standard text format. It uses WML (not HTML) to create Web applications for mobile devices so that they can be displayed in a WAP browser. As such, WAP is a protocol designed for microbrowsers. The WAP standard is based on Internet standards (HTML, XML, and TCP/IP). WML is defined as an XML application. It consists of a WML language specification, a WMLScript specification, and a wireless telephony application interface (WTAI) specification.

The functions of the different layers of the WAP are as follows: The WAP datagram protocol (WDP) is the transport layer that sends and receives messages via any available bearer network, including SMS, USSD, CSD, CDPD, IS-136 packet data, and GPRS. The wireless transport layer security (WTLS), an optional security layer, has encryption facilities that provide the secure transport service required by many applications, such as e-commerce. The WAP transaction protocol (WTP) layer provides transaction support, adding reliability to the datagram service provided by WDP. The WAP session protocol (WSP) layer provides a lightweight session layer to allow efficient exchange of data between applications. The HTTP interface serves to retrieve WAP content from the Internet requested by the mobile device. Wireless markup language is used to create pages that can be displayed in a WAP browser.

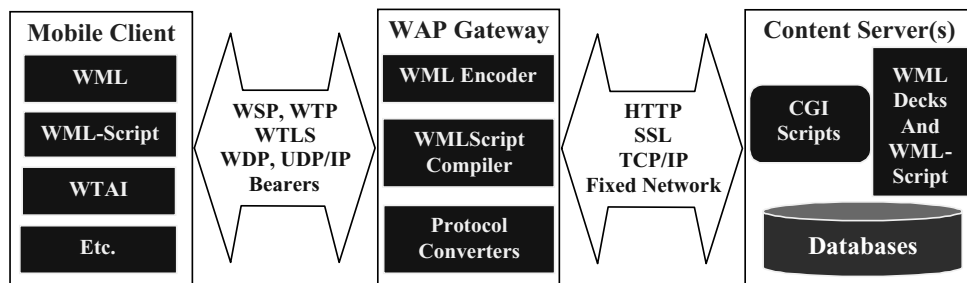

Figure 3: Architecture of the WAP gateway. Source: WAP Forum.

The WMLScript is a restricted JavaScript language used by WML to run simple code on the client machines. WML pages do not embed WML scripts, but only contain references to script URLs. Similar to the Java script, the WML scripts also need to be compiled into byte code on a server before they can run in a WAP browser. WAP uses a microbrowser to accommodate the small screens of the wireless devices. The microbrowser is a lightweight piece of software to display information written in WML and to interpret WMLScript.

SECURITY ISSUES

Similar to the traditional electronic commerce in the wired world, mobile commerce is also vulnerable to a range of security threats. However, since mobile commerce is a radio frequency-operated system, it is easier to perpetrate some types of attacks compared to those in wired systems. The security requirements include the following:

1. *Confidentiality*: requires the messages be kept secret from unauthorized recipients;
2. *Integrity*: requires that messages are unaltered during transit from sender to receiver;
3. *Authentication*: requires ensuring each party is who it claims to be;
4. *Nonrepudiation*: guarantees that neither the sender nor the recipient can deny that the message exchange took place; and
5. *Replay attack prevention*: ensures that any unauthorized resending of messages is detected and rejected.

Several standards have been established in WAP to provide security at the application, transport, and management levels, which are described in the following.

WTLS

The basis of WAP security is in the wireless transport layer security protocol, which is analogous to the Internet's transport layer security (TLS) accomplished using the standard SSL protocol. WTLS is similar to the TLS with a few differences. However, WAP 2.0 uses TLS instead of WTLS to overcome the WAP gap vulnerability (discussed in the next section), and to provide end-to-end security at the transport level. WTLS provides security services including authentication and digital signatures, confidentiality by encrypting data, integrity by employing hashing for detecting data modifications, and denial of service protection that detects and rejects data that have been replayed or not successfully verified. The WML script enables a user to digitally sign a message using the public key infrastructure.

Elliptic curve cryptography (ECC) is emerging as an attractive public key cryptosystem for mobile and wireless environments. Compared to traditional cryptosystems like RSA, ECC offers equivalent security with smaller key sizes, which results in faster computations, lower power consumption, and memory and bandwidth savings. As such, this is a more suitable choice for mobile devices

since mobile devices typically have limited CPU, power, and network connectivity. In fact, traditional signature schemes are viewed as impractical to implement in the wireless environment, as they require much more processing, memory, and storage resources than those with ECC. The keys for elliptic curve are typically on the order of six times smaller than equivalent keys in other signature schemes, for example, 164 bits versus 1024 bits. This creates great efficiencies in key storage, certificate size, memory usage, and digital signature processing. ECC is fully supported by the WAP security standards and has been widely accepted by WAP device manufacturers.

The WAP identity module (WIM) is a tamper-resistant computer chip that resides in the WAP enabled device, e.g., a mobile phone or PTD. It is used to store the user's private key, the root public key of the PKI, etc. Mostly, WIMs are implemented using smart cards that typically have a CPU and some memory and storage for data and programs. WML Script Crypto API (WMLSCrypt) is an application programming interface that allows access to basic security functions in the WML Script Crypto Library (WMLSCLib), such as key pair generation, encryption and decryption of data, generation and verification of digital signatures, storage of keys and other personal data, and controlled access to stored keys and data. WMLSCrypt also allows WAP applications to access and use the security objects and basic security services managed by other WAP security standards. WML script may optionally employ WIM to provide the crypto functionality. Wireless profiled TCP (WP-TCP) provides connection-oriented services. It is optimized for wireless environments and is fully interoperable with standard TCP implementations in the Internet.

Wireless application PKI (WPKI) is not an entirely new set of standards for PKI, but it is an optimized extension of traditional PKI for the wireless environment. WPKI is concerned primarily with the policies used to manage the mobile business and security environment by WTLS/TLS and WMLSCrypt in the wireless application environment. WAP Forum provides the standards for WPKI (discussed in detail in the section Trust Issues).

The WAP Gap

One of the major security breaches in mobile commerce is due to the mobile network infrastructure employed. When the user information is transmitted from one mobile network to another, all the encrypted data need to be decrypted in order to send them to another network. When mobile devices make requests to the Web pages of a network server, these requests originating from the WTLS protocol need to be translated at the originating WAP gateway. They are then encrypted, typically using SSL, and sent to the destination network. This is then processed by the HTTP protocol in the destination network. During the translation process from one protocol to another, the data must be decrypted and then re-encrypted. Because those data are in cleartext, they are vulnerable to attacks if an intruder gains access to the mobile network. This vulnerability is commonly known as the WAP gap. To alleviate this problem of WAP gap, Juul (2002) proposes three

alternative solutions: putting the WAP gateway inside the server, application layer, and mobile Internet.

PRIVACY ISSUES

The privacy of mobile users can be compromised either:

- (1) by disclosing the location and movement (location privacy) or
- (2) by revealing the sensitive profile information (user information privacy) of the mobile users to unintended users.

Location Privacy

Identifying the location of a mobile customer is required because of two reasons. First, to effectively function, location-based services require information about the location of the communication device. As described under Mobile Commerce Applications, the location-based services present a major new market for the mobile industry. Second, in places like the United States, Europe, and Japan, laws require that mobile telephones be able to provide location data with a fairly detailed accuracy for the purposes of emergency situations.

Unlike the Internet, location information has the potential to allow an adversary to physically locate a person, and therefore most wireless subscribers have legitimate concerns about their personal safety, if such information should fall into the wrong hands. The 1996 Telecommunications Act included location information as customer proprietary network information (CPNI), along with time, date, and duration of a call, and the number dialed. Because of the sensitive nature of location information, legal and regulatory approaches for controlling access to location information should be different from other CPNI. Specifically, consumers must be comfortable that they have control over who can obtain location information and when such information can be obtained in order that they will be willing to buy location-based services. Laws and rules of varying clarity, offering different degrees of protection, have been or are in the process of being enacted in the United States, the European Union, and Japan (Ackerman, Kempf, & Miki, 2003).

Beresford and Stajano (2003, 2004) have proposed techniques that let users benefit from location-based applications, while preserving their location privacy. Mobile users, in general, do not permit the information being shared among different location-based services. Primarily, the approach relies on hiding the true identity of a customer from the applications receiving the user's location, by frequently changing pseudonyms so that users avoid being identified by the locations they visit.

User Information Privacy

The needs of mobile commerce applications go beyond tracking users' locations; for example, they may additionally need to track user profiles and preferences in order to achieve mass personalization. This is because, to be effective, targeted advertising should not overwhelm the mobile consumers and must push information only to a certain segment of mobile consumers based on their preferences and profiles, and based on certain marketing

criteria. Obviously, these consumers should be targeted only if they are in the location where the advertisement is applicable at the time of the offer. It is important to note here that user profile information may include both sensitive and nonsensitive attributes, such as name, address, linguistic preference, age group, income level, marital status, and education level.

Although mobile consumers like to benefit from personalization, they usually are not willing to share their sensitive profile information with all merchants. To ensure the privacy of mobile users, it is important that sensitive profile information is revealed to the respective merchants only on a need-to-know basis. Therefore, it is essential that the profile information be maintained by a third-party service, rather than by the merchant's system, to ensure the privacy of the mobile users. Typically, the tracking of mobile objects (consumers), i.e., maintaining the moving object database and responding to queries, is performed by the location service (LS). Obviously, this third-party service can be carried out by the LS. This is because it is prudent and economical to use the same service to maintain the profiles, instead of using another service just for this purpose. To ensure privacy of the mobile customers, a fine-grained access control mechanism that could be placed at the LS so that the customer profile information is disclosed to the merchants based on the choice of the customers has been proposed (Atluri, Adam & Youssef, 2003). A system for delivering permission-based location-aware mobile advertisements to mobile phones using Bluetooth positioning and wireless WAP push has also been developed (Aalto, Göthlin, Korhonen, & Ojala, 2004).

TRUST ISSUES

The public key infrastructure is considered wireless when the client devices used to communicate with other parties are wireless although the server could still be on a wired network. The fundamental concepts of PKI in wireless environments are not totally different from those of the wired network environment, and therefore the same concepts that have already been successfully employed in the traditional network environment can be directly applied to the wireless environment. However, access to the PTD over the mobile network environment poses some unique challenges. When compared to the traditional PKI, WPKI applications have to work with a diverse set of PTDs that typically have limited memory, processing, and battery power and smaller displays. Despite these limitations, the PTDs must be able to generate and register keys, manage end-user mobile identities, encrypt and decrypt messages, and receive, verify, store, and send certificates/digitally signed data. In many cases, PTDs are not able to fulfill all these requirements. The PTDs must at least be able to perform a digital signature function to permit the establishment of a WPKI. Typically external agents are responsible for performing certificate validation, archiving, and delivering certificates.

As noted earlier, the private keys are stored in tamper-resistant modules such as WIM/SWIM of PTDs or on a proxy server. However, the WIM/SWIM solutions are not mature enough, particularly in the area of key pairs

generation by end users. Establishing trust is crucial for the success of applications that will exploit the opportunities created by PTDs. This trust is not only based on the technology itself, but also on the implementation of laws, policies, standards, and procedures, which includes the management of certificates by trusted certificate authorities. Unfortunately, currently there are no standards for the WPKI, which could be a major obstacle for the success of mobile commerce. However, the situation is similar to that of the wired environment. The issues of anonymity, privacy, and other policies and standards present challenges that must be addressed to enhance the level of trust.

WPKI requires the same components used in traditional PKI. However, the mobile device's applications and registration are implemented differently, and a new component referred to as the PKI portal is also required. The mobile device application in WPKI is implemented such that it runs in the WAP device. It relies on the WMLSCrypt API for key services and cryptographic operations as well as the traditional PKI functionalities.

WPKI is an optimization of the traditional IETF PKIX standards for the wireless environment. More specifically, it comprises optimized PKI protocols, certificate format, and cryptographic algorithms and keys. As opposed to using the traditional basic encoding rules (BER) and distinguished encoding rules (DER) to handle PKI service requests, WPKI protocols are implemented using WML and WMLSCrypt. Similarly, the WPKI certificate format specification is a new certificate format for server side certificates, which significantly reduces the size when compared to the standard X.509 certificate. Another significant reduction in the WPKI certificate can be attributed to ECC, with the savings in size being typically more than 100 bytes because of the smaller keys needed for ECC. WPKI has also limited the size of some of the data fields of the IETF PKIX certificate format. Since the WPKI certificate format is a subset of the PKIX certificate format, it is possible to maintain interoperability between standard PKIs.

RESOURCES

The various resources for this chapter include the Web pages of mobile technology vendors, conferences, and journals in the area of mobile networks, mobile commerce, and electronic commerce. Examples include the following:

GLOSSARY

802.11b (also 802.11) High rate or Wi-Fi applies to wireless LANs and provides 11-Mbps transmission (with a fallback to 5.5, 2, and 1 Mbps depending on range and signal strength) in the 2.4-GHz band. 802.11b uses only DSSS (direct-sequence spread spectrum), which is one of two types of spread spectrum radio. 802.11b was a 1999 IEEE ratification to the original 802.11 standard, allowing wireless functionality comparable to Ethernet.

3G (Third-Generation Wireless) A development in mobile communications that included increased bandwidth from 128 Kbps while moving at high speeds up to 2 Mbps for fixed stations, enabling multimedia applications and advanced roaming features.

AP Access point.

CCMP (The Counter-Mode/CBC-Mac Protocol) An IEEE 802.11i encryption algorithm. In the 802.11i standard, unlike WPA, key management and message integrity is handled by a single component CCMP built around an advanced encryption standard (AES).

CDMA (Code-Division Multiple Access) A digital method for simultaneously transmitting signals over a shared portion of the spectrum by encoding each distinct signal with a code chip. Terminals receive the aggregated signal from the tower and use specific codes to unbundle the signals. CDMA devices are noted for their excellent connection quality and long battery life.

DSSS (Direct-Sequence Spread Spectrum) A transmission technology used in wireless LAN (WLAN) transmissions where a data signal at the sending station is combined with a higher data rate bit sequence, or chipping code, that divides the user data according to a spreading ratio. The chipping code is a redundant bit pattern for each bit that is transmitted, which increases the signal's resistance to interference. If one or more bits in the pattern are damaged during transmission, the original data can be recovered because of the redundancy of the transmission.

GPS (Global Positioning System) Satellite-based radio-positioning system capable of providing specific location information to suitably equipped users anywhere.

GPRS (General Packet Radio Service) An enhancement to the GSM mobile communications system that supports data packets. GPRS enables continuous flows of IP data packets over the system for such applications as Web browsing and file transfer. GPRS differs from GSM's short messaging service (GSM-SMS), which is limited to messages of 160 bytes in length.

GSM (Global System for Mobile Communications) A digital cellular phone technology based on TDMA that is the predominant system in Europe, but is also used widely around the world. Developed in the 1980s, GSM

was first deployed in seven European countries in 1992. Operating in the 900-MHz and 1.8-GHz bands in Europe and the 1.9-GHz PCS band in the United States, GSM defines the entire cellular system, not just the air interface.

QoS (Quality of Service) The ability to define a level of performance in a data communications system. A high QoS would ensure that the packets of data all arrive in time for undetectable reassembly.

UMTS (Universal Mobile Telecommunications System) The ITU standard for 3G wireless phone systems. UMTS, which is part of IMT-2000, provides service in the 2-GHz band and offers global roaming and personalized features. Designed as an evolutionary system for GSM network operators that will marry the benefits of CDMA with the interoperability benefits of GSM, multimedia data rates up to 2 Mbps are expected. There are three branches of the UMTS standard: TD-SCDMA, UMTS TDD, and W-CDMA. CDMA2000 is not UMTS.

WAP (Wireless Access Protocol) A set of standards that allows Web access on mobile devices, and is supported by most wireless networks and operating systems. It supports HTML and XML but is designed for WML.

Wi-Fi (Wireless Fidelity) Another name for IEEE 802.11b. It is a trade term promulgated by the Wireless Ethernet Compatibility Alliance (WECA). Wi-Fi is used in place of 802.11b in the same way that "Ethernet" is used in place of IEEE 802.3. Products certified as Wi-Fi by WECA are interoperable with each other even if they are from different manufacturers. A user with a Wi-Fi product can use any brand of access point with any brand of client hardware built to the Wi-Fi standard.

WLAN (Wireless LAN) A type of LAN that uses high-frequency radio waves rather than wires to communicate between nodes.

WML (Wireless Markup Language) A language developed to control the presentation of Web pages on mobile phones and PDAs in the same way that HTML does for PCs. Part of the wireless access protocol (WAP), WML is an open standard and is supported by most mobile phones.

XHTML A reworking of HTML 4.0 designed to work as an application of XML. It allows anyone to create sets of markup tags for new purposes.

INTRODUCTION

Early efforts in correspondence courses and self-learning through programmed instruction methodologies were ventures in alternatives to the traditional face-to-face, in the classroom modality of delivering and receiving education. Subsequent technologies have provided new and improved ways of delivering these self-paced course materials. Wrapped in today's technology and incorporating revised educational models e-education has evolved. In this chapter, e-education refers to the replacement or supplement of traditional face-to-face delivery of learning components with electronically based elements. Further, primary focus is on e-education where there is:

- Mediation, i.e., an instructor to evaluate the progress of the student;
- An acknowledgement of completion i.e., a degree, a certificate, or a grade; and
- Some form of measuring the student's progress or evaluation of accomplishment.

E-education is also referred to as online learning, virtual learning, and Web-based learning.

Societal needs for education in vocations and professions that are new or that now require more training or skills than in the past have increased the demand for knowledge and learning. At the same time the ability of many individuals to fit into the rigid schedules of traditional education because of work or family constraints has declined.

In a report addressing its internal computing plan, the University of Indiana noted that "The same array of teaching and learning technologies should be available for local or remote learners—in campus classrooms or residence halls, at students' homes, or in the workplace—to be chosen as appropriate to the instructional needs, and not constrained by location" (Indiana University, 1998). Although there are significant differences between virtual and traditional learning, there are also many characteristics that they have in common. Common elements include:

- Delivery of content;
- Discussions of topics;

- Questions and answers;
- Personal consultation;
- Research;
- Testing and assessment;
- Writing exercises; and
- Problem solving.

Two characteristics of e-education that set it apart from traditional education are that virtual education usually:

- Can be asynchronous in nature; and
- Is electronically based.

The issue of privacy associated with offering a course online takes on its own unique characteristics. While teaching a recent virtual learning class Lisa Neal made the following observation: "In the virtual classroom, keyed-in responses, virtual hand-raising, and feedback indicators provide information to the instructor—information that has traditionally remained private. All of this idiosyncratic, subjective and contextual data is captured and recorded" (Neal, 2003).

E-EDUCATION EXAMINED

Winograd and Moore (2003) paint an interesting picture of the e-education student in contrast to the traditional student struggling to get to class: "an estimated 2.23 million didn't [struggle]. Instead they stayed home, studied, listened to and spoke to or wrote to their teachers, chatted, . . . , did research . . . , took exams . . . and turned in assignments—without ever entering a classroom." Describing the extent of institutional participation in virtual learning Winograd and Moore reported that 85% of two-year colleges and 84% of four-year institutions were expected to offer distance education course by 2002 and most of the growth would utilize the Internet.

In an article examining e-education in higher education, Ralph Gomory of the Sloan Consortium states:

They are continuing to provide the basic elements that are associated with classroom teaching, but

they are providing them in a different way. Those basic elements of classroom teaching are, first, the professors. Then, second, there is the course material. A third important element is classmates. They help both in and out of class. They provide an element of shared experience, and they are people with whom both the course content and what the professor meant can be discussed between classes. They also provide important emotional support. (Gomory, 2001)

Gomory further suggests “using asynchronous learning networks provides a form of these elements electronically, without a campus, without a classroom, and without the necessity for either the learner or the professor to be at some fixed place or time when a lecture is being given.”

There exists an ongoing debate concerning the quality and value of online learning and the online degree. There are both skeptics and proponents. Although the jury has not provided a final verdict, there is much evidence that the quality of online learning is not different from the quality of a brick-and-mortar counterpart (Winograd and Moore, 2003).

In a 2003 study of higher education academic leaders it was found that when asked to compare the quality of online courses with face-to-face instruction:

- 57% believed learning outcomes for online education are equal to or are superior; and
- Nearly one-third expected outcomes for online courses will be superior in three years.

The study further suggests that rather than examining the question of “Is it as good as?”, one should perhaps ask “How is it better?” (Sloan Consortium, 2003). Although the Sloan study addresses institutions of higher education, there is no reason to believe that similar trends do not exist for other instances of e-education.

A framework for understanding important aspects of e-education that define its current state includes the following:

- E-education is driven by technology.
- Societal changes and pressures have altered the way many students view the whole educational process.
- There are many levels of participants in e-education including K–12, post-secondary two- and four-year and graduate degree programs, vocational education, and continuing education programs. This participation includes traditional educational institutions both public and private, professional organizations, and new educational ventures.
- E-education stakeholders include students, educators, course and media designers, providers of technology platforms, and consortiums of interested groups.

The Enabling Technologies of E-Education

Several technologies working together have created a reliable platform for e-education efforts. These technologies

include the Internet, data communication systems, and personal computer hardware and software systems.

The Internet

The Internet has become almost a natural part of life for a great number of people. A report on Internet connectivity in the public school system revealed that at the end of 2001 99% of all public schools were connected (NCES, 2003). Efforts to improve connectivity can now focus on the availability and speed of these connections.

Data Communication Systems

One of the highly publicized and acknowledged constraints that the Internet faces is capacity or bandwidth. Increased availability of high-speed connections to the Internet will be a key factor in the success and acceptance of e-education efforts. Increased bandwidth will not only afford opportunities for increased use of valuable graphics, video, and audio within course content, but will also enable more synchronous connections among course participants using technologies supporting group activities such as net meetings and video conferencing. Several solutions to the problem of access and transfer at high speed are available today and the trend is to make broadband connections available at increasingly more affordable rates. Many support the notion that one of the keys to successful e-education is growth in high-speed connections.

Bringing connections and bandwidth in particular to schools and libraries has been a top priority in expanding the capabilities of the Internet. Much of the effort directed toward the well-publicized “information super highway” efforts of President Clinton’s administration addressed the infrastructure. Concurrent with establishing connections, there has been an attempt to upgrade dial-up connections in homes to broadband. President G. W. Bush proposed an increase in broadband access in part to “be accessible in every corner of our country by the year 2007 to enhance educational and health-care services, particularly in rural areas. Ubiquitous broadband would let colleges offer education to students in their homes” (Primedia, 2004). About one U.S. household in five now pays up to \$50 a month for high-speed Internet service delivered via DSL phone lines or cable TV modem connections (Bray, 2004). America Online (AOL) illustrates the challenge of shifting to broadband in two trends it recently noted with its customers as they shifted to higher speed connections: AOL lost 399,000 dial-up subscribers in the fourth quarter ending 2003, whereas they added nearly 400,000 broadband customers in the same time period (Yang, 2004).

Computer Hardware and Software

Ongoing developments in Internet browser capabilities are creating products that are more robust and feature rich. Many of these new features support the interactive, dynamic capabilities needed in e-education. Competition and ongoing improvements and upgrades in multimedia software are enabling more educators to become developers of course content and the standards and quality of the content to increase. The ability to use and create CD and DVD media with their large capacities reduces the cost of distributing large amounts of learning content.

Societal Changes

Societal changes are impacting the extent and format of the demand for education. Included in these changes are:

- The increase in degree requirements for many jobs;
- The need for continuing education and knowledge updates;
- Individuals reentering the job market after life-changing events;
- Mobility and job-related travel;
- Increased user familiarity and computer skills; and
- The increase in home schooling.

Societal changes and the impact they have on educational endeavors of individuals contribute to the growth of e-education. There are more potential students/learners. Family and work obligations are making traditional brick-and-mortar offerings not a viable solution for many. Increased demand for education comes from both new learners and additional needs of existing learners. Societal changes with respect to gender equity increases the demand for education. "One of the most notable changes since the 1960s resulting from social change and education reform is undoubtedly the large-scale enrollment of women at post-secondary institutions, especially universities" (Corbeil, 2003).

The financial value of education is widely known and accepted. The financial incentives associated with the successful pursuit of additional education are high. According to recent findings, "male graduates pocket 58 percent more and women 92 percent more than their peers with a high school diploma." In addition, the same study found "college graduates also enjoy a much lower rate of unemployment throughout the business cycle" (Farrell, 2003).

An Adventures study reveals that "despite the increasing premium placed by employers on having an undergraduate degree, almost three-quarters of Americans under 25 lack one." As fewer students go directly from high school to post-secondary education, larger numbers of nontraditional students seek alternatives to the traditional classroom setting to complete their degrees. Another avenue of education experiencing an increase in demand is certification. "We are moving to a certification-based society—there's great demand for getting a degree in addition to training" (Phillips, 2003).

Where E-Education Occurs

E-education is a delivery strategy present at all levels of education and training including preschool, K–12, post-secondary 2- and 4-year and graduate schools, and professional, adult, community, military, government, and industrial efforts.

Formal Education

E-education has a large presence in formal education including K–12, undergraduate, and graduate schools where diplomas and degrees are granted for completing an approved, accredited program of studies. Application

of e-education technologies is widespread and pervasive in this traditional sector of education.

A Sloan Institute-sponsored study of institutions of higher education concluded the following:

- Students are willing to take online courses;
- Institutions of higher education are willing to embrace online courses;
- Some, but not all, faculty have embraced online education; and
- The quality of online education is as good as that of traditional education.

The study also noted that in 2002 more than 1.6 million students (11%) took at least one online course, 81% of all higher education institutions offer at least one online course, and 34% of institutions offer complete online degree programs. In addition, 57% of academic leaders believe learning outcomes for online courses are equal to or superior to traditional face-to-face instruction (Allen & Seaman, 2003).

According to a study of remedial education in post-secondary institutions in the fall of 2000, 64% of post-secondary institutions responding indicated that the Internet was the primary delivery method for remedial instruction (NCES, 2001).

Traditional Institutions and New Institutions

Traditional educational institutions are those that were in existence prior to the existence of e-education: the public and private K–12, trade schools, and institutions of higher education.

New organizations have been formed to take advantage of the explosion in e-education. Some of these organizations are completely new, whereas others have evolved into a new form to grow with the opportunities that participating in e-education offers. An interesting example of old institutions participating in the virtual learning world is the MIT OpenCourseWare initiative model, which offers the content of over 500 of its courses online (MIT, 2003). Additional examples of institutions that either are new or have incorporated online delivery of coursework as a significant part of their mission include:

- University of Phoenix;
- Nova Southeastern University;
- Devry Institute Online;
- American Intercontinental University Online;
- Capella University;
- Colorado Technical University;
- Regis University Online;
- Jones International University; and
- Western Governors University.

Professional and Continuing Education

Companies and professional organizations utilize e-education to provide continuing education and certification courses. An example of a company-sponsored venture into e-education can be found at Motorola, which has a developed number of courses to keep their employees

current in their areas of employment. Many of these courses are online and can be found on the Motorola Web site (Motorola, 2003). A U.S. Congressional Commission study found in part that “Motorola, long the standard for industry, provides every employee with at least 40 hours of training each year” (Fulton, 2001).

The Public Broadcasting System (PBS) makes available a broad range of courses for various levels of credit to the general public through associated institutions. The offerings available through the PBS associates can be found on their Web site (PBS, 2003).

In professional fields such as medicine, continuing education is available from many sources in e-education format. The Harvard Medical School’s Department of Continuing Education Web site is a representative example of professional continuing education credits being provided online (HMS-CME, 2004). Many other professional fields including accounting, nursing, architecture, project management, and law enforcement have similar providers of e-education-based continuing education.

Commercial and Other Support Organizations

There exists an industry of organizations providing support services and products for e-education. The mission and objectives of these companies are often focused on being third-party providers of solutions to the technical aspects of e-education.

Blackboard, Inc. (<http://www.blackboard.com>) and eCollege.com (<http://www.ecollege.com>) are examples of this type of organization. Both provide software products and services used by many institutions and organizations involved in e-education. Estimates of the size of this market sector suggest it reached a revenue level of \$6 to \$7 billion in 2002, and there are forecasts that revenues of \$50 billion will be reached by 2010 (BizReport, 2003). *Business Week* recently reported that more than 2000 schools were using the software from Blackboard when schools opened in the fall of 2004 and that Blackboard is gaining presence in K–12 and foreign universities (*Business Week*, 2004). Organizations that are part of this group are often referred to as dot-coms, or they have a significant component that includes Web-related technology capabilities.

The Participants in E-Education

To understand the interrelationships present in e-education, a valuable perspective comes from examining the participants. Stakeholders in e-education include students, educators, providers, developers, sponsors, and consortiums. The following sections discuss each of these participants. In many implementations of e-education a single organization may provide multiple or even all of the components.

Students

Students are the recipients of the e-education product. The student group can be classified as K–12, post-secondary 2- and 4-year schools, graduate schools, training, and continuing education. Students participate in e-education from remedial to doctoral levels.

Educators

In all cases course content and delivery strategies need to be developed and implemented. The individual or group that puts the course together and is responsible for the evaluation of the success of the student in completing the course is considered to be the primary educator for a course. It is important to distinguish between course content and course management. In some instances content and management may be integrated; in others they may be separate. A computer science professor might use the BlackBoard system to manage the course and present course information while utilizing a series of CD-based MS PowerPoint presentations to present topic content on database design.

Providers

Providers supply the technical platform, the software, and the computer servers that students connect to and where educators store their courses. For institutions or organizations that do not have the ability to supply the technical platform needed to deliver courses themselves, they can subscribe to a wide range of services from a third party. An example of an organization that provides a wide range of services supporting virtual learning is eCollege. In their own words: “eCollege provides all of the necessary technology and services in an integrated approach to power the profitable growth of online distance programs” (eCollege, 2004).

Developers

In a report to President Clinton on the use of technology to strengthen K–12 education in the United States the Web-Based Education Commission pointedly observes that “There is widespread agreement that one of the principal factors now limiting the extensive and effective use of technology within American schools is the relative dearth of high-quality computer software and digital content designed specifically for that purpose” (Fulton, 2001). Although this comment was aimed at the K–12 area, especially the secondary schools, it probably applies equally to all forms of e-education. Third-party companies have formed and grown to fill the needs of educational institutions who do not have the internal resources to develop their own online course materials. An example of an organization that has been developing materials for online learning since 1971 is Bisk Education, Inc., which works with nationally known organizations and accredited universities to assist in creating course content (Bisk, 2003).

Sponsors

In e-education the sponsor is represented by the institution granting credit or certification for the successful completion of the course. The sponsor is the institution that the student interfaces with, often a school or professional organization. The standard practice for most sponsors is to be involved in all aspects of course development, delivery, and management, although some components may come from third parties.

Consortiums

To leverage and take advantage of the efforts being put into e-education and to be cost effective in implementing the

results, several consortiums have developed to assist in the delivery of e-education. In many instances these consortiums serve as evaluators of life experiences and brokers of course completion work provided by members of the consortium. A good model for this approach is Western Governors University, founded by the governors of 19 western states and the only university to be accredited by four regional commissions (WGU, 2003). The consortium model varies greatly. Examples of other consortiums include:

- *Edlearn Consortium*: Member colleges have combined their course and program offerings on the consortium's Web site. Students can apply, register, and access student services from any of the member colleges with a single Web-based transaction. Students can take courses from across the consortium in completing their degree or program requirements (Edlearn, 2003).
- *Electronic Campus of the Southern Regional Education Board*: A consortium of several southern states that has the objective to "improve every aspect of education—from early childhood education to doctoral degrees and beyond" (SREB, 2003).
- *Keystone University Network*: Keystone University Network offers multiple degree and certificate programs through the 14 Pennsylvania state system universities (Keystone University, 2003).
- *Ohio Learning Network*: Currently there are more than 60 degrees and certificates listed in OhioLearns (Ohio Learning Network, 2003).
- *SUNY Learning Network*: Students can study, take classes, and complete entire degree programs at any time and from any place from more than 3,000 online courses with more than 50,000 statewide, national, and international student enrollments (SUNY Learning Network, 2003).
- *The Connecticut Distance Learning Consortium (CT-DLC)*: The Consortium was created in October 1996 when over 30 colleges and universities met and agreed that Connecticut needed to systematically mount distance deliverable education (CTDLC, 2003).
- *Cardean University*: Cardean University is an academic consortium with five elite institutions: Columbia School of Business, Stanford, University of Chicago, Carnegie Mellon, and the London School of Economics, collaborating with Cardean course designers and technology experts to create effective Internet learning (Cardean, 2003).

There can be little doubt in the presence of all of the enabling technologies, the societal pressures, and the wide and extensive participation that e-education has become a permanent part of the educational mix.

LEGAL FOUNDATIONS AND SECURITY AND PRIVACY ISSUES

The legal foundation controlling the establishment of policies and procedures for the participants in e-education comes from several directions as they apply to various aspects of privacy and security.

The Buckley Amendment, the Family Education Rights and Privacy Act (FERPA), in 1974 was the original enabling legislation providing guidelines for the proper handling and treatment of student information (NCES, 2002). This legislation preceded the advent and widespread usage of the Internet and e-education and the widespread electronic transmission of student data. Implementing compliance with FERPA since its initial passage has had to evolve to incorporate electronic data. One of the specific areas covered by FERPA is the definition of education records as they relate to the classroom. A definition of education records includes the statement "(1) contain information directly related to a student; and (2) are maintained by an educational agency or institution or by a person acting for such an agency or institution." This has been interpreted to include the collection of data from students while participating in a course (Bauer & Decman, 2002). FERPA and subsequent updates provide strong legislation that protects the privacy of student records. Institutions and agencies need policies and procedures that comply with these laws.

More recently the Uniting and Strengthening America by Providing Appropriate Tools Required to Intercept and Obstruct Terrorism (USA PATRIOT) Act has added an additional layer of legal requirements governing the correct collection and in particular the dissemination of data collected by institutions about their students. In effect the USA PATRIOT Act overrides and in some cases contradicts the FERPA rulings. FERPA protected the privacy of student information and restricted the release of student data without notice to and permission from the students. The USA PATRIOT Act requires immediate access to student data for identified law officials in tightly defined circumstances and prohibits notification that this access has been made (NCES, 2002).

Special privacy considerations are present when young users are considered. When there is e-education activity in the K–12 years, the legal ramifications of COPPA need to be understood and translated into policies and procedures that create compliance (TRUSTe, 2003b). Under COPPA requirements, a Web site directed toward children less than 13 years of age must comply with strict rules relating to data gathering and use (Gale Group, 2003).

Signed into law in 2002, the TEACH Act defines the terms and conditions that accredited, nonprofit educational institutions throughout the United States must follow when using copyright protected materials in distance education. Although this Act makes usage of copyright materials in distance education easier, it also requires strict institutional adherence to rigorous requirements of the law (American Library Association 2004).

An issue that needs to be understood and addressed in a balanced way is noted by the American Library Association: "the right of anonymity and privacy while people retrieve and communicate information must be protected as an essential element of intellectual freedom" (American Library Association, 2003).

In an article that addresses balancing security and privacy, Steve Worona notes that "And then came 9/11 and the need to find ways to protect the public against further terrorist attacks. Inevitably the balance between security and privacy shifted" (Worona, 2003). When the USA

PATRIOT Act is applied to educational settings it alters many of the aspects of student information guardianship. As Worona further notes, authentication has become an important issue. The creation of complete audit trails of all digital traffic with the ability to identify the originator has been proposed by some. It is not surprising that the proponents of anonymity oppose a push toward extreme implementation of authentication procedures.

Identity theft and other improper and illegal information misappropriations are related to authentication in education as digital requests for information are processed. In an article addressing identity and privacy issues, Joe F. Thompson writes:

Businesses and institutions, such as colleges and universities, must recognize their role as inadvertent enablers of identity theft and must exercise due diligence in the confirmation of proffered identity, the quality control of marketed credit history information, and the adaptation of business practices to the speed and range of IT. (Thompson, 2002)

SECURITY AND PRIVACY IN E-EDUCATION

Industry Best Practices

There are many strategies employed by organizations developed to reduce risks related to security and privacy. General practices particularly relevant to e-education include the use or implementation of:

- Passwords and other access controls;
- Firewalls;
- Virus control;
- Backup and recovery plans;
- Hacker protection;
- E-mail attachment handling; and
- Retention and disposition of course-related materials.

Most institutions are aware of the issues and the strategies available to address these potential vulnerabilities, and they implement actions to guard against the obvious and known threats. Technical security should be implemented at the provider level and be end-to-end in nature. Explanatory statements of security and privacy policies are present on almost all Web sites for organizations involved in e-education. The educational environment is not one that generally welcomes controls. Long-held notions of academic and intellectual freedom may be at odds with controls that may not protect the privacy of activities engaged in by learners.

Issues

In a recent study addressing the issue of privacy and online learning, it was found that "Today students expect colleges and universities to protect these rights throughout the campus intranet and the Internet, that is, throughout the virtual learning environment." Students

additionally expect protection to apply to information about personal activities such as card key access to buildings, purchases, access to online library resources, and login activity to campus networks and the Internet (Educause, 1998). There appear to be three areas receiving attention as organizations attempt to ensure both security and privacy in e-education activities:

- Selection and use of proper technology;
- Establishment and communication of policies; and
- Usage and updating of proper procedures.

Selection and Use of Proper Technology

Much has been written about the development and usage of computer protection models (Caruso, 2003; Kuavik, 2004). Proper security measures that generally apply to user and server security apply to e-education applications as well. All of the warnings and aptly described consequences resulting from improper Internet procedures are well documented (Educause, 2004).

Establishment and Communication of Policies

Most organizations involved in e-education appear to be aware of the need for policy statements regarding their position on security and privacy. Likewise, most Internet sites provide a link to policy statements concerning security and privacy. These policies typically address FERPA-related personal data, data collected from queries to the site, and data provided to register and gain access to the site. It is unusual for a privacy statement to address data collected by educators while a student is completing coursework. At a minimum, how the institution will implement adherence to the existing body of law including FERPA, the USA PATRIOT act, and appropriate state laws needs to be articulated and communicated. Most policies appear to focus on administrative tasks and related data and are not directed toward academic tasks and data related to academic activities. Although there is a legal basis for the custodianship of personal data, it is less clear how the guidelines for course-generated data should be treated. At a minimum, applicable legal dictates need to be followed.

Many educators do not keep current with the legal foundations controlling the privacy of data. This suggests that educators who are involved in e-education need to keep current regarding the consequences and legal implications of existing law. As a general guide for the creation of a policy statement, Dr. Armand Prieditis offers a 14-point question outline (Prieditis, 2001). These questions include asking whether the policy:

- Is prominent;
- Is explicit;
- Is clear;
- Is short;
- Defines what data are collected;
- States what the user gets;
- Explains how the organization uses the data;
- Identifies who else receives the data;
- Explains how often the data are distributed;

- Defines how permanent the data are;
- Describes how to correct/update/delete data;
- Has an opt-out feature;
- Includes special handling for children; and
- Includes contact information.

The content of privacy and security policies can be framed in an eight-point set of issues and recommendations from the Educause study on policy formulation (Educause, 1998):

- *Notification*: Students are informed concerning the what, who, and why data are being collected and what steps are being taken to guarantee the security of the data.
- *Minimization*: No more data are gathered than is necessary and the data are retained no longer than necessary, then they are properly disposed of.
- *Secondary use*: In most cases data are only used for the purpose for which they were collected or an academically sound related purpose.
- *Non disclosure and consent*: Student information should not be distributed to parties external to the institution. With online courses and a presence on the Internet, new questions arise because of the inherent availability associated with Internet access.
- *Need to know*: An individual within the virtual learning environment should be granted access to data only if they have a legitimate educational interest in the data.
- *Data accuracy, inspection, and review*: Data maintained by an educational institution must be correct, and students should have the right to examine and audit the information stored about them.
- *Information security, integrity, and accountability*: Security refers to the protection of information, integrity ensures the data will not be inappropriately altered, and accountability ensures an audit trail for the data exists.
- *Education*: A basic responsibility to ensure that faculty, staff, and administrators are educated about the privacy rights of students and the potential implications of misuse of the information exists.

If these eight issues are addressed in an ongoing effort, a comprehensive framework for establishing a broad and strong policy base will be in place.

To enhance the understanding of privacy issues relating to e-education perhaps something may be learned by examining the history and experience the medical field has had addressing concerns of privacy as it has gone online. Some experiences with the privacy issue in the health care field include the following (Goldman & Hudson, 2000):

- GlobalHealthtrax, which sells health products online, inadvertently revealed names, home phone numbers, and bank account and credit card information of thousands of customers on its Web site;
- Kaiser Permanente mistakenly sent an e-mail containing sensitive information to the wrong recipients; and
- Thousands of patient records were accidentally made

available to the public on the University of Michigan Medical Center's Web site.

In a fairly comprehensive study examining the privacy policies and their implementation, Goldman and Hudson concluded that "On the whole, it appears that while web sites are generally more attentive to the need for privacy policies—as evidenced by the growing number of sites with privacy policies—these policies still fall short of a comprehensive privacy scheme" (Goldman, Hudson, & Smith, 2000). One of the results of this research is a fairly comprehensive set of guidelines for developing a Web site privacy policy.

In addition to the presence of a privacy policy, trust appears to play a large part in the acceptance of any privacy statement. Anything can be stated in a privacy policy. The question remains regarding what assurance does a visitor to a Web site have that the site will actually comply with its posted policy? A number of online privacy seals have been established in an attempt to reassure consumers about often confusing privacy policy provisions. These seals include TRUSTe, CPA WebTrust, BBBOnline, and SecureAssure. All of these seals set standards that participating sites must meet (TRUSTe, 2003a). A good outline for both students and teachers that focuses on the guidelines, specifically in educational settings, for trust development in creating privacy policies has been created (TRUSTe, 2003b).

Collection and Custodianship of Classroom Data

Supplemental to the legal issues about the custodianship of personal information there also are concerns regarding the collection of information generated during the conduct of a class. These concerns may be in at least three areas:

- Collection;
- Access and usage; and
- Disposition.

While sharing her recent experiences in teaching an online course, Lisa Neal stated "we need explicit policies clearly setting forth what data can be collected, for what purposes, who has access, and how long the data will be retained" (Neal, 2003). The issue of privacy in e-education is no different than that in traditional education. Even though the contact and conduct of the class is online rather than face-to-face, the elements of a course are approximately the same. The traditional elements and some of their online counterparts include the following, all of which may create a digital audit trail of data that can be associated with a particular student:

- *Presentation of content*: audio, video, and multimedia presentations;
- *Classroom discussions*: chat rooms, threaded discussion groups, and peer reviews;
- *Critical thinking*: research and assignments;

- *Testing and assessment*: online testing with immediate feedback and portfolio assessments;
- *Submission and grading of assignments*: e-mail with attachments;
- *Feedback*: e-mail, online discussions; and
- *Research*: online library access, Web search engines, and Internet databases.

Because of the virtual nature of e-education, communications that would have taken place in the classroom are now recorded digitally using a permanent storage media. This content is available for later retrieval and use by whoever has access. Information that in traditional settings would disappear immediately may now be permanently recorded.

What is not usually addressed in most formal policy statements is how information transmitted during the conduct of classroom activities such as discussion groups, assessment activities, and e-mail is to be treated. Policies often do not discuss the ownership, availability, and disposition of this level of information generated by participating in an e-course.

Whatever the answers to these questions are, it is only correct that they should be known to the students. In an editorial, Lisa Neal, editor of *eLearn Magazine*, shares a concern that came up in a class she was teaching online:

When taking a course, students implicitly agree to the instructor's rules. Instructors have a certain amount of power over students through grades and other information they provide to the institution offering the course. However, most institutions deploy technology without providing adequate—if any—information about what data is captured and how it can be used. I first became aware of this when, years ago, I ran strategic planning sessions using anonymous brainstorming and voting tools. My client never asked me how the data was stored, but I could easily see who contributed which idea and how everyone voted. I'm glad no manager ever asked me to divulge this data because there was nothing in writing that would have protected my refusal on ethical grounds. (Neal, 2003)

One of the potential advantages of collecting data during the normal conduct of the course is in its potential to study and analyze patterns of success and failure that may exist. As is further stated in her editorial, "we need explicit policies clearly setting forth what data can be collected for what purposes, who has access, and how long the data is retained" (Neal, 2003). This common oversight in privacy policies needs to be addressed.

CONCLUSION

Often a birth date is used as an initial, temporary password, presumably a piece of information known to few people. This is likely not to be true. Visiting the Web site anybirthday.com allows you to discover the birth date of almost anyone. This ability should not surprise very many

people, although it probably does. This ready access to personal data serves as an example of the type of information available on the Internet information that is often used for security purposes.

Several things seem apparent regarding e-education and issues relating to privacy and security. It is important that policies addressing privacy and security issues be developed and communicated at all levels. These policies should directly address the gathering, storage, usage, and disposal of both personal data and data collected during the conduct of a class. There is a consensus among professionals that these policies need to be complete and honest, follow industry standards, and be communicated to the user. To make these policies an important component of the course, trust in their usage must be established.

Specific focus on the importance of privacy and security in part depends on where in the educational delivery supply chain an individual resides. In a broader context that would include privacy and security, Professor Sarah Redfield suggests that "Since the liability will lie only where there is 'deliberate indifference' a reasonable, preventive, pre-existing system for review and response . . . can put the administrator in a position to avoid liability." Professor Redfield argues that educators need to know more law. They need to have a good knowledge of legal frameworks and to utilize a system to be kept current (Redfield, 2003).

If you are a student, you want assurances that personal information about you is kept private, is available for you to review, and is properly guarded from improper release. You want assurances that information generated by you and about you while taking a class is treated properly and is not used in ways other than intended and that you have been made aware of. You want to be sure you can pursue relevant research without fear of retribution. As the American Library Association has noted, "The rights of anonymity and privacy while people retrieve and communicate information must be protected as an essential element of intellectual freedom." This freedom received a fresh look after the events of September 11 and the subsequent passage of the USA PATRIOT Act, which may have caused the existing balance between security and privacy to shift in favor of the former (American Library Association, 2003). As a student you also want to be sure that services you subscribe to will not cause you any harm.

If you are an educator you need to understand the laws that govern data privacy issues and that the practical implications of these laws in the conduct of your classes. You also want to be sure that policies are in place to protect the privacy of instructor and student interactions and that these policies are communicated.

Sponsors need to be aware of all of the federal and state regulations appropriate to their business venture. A sponsor needs to make sure a written policy regarding security and privacy is created and that the policy is communicated, understood, and followed by the administration, the educators, and the students.

If you are a provider you need to be sure you understand the laws and liabilities that govern your interaction with your subscribers. Since the provider is the repository

and source of content and connections to the participants, they need to be up-to-date on all of the current secure site technologies. Proper technology tools that ensure security and privacy need to be utilized.

Developers need to be aware of legal frameworks that govern appropriate content for the audience their products are intended and any controlling regulations that might determine how they can conform to regulations. The Americans with Disabilities Act might influence design and implementation strategies as products are developed.

Often consortiums and brokers are representing the products and services of others. They need to know the legal framework of the relationship between student and administration and that the true relationship between the student and sponsors, especially regarding privacy and security, is communicated and followed. This may be a source of liability concerns.

It is evident that e-education in its many forms is here to stay, and likely will increase in both size and quality. As the e-education industry matures, it will be interesting to observe how this new mode of education seeks its appropriate level.

GLOSSARY

ALN Asynchronous learning networks.

Asynchronous An activity that can occur without coordination with other similar events. In e-education it refers to the timing of course events and the fact that the student works on their schedule rather than a fixed schedule that everyone adheres to.

Bandwidth A measurement of how much data can be transmitted over a communications line; often used to describe the data communications capacity on an Internet connection.

Brick and Mortar Traditional classroom setting that takes place in a room where a teacher and students meet together.

Broadband A high-speed, high-capacity data communications connection.

Buckley Amendment Legislation passed in 1974 that provided rights and privacy protection. See the Family Education Rights and Privacy Act (FERPA).

Certification A formal recognition of achievement or knowledge in a specific area.

Chat An online tool for communicating in an asynchronous discussion group mode.

COPPA The Children's Online Privacy Protection Act applies to the online collection of personal information from children under 13. The new rules spell out what a Web site operator must include in a privacy policy, when and how to seek verifiable consent from a parent, and what responsibilities an operator has to protect the privacy and safety of children who are online.

Dial-up A data communications connection that utilizes the existing voice grade telephone system; a slow, low-capacity connection.

Digital Signature Encrypted transmission including the message plus the sender's key information.

Distance Learning Interaction at a distance between instructor and learners, enabling timely instructor reaction to learners. Simply posting or broadcasting

learning materials to learners is not distance learning. Instructors must be involved in receiving feedback from learners.

E-Course An offering of an electronically based course; an instance of an e-education offering with content, completion, and assessment.

E-Education Education that utilizes electronic media, including the Internet, as the primary mode for interacting with students.

Face-to-Face The traditional educational setting where students and teachers are physically present together.

The Family Education Rights and Privacy Act (FERPA) Legislation passed in 1974 that provided rights and privacy protection; see also Buckley Amendment.

Life-Long Learners The trend that recognizes that learning will take place over a lifetime and does not end when a student "graduates."

Online Class A course where the content and communications take place over the Internet.

Online Learning Learning that is associated with content readily accessible on the Internet. Course content may be on the Internet, or simply installed on a CD-ROM or a computer hard disk.

Synchronous Events that adhere to a schedule. Traditional classes that meet at a certain time and cover specific topics at those specified times refer to synchronous learning. All students are approximately at the same point in the course at any given time.

TEACH Act Federal legislation that defines the rules for copyright usage in distance education and the requirements for qualifying institutions.

Uniting and Strengthening America by Providing Appropriate Tools Required to Intercept and Obstruct Terrorism (USA PATRIOT) Act Legislation that reduces the level of privacy of information in situations that have been deemed important to the security of the nation.

Virtual Learning A term often used to mean the e-education process.

Web-Based Learning Learning that is associated with materials delivered in a Web browser, including when the materials are packaged on CD-ROM or other media.

INTRODUCTION

This brief introductory section begins by defining the term *e-learning*. I then provide a brief overview of security issues relevant to understanding the subsequent sections. The last subsection explains how the rest of this chapter is organized.

E-Learning

E-learning has been a buzzword for quite some time and is recently gaining even more importance. In this chapter, the term *e-learning* encompasses both Web-based *distance education* and Web-sites supplementing *in-class* teaching. Such course sites typically offer downloads of additional reading, online forums, journals, quizzes, and so on. The chapter does not explicitly cover non-Web-based forms of e-learning such as computer-based training (CBT) on CD-ROMs.

Research in e-learning is multidisciplinary, combining very different research areas. Some publications focus on the teaching process and pedagogical issues; others address mainly technical issues such as multimedia transmission, storage, indexing, and networking infrastructure; finally, research on project management in (public) universities, educational policies, and syllabus design contribute to the area of e-learning as well.

As e-learning increases in popularity and reach, more people run online courses and thus need to understand security issues relevant to this topic. Similar to all IT-projects, e-learning projects should commence with a thorough security risk analysis. The following sections therefore discuss typical threats to e-learning projects and show how these issues have been and should be addressed. This knowledge is essential to conduct a security risk analysis efficiently and effectively because participants need to be aware of common threats, protection mechanisms, and effort and cost issues.

As Neal (2004) pointed out, using electronic systems in an area leads to new security and privacy issues. For

example, wireless transponders used for toll collection on roads also create electronic traces of the drivers. Similarly, participation rates and reaction times of students are recorded by e-learning systems.

Chadwick, Olivier, Samarati, Sharpston, and Thuraisingham (2003) presented opposing views on privacy and defined related terms such as pseudonyms, aliases, nicknames, anonymity, privacy, and confidentiality.

Anonymity ensures that others cannot determine your true identity. An anonymous person effectively does not have an identity. A pseudonym on the other hand is an alternative (fictitious or assumed) identity for a person. Aliases are identical to pseudonyms, but the two are used with different connotations in different contexts. . . . Pseudonyms and aliases will usually not prevent the true identity of a person from being determined, although it may be difficult and may require law enforcement to enable it. Anonymity on the other hand should ensure that the true identity of a person is never found out, nor is capable of being found out. A nickname is also an alternative name for a person, and is often chosen as a friendlier variant of the person's formal name. Nicknames are not chosen so that the person's identity can be hidden (p. 332).

The importance of privacy considerations is reflected by recent laws such as the USA Patriot Act (2001) in the United States or the Rip Bill (2000) in Great Britain. The Patriot Act allows "a much broader category of cases to use information developed under the Foreign Intelligence Surveillance Act, where those subject to wiretaps are not informed of the surveillance even after the fact" (Swire and Steinfeld, 2002). In Great Britain, a comparable law, the Rip Act has been passed. Some provisions require that systems must allow law enforcement agencies to access to the data and that keys can be provided to decrypt

encrypted content. Nonetheless, there seems to be no legal requirement to keep all data in long-term archives. Thus, the privacy of individuals can be increased in the long term by regularly reusing backup tapes so that old content is replaced.

Security

The term *security* cannot be defined without knowing specific requirements or potential threats. If defined formally, a system is secure if it is in an initial state that is secure and if from this state only transitions to secure states exist. A breach of security occurs when a system enters an unauthorized state (Bishop, 2002, p. 96). Whether a state is considered secure cannot be defined without requirements.

In more practical terms, there are four basic security requirements to which all real-world (composite) requirements can be traced:

1. Secrecy
2. Integrity
3. Availability
4. Nonrepudiation

The perhaps best known security requirement is *secrecy*. Users may obtain access only to those objects for which they have received authorization. They never get access to information they must not see.

Privacy can technically be seen as a form of secrecy, in which only an individual should have access to private information, whereas the public should be denied access. According to Palen and Dourish (2003), privacy is not a static concept but it changes dynamically. Clearly, individuals usually do not want to keep all personal information secret. Instead, they choose to disclose parts to participate in social processes. The teacher, for instance, needs to know name, student ID, and other information from students to be able to grade them.

Just as important but frequently neglected in daily life is the *integrity* of the data and programs. Integrity means that only authorized users or processes are permitted to modify data (or programs). *Secrecy of data* is closely connected to the *integrity of programs and operating systems*. If the integrity of the operating system is violated, then the reference monitor may no longer work. The reference monitor is a mechanism ensuring that only authorized users or processes are able to access data. Once this mechanism is compromised, the secrecy of information cannot be guaranteed. For this reason, it is important to protect the integrity of operating systems in order to guarantee secrecy of information.

Many users have become aware only through the Internet that *availability* is one of the major security requirements for computer systems. Productivity decreases dramatically if network-based applications are not available or are too slow because of denial-of-service attacks. If, for example, a Web-based authoring tool is too slow, then not only do users require more time to complete their tasks, they also might become frustrated, impairing productivity even more.

The fourth important security requirement, *nonrepudiation*, is that users are not able to deny (plausibly) to

have carried out operations. This requirement is important when e-learning systems are used for exams and grading.

Organization of This Chapter

The second section explains how a security risk analysis works in the context of e-learning and briefly presents a standard method for conducting it. In addition, the perceptions of threats relevant to e-learning given by unprepared participants of a risk analysis are summarized.

Section 3 commences by analyzing typical threats to common activities in e-learning such as *creating content* or *teaching online*. Subsequently, we show how two major security requirements (secrecy of data, privacy) can be addressed in theory.

The fourth section elaborates how these theoretical results have been implemented in a modified version of Moodle, an open-source learning platform. Details on the implementation and data structures will help readers as a technical guideline when implementing similar features in other systems.

The fifth section points out additional security threats that implementers of e-learning programs will need to address once mobile e-learning (m-learning) is used in larger production environments. Although m-learning is still in its infancy and most current m-learning projects are mainly research prototypes, typical mobile services in e-learning can already be identified along with their corresponding threats to security and privacy. The final section offers a brief conclusion.

SECURITY RISK ANALYSIS

Before dealing with risk analysis, it is necessary to define the terms *risk* and *threat*, which are closely related and often wrongly used as synonyms. *A threat is a bad thing that can happen; a risk is the relative likelihood that a bad thing will happen* (Schneier, 2003, p. 20). Not every threat develops into a problem. A risk can also be considered to be a measure of financial loss for an organization. Clearly, threats lead to risks. Whether the risk is relevant depends not only on the threat but also on the environment and the nature of an organization.

With the help of a standard method, the basic procedure of a risk analysis is presented in this section. Peltier (2001) contained a detailed introduction to this topic that is recommended as a reference when conducting a security risk analysis for the first time.

Scope and Importance

Information is an important asset—not only for companies, but also for universities. Universities, in particular, depend on the transmission (aka *teaching*) and creation of information (aka *research*). To limit the maximum expenditure on security measures, it is necessary to estimate the value of the created assets accurately.

The following ways of evaluation are possible:

- Costs of (first) compilation of information
- Costs of restoration of information after destruction
- Damage caused if the information cannot be used

- Advantage another university or another researcher would have if he or she could use, modify, or destroy the information
- Sales revenue if information is sold
- Costs if secret information is published, modified, or destroyed
- Damage through decline in student numbers and loss of credibility in the academic arena

According to these estimates, one can decide which assets are worth protecting and which effort seems justified. Furthermore, one should bear in mind that too much security is just as unfavorable as too little security, especially in research and education. Apart from high costs, a system that is too prohibitive is inflexible and constricts users in their daily routines. Therefore, certain risks have to be accepted in e-learning in order not to prevent students from learning. For instance, in computer science, students should be able to so set up and maintain their own servers.

Standard Method

The following subsection takes a look at the most important steps of a risk analysis:

1. Identification of assets
2. Estimation or calculation of threats and risks
3. Setting priorities
4. Implementation of controls and countermeasures
5. Monitoring of risks and of the effectiveness of countermeasures

Identification of Assets

For a *qualitative risk analysis*, the exact asset values need not be known. Assets that may be worth protecting include networks and hardware, software, buildings, equipment, people, and operational procedures. For most e-learning projects, a qualitative risk analysis is the method of choice because it requires little effort and the results are sufficiently precise for small and medium-sized projects—the typical e-learning initiative at universities. With the help of a table (Table 1), value classes instead of the actual values can be determined. The values have to be chosen depending on the project to separate the assets clearly into different classes. The advantage of this method is that it is extremely fast. If e-learning is the focus of a business, however, more precise methods are required.

All the aforementioned items are related to the protection of information—the core of all large e-learning courses. In addition, hardware, buildings, and software are also obviously necessary to process data electronically.

Table 1 Example of Value Classes to Calculate the *Financial Loss Valuation Score*

Loss in EUR	Evaluation Score
<2000	1
2–15K	2
15–40K	3

Furthermore, the protection of people is essential because they affect the real value of the data. It is the people who turn data to information.

At first, it is important to define the scale of the security risk analysis. Usually, the risks for buildings, people, and so on are not covered within the framework of an e-learning project. In large-scale e-learning programs, however, in which larger parts of buildings are used exclusively for the planning, administration, and implementation of e-learning classes, these risks should be taken into consideration. However trivial the risk of fire may sound, it can threaten one’s existence if the only e-learning lab is destroyed.

Estimation of Threats and Risks

Two basic forms of threats can be distinguished: *deliberate threats* such as attacking a system and *accidental threats* such as forgetting to create backup copies or a flood. For each asset, a list of threats needs to be compiled; a matrix (Table 2) can be used to organize this process. This list is not a complete taxonomy of threats; it serves as a template and needs to be adapted to the specific requirements. Some threats, such as power outage could also be classified as a “deliberate act.” Whether such a threat needs to be considered in the security risk analysis for a specific e-learning project depends on the project’s scope. Deliberate power outages (e.g., by cutting wires leading to the university) might already be covered in the security risk analysis of the campus and do not need to be considered in the security risk analysis of the project.

Setting Priorities

The vulnerability of an organization depends on various factors such as confidentiality of the data, training of staff, and staff members’ familiarity with emergency procedures, protective mechanisms and monitoring, morale, and attitudes toward the university, economic environment, backup plans, etc.

To set priorities correctly, the *expected annual damage* can be calculated.

$$\text{Expected annual damage} = \text{Value of assets} * \text{Probability of occurrence}$$

The disadvantage of this simple formula is that extremely rare events might not be taken into consideration at all, although their damage can be enormous. This is reinforced by the fact that the probability of rare events cannot be estimated very accurately. How likely, for example, is a war in Western Europe?

Many countermeasures reduce a risk but do not eliminate it completely. With regard to the estimate of costs, four types of costs have to be considered.

- Damage without countermeasure,
- Damage with countermeasure (usually smaller than damage without countermeasure, although additional threats may be introduced by a countermeasure. Consider, for instance, the threat of a hard disk failure. This interferes with the requirement ‘availability.’ However, the countermeasure ‘backup tapes’ creates new threats: Tapes can be stolen more easily than hard disks. Since

Table 2 An Example of Threats Relevant to Specific Assets

Type	Threats	Asset 1 Server	Asset 2 HTML Content
Natural	Fire	X	
	Storm		
	Volcanic eruption		
	Earthquake	X	
	Floods	X	
	Avalanches		
Deliberate act	Fraud		X
	Fire	X	
	Blackmail		
	Theft		X
	Bomb threat		
	Riots, war		
Unintended	Vandalism	X	
	Computer bug	X	
	Power outage	X	
	Handling error	X	
	Spilling of drinks	X	

all data are stored on these tapes, the new threat interferes with the requirements 'secrecy/confidentiality'),

- Costs of the countermeasure, and
- Costs of plan B.

Plan B is an alternative plan that can be implemented when the threat is about to turn into a problem. In some cases it may be advantageous not to implement a countermeasure, but merely to provide an alternative plan that is used when required.

Implementation of Controls and CounterMeasures

During implementation, the costs of countermeasures should be recorded. This is useful for subsequent projects and improves the accuracy of future estimates.

The point of documentation is not just to fulfill the requirements of an audit; the real purpose should be clear to everyone involved: By being able to compare the costs and the benefits, the importance of risk management can be demonstrated. Moreover, staff, faculty, and students become aware of the real costs of security threats.

Case Study: Tutorial and E-learning Module

Before performing a security risk analysis as previously described, it is advantageous to learn about the specific risks encountered by other academic staff in e-learning situations. Questionnaires used in tutorials at several conferences (Edmedia 2003, 2004; IIWAS 2003; ViewDet 2003) and a case study have provided insight into the current level of awareness of unprepared participants.

Most (72%) teachers and content authors had previous experience with two or three e-learning platforms. When using electronic bulletin boards, the three concerns mentioned most often were the following:

1. *Abusive language* (in open discussion boards)
2. *Stealing of e-mail addresses* by Web spiders (A search

engine uses *robots* to index the Web. These robots are also referred to as *spiders* because they *crawl* through the Web. While visiting pages, spiders extract information such as key words or e-mail addresses. Franklin (2003) described Web spiders in more detail.)

3. Posting and downloading of *illegal content* or *viruses*

Concerning security issues, participants saw no significant difference between online and in-class discussions; the main difference they identified was *social incentive* to (or the fear of having to) participate in in-class discussions. The implicit archiving of discussions was perceived as an advantage of bulletin boards, not as a threat to privacy.

Denial of service attacks by students during exams were not seen as a major issue whereas unauthorized copying of digital content was considered a huge threat. This is probably caused by the media hype about peer2peer file sharing. Faculty acknowledged that they use resources retrieved from the Internet in their classes (readers, handouts) without considering copyright issues.

The central computing services of universities *backs up* data in many cases, but most people hardly ever test whether the procedure to restore data works reliably.

Sharing of passwords is still common, even though technical and science faculty seem to protect their passwords better than others.

Faculty does not feel uncomfortable discussing sensitive topics via e-mail. They *trust* that the *e-mail* servers are well secured. Teachers indicated some interest in logs showing which pages are viewed how often by students, but they also realized the impact this has on students' privacy.

Based on these experiences, an e-learning module on *security in e-learning* (Planet-ET, 2003) was designed. This course instructs teachers how to improve security in their online courses.

FROM REQUIREMENTS TO DESIGNING AND IMPLEMENTING SOLUTIONS

This section elaborates the most important security requirements in the context of e-learning and provides insight into how they have been and should be addressed in various projects.

General Discussion

Usually, there are three main processes in e-learning scenarios.

1. Creating Content
2. Teaching and Learning
3. Organization

Creating Content

Too often, security is considered a technology of hindrance. Things that work smoothly without security measures seem to become more complicated and complex by installing security mechanisms. Security, however, is an *enabling technology*.

Only if an adequate security standard has been implemented can people make use of the services offered. For example, distrust of e-banking was initially profound. It was not until confidence in the secure transfer of data had been established and transaction numbers (TANs) were used that e-banking gained acceptance.

The situation is similar when writing academic teaching material. Thanks to today's networking it would be easily possible for authors to provide access to teaching materials to a wide audience—colleagues and students. The reason many authors refrain from doing so is the fear that their compiled material might be passed on and processed without their knowledge.

When discussing security in e-learning, it is important to distinguish between the knowledge as such and the type of knowledge transfer. The knowledge imparted at universities can normally be acquired in self-study from books and other sources. The information (e.g., how to multiply matrices) is not a secret. It is the teaching style that makes a course worth protecting.

An example proving this distinction is provided by the Open Courseware initiative of the Massachusetts Institute of Technology. Although a variety of teaching contents are offered to the students on the Internet, this initiative does not endanger the existence of MIT. Not the teaching material but the interaction with fellow students and professors is why a course is worth its tuition fee.

The problem of controlling who is doing what with teaching materials is analogous to the music industry's problem with digital copies in MP3 format available on the Internet. In addition to the authors' intuitive need for copy protection, however, there are numerous other aspects of security.

The essential security requirements in e-learning are (Weippl, Essmayer, Gruber, Stockner, & Trenker, 2004):

- Readers must be able to rely on the correctness of the content.
- Readers want to read unobserved.

- There must be protection against unauthorized use.
- There must be protection against unauthorized modifications and reuse.
- There must be protection against destruction and loss of data.

In this context trust is essential. Even though undergraduate students tend to accept everything they read as true (Graham and Metaxas, 2003), they soon learn to value the trustworthiness of a source. Therefore, integrity of content including the author's identity is of paramount importance.

Teaching and Learning

Even though continuous evaluation has gained popularity over the last few years, the distinction between teaching and examining is still frequently drawn. Because there are different threats and security requirements in these two areas, a distinction between teaching and examining seems reasonable when discussing security.

Particularly in arts subjects and the social sciences, *discussions* are an essential component of the courses. Newsgroup discussions can complement in-class discussions or substitute them in distance teaching. A major difference between oral discussions in a classroom and online forum discussions is that all messages can be stored electronically.

Students legitimately have concerns that their contributions to a discussion might be stored and quotations might be published out of context. The implementation of security mechanisms and a policy that clearly states what will be stored for how long can minimize this risk for students. Privacy expectations are, however, dependent on the cultural environment and may differ significantly, for example, between the United States and Austria. In Austria, for instance, grades along with student names are normally published on printed lists at the university so that anyone who enters the building can read them.

In principle, an interaction in teaching is valuable (King, 2004), and only sound security mechanisms enable such interaction. For example, only course participants should have access to the corresponding forums and annotations, and they should be allowed to use pseudonyms. In this context, different forms of pseudonyms and anonymity can be distinguished: Students' identities may remain hidden (a) for teachers only, (b) for all course participants, or (c) entirely, even for system administrators.

The first option can be useful for surveys if teachers want to receive feedback on their courses but also allow students to know who posted which feedback. Using this approach, however, a student's anonymity can easily be disclosed either by fellow students or by the teacher who can register him- or herself as a student. It is common practice for teachers to create "student users" for themselves to preview and test courses from the students' perspective. The second option—remaining anonymous to all course participants—is the most common approach to surveys. The implementation is fairly easy, and privacy expectations of students are met. Because system administrators can still identify users, discussions on politically

sensitive topics may be impaired. The third option is to guarantee anonymity at all levels. As discussed in a subsequent section (Privacy of Usage), there are still several locations where information is (temporarily) stored so that the users' privacy expectations might be compromised.

Exams

Thinking of "security" in connection with *examinations*, one frequently thinks of the prevention of cheating. When using new media and e-learning, new concepts of knowledge transfer and learning are frequently employed. Even though the mode of assessment is likely to change, traditional exams will certainly continue to be used for some time. Apart from students' cheating attempts, other security requirements such as availability and nonrepudiation of assessments are major factors that influence the success of an electronic examination system.

The first step of exams is the *identification* of students. In traditional paper-based exams, they simply fill in their names; electronic examination systems usually require a login name. *Authentication* of students (i.e., the process of verifying a claimed identity) is done during paper-based exams by checking the students' IDs. Taking the exam at home without supervision is not feasible because a student might collaborate with another person providing illegal support. As Weippl (2002) pointed out, the only way to know that a student does not receive outside help is a trusted examination center that checks students' IDs (or biometric features) and restricts access to exam rooms. The alternative is to grade on a continuous basis throughout the whole term. Although this does not render cheating impossible, it substantially increases the required effort. Another option is to enforce strict time constraints on multiple choice exams. Hamlin and Ryan (2003) stated that "if an exam consists of 10 multiple choice questions and a student has nine minutes to complete the exam, the chances of the student looking up each answer is slim because of the time restriction." Recording the completion time of exams can provide additional hints as to whether a student has cheated. The Associated Press (Weller, 2004) reported that 70 freshmen at the U.S. Air Force Academy were accused of cheating at an online test. The cheating was detected because cadets worked too quickly, answering 25 questions in 3 minutes.

The risk of cheating by helping other students also depends on the environment and the cultural setting. In Europe, for instance, schools usually grade on an individual level so that all students may fail a difficult exam, or a class of excellent students may receive above average grades. Such a setting makes mutual assistance (i.e., cheating) of students more likely. If however, only the top 10% receive an A grade—independent of the objective level they reach—the competitive situation dramatically reduces the risks of cheating and collusion.

Apart from collusion, there are other security threats to examinations. For example, a student might try to crash the testing application to avoid getting graded—an attack on system *availability*. He or she might also later deny having given the recorded answers. In a system that guarantees *nonrepudiation*, the student's claim can easily be refuted. The users' (i.e., students') confidence in the availability, nonrepudiation, and security of an e-learning

system is a precondition for user acceptance and thus a condition *sine qua non* for the use of the system.

Organization

Even in classical in-class teaching at universities, new media are frequently used to amplify and enrich teaching. The security issues arising are similar to those in pure distance teaching. In this context, security is not so much a technical issue but more an organizational one. Using simple procedures for security can increase compliance of users and thus security much more effectively than the implementation of complex and theoretically more secure solutions. For instance, implementing a public-key infrastructure (PKI) system ensuring that only authorized people correctly transmit grades via e-mail may sound secure, but confirming unsigned e-mails via telephone might be a much better and simpler way of guaranteeing the authenticity of grades.

Security is an aspect that is often regarded as an additional supplement. It is the managers' responsibility to demonstrate the benefits of security to anyone involved in teaching, so that an appropriate concept of security can be developed and successfully implemented.

Secrecy of Uploaded Data (Preventing Unauthorized Views)

E-learning platforms are commonly used for both distance learning and to support in-class teaching. The widespread use of platforms such as Blackboard (2004), Web-CT (2004), or Moodle (2004a) makes it easy for faculty to publish supporting material and to share material (e.g., exam questions) with colleagues. When sharing teaching materials, however, many people accidentally also share content that should remain private, because, as Good and Krekelberg (2002) pointed out, many users do not exactly know which files they share with whom.

This subsection provides some examples that highlight why *mandatory access control* (MAC) and the Bell and LaPadula (BLP; 1975) model in particular make sense for e-learning systems. The BLP model is easy to understand and provides sufficient granularity of basic access control. In most cases, the BLP model is implemented using role-based access control (RBAC) as shown by Osborn et al. (2000), because RBAC is readily available in most operating systems and database management systems. The rationale for explaining the access control based on the BLP model and RBAC is BLP's straightforwardness. The no-read-up property is intuitive, and the no-write-down property is easy to understand for teachers and students. Explaining the underlying RBAC definitions, as shown in Figures 1–5, would be too confusing for the average user. Another option would be to use object-oriented access control (OOAC) as proposed by Essmayr, Pernul, and Tjoa (1997), which would rely on an object-oriented database as storage system.

Alice and Bob are users of a system. Alice is a student (*s*) in course *C1* and a teacher (*t*) in *C2*. Bob is teacher (*t*) of *C1* and student (*s*) in *C2*.

$$\text{Alice} = (c1-s), (c2-t)$$

$$\text{Bob} = (c1-t), (c2-s)$$

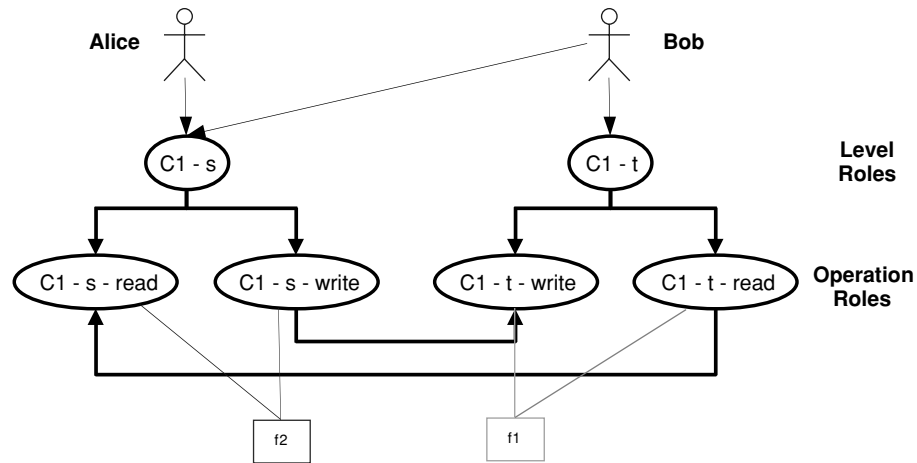

Figure 1: Two new files are created. f1: c1-t, f2: c1-s

Creating (Private) Files

In the first step, Bob creates a new file f1 as c1-t. Alice creates a file f2 as c1-s.

Bob can read files f1 and f2; he can write to f1 and not to f2—that is, the *no-write-down* property prevents the reading of f2. The *no-write-down* property protects data from being accidentally written to a lower level. Neither the user nor Trojans on his behalf can *downgrade* data, for example, from the teacher level to the student level. In our example, this means that Bob cannot create a file c1-s as long as he is logged in as teacher of C1. Only if he logs in as a student, he can create a c1-s-file. Alice can read and write f2 but cannot access f1.

Commenting Files

Bob reads f2 and wants to add comments in f3 as feedback to Alice. Due to the *no-write-down* property he first has to login as c1-s. Clearly, Alice can read f3.

Creating Exams

Bob wants to create an exam from a template that is stored at level c1-t. Obviously, he has to login as c1-t to read it.

Based on this template, he creates the exam f4. As mentioned earlier, he cannot create files at a lower level.

Making Exams Available

Bob wants Alice to take the exam and therefore needs to provide her with read access. Because not only Alice but all students in the course c1 should be able to see the exam, he needs to *downgrade* it from c1-t to c1-s. This operation violates the *no-write-down* property. To avoid compromising overall system security, we propose allowing downgrading only with a special *system call* (Weippl & Essmayr, 2003).

Completing Exams

Alice writes answers to the exam f4 into a file f5. She chooses to write this file at level c1-t so that only Bob can read this file. Alice still sees her answers in the graphical user interface (GUI) but cannot access the file for reading. The rationale is that Alice can be sure that no fellow students can read her answers and use them to cheat.

This operation is permitted because the BLP model allows *write-up* operations since they do not compromise confidentiality (but integrity).

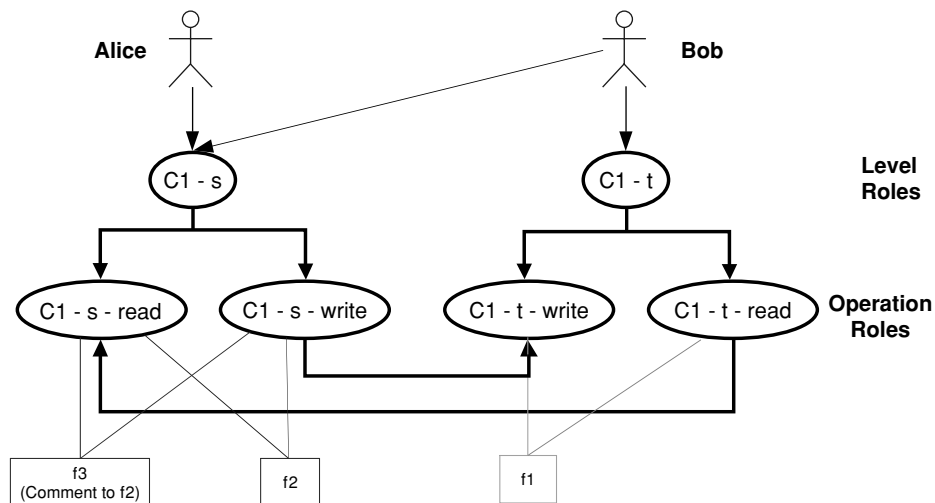

Figure 2: A third file is added. f3: c1-s

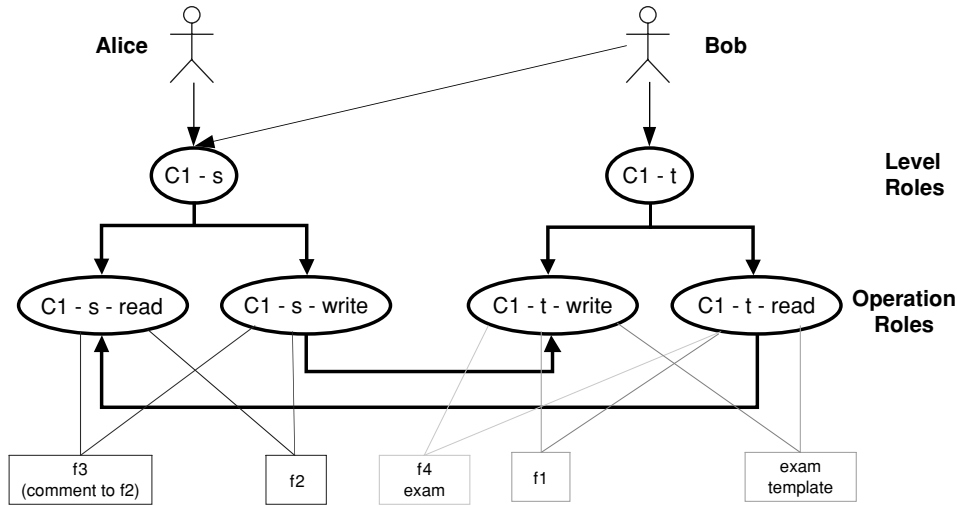

Figure 3: An exam is created based on an existing template. f4: c1-t

Implementing MAC With RBAC

The level role c1-t (Figure 5) comprises two operation roles, c1-t-write and c1-t-read. File f1, for instance, can be written by anyone who has role c1-t-write. c1-s-write contains c1-t-write as hierarchical subrole. Thus, Alice (c1-s) can write to file f1 (“write-up” via c1-s, c1-s-write and c1-t-write), but she cannot read it.

Bob can choose whether to use the level role c1-t or c1-s. To create f3—the comments to f2 that Alice should be able to read—he needs to use role c1-s. To create the exam (f4) based on the exam template, he has to change to c1-t again.

The dotted line in Figure 5 connecting f4 with c1-s-read indicates that this connection has not been generated by the default rules, but that system calls were used to *downgrade* levels.

Privacy of Usage (Tracing Users)

Users are becoming increasingly aware that all their actions in Web applications can be logged. Regarding

e-learning applications, several locations can be identified where users leave traces (Figure 6).

Local Computers

If users share computers (e.g., in labs), browser caches, histories, and temporary files may reveal their actions. In addition, malicious software such as keystroke loggers could be installed to intercept passwords and other sensitive information. At university labs this threat should be taken seriously.

Internet Service Providers

The computer is connected via an Internet service provider (ISP) to the Internet. Most ISPs keep a record of which IP address was assigned to whom. Furthermore, all visited Web pages and interactions with e-learning platforms *could* be logged. Of course, storage of this information is illegal in most cases. It is simply because of the volume of data that ISPs will most likely not store this information.

Figure 4: Alice, the student, is permitted access to the exam. f4: c1-s

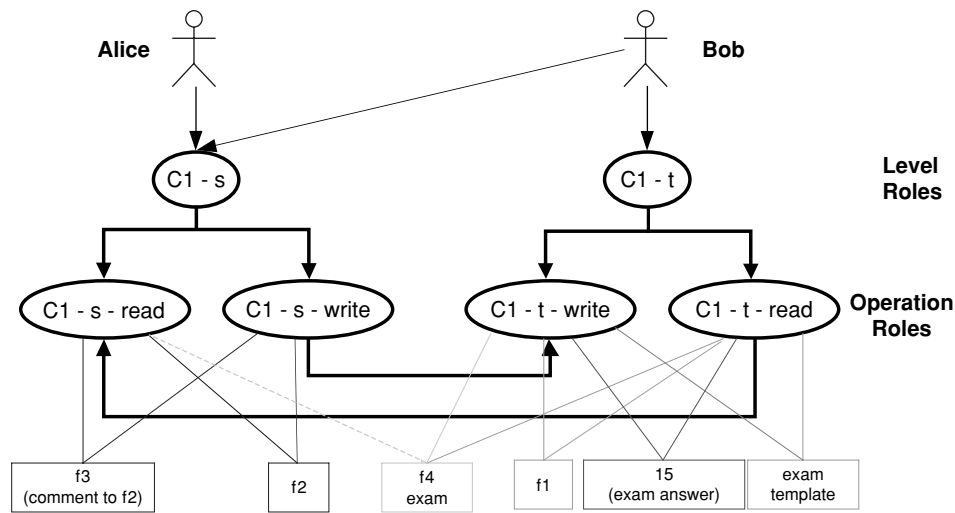

Figure 5: The answers given by Alice are only accessible for the teacher. f5: c1-t

Internet

Traffic routed through the Internet is subject to all known threats such as eavesdropping, spoofing, and so on. Well-targeted attacks against a specific user’s privacy are improbable. Usually, high-profile companies such as Microsoft are victims of attacks (generally distributed denial of service attacks).

Web Server

An e-learning platform is hosted on a Web server. Most Web servers create log files that identify and store the IP addresses of each inbound connection along with the URL visited. These logs are usually discarded on a regular basis to limit their size.

E-Learning Application

Unlike in the aforementioned layers, the application layer can create much more specific and thus useful logging

data because the user is known with her login, and the application knows which clicks are important and which are not.

Many e-learning systems are not only used as learning managements systems (LMS) but also as content management systems (CMS) to allow students to read course-related material. What used to be put on reserve at the college library is now accessible online. Although this may be more convenient for students, teachers can check who reads which material—information that according to Gorman (2000) a library would never provide to teachers. Privacy rights are affected by the Patriot Act (2001) and any information retained may have to be disclosed to the FBI. The American Library Association (2002) recommends that libraries establish clear policies with the help of legal counsels as to which information needs to be stored. Because CMSs may be used in a similar way as libraries, universities should create corresponding policies in cooperation with libraries.

Figure 6: Each user’s request is passed through several interfaces leaving traces.

Database

Most e-learning applications use a database to store data. DBMSs offer sophisticated tracing and login facilities. In many cases, however, the e-learning application connects to the database with a single user. Thus, user-specific traces are not as easy as on the database level.

Possible Solutions: Open Source Systems and anonymizers

As mentioned earlier, the functions that are most critical to privacy are based on the application layer. Open source software offers (experienced) users the option to check the code for any hidden functions or bugs by themselves (Cowan, 2003). Students cannot be absolutely sure that the university did indeed install the unmodified source code and that no Trojan compilers (Spinellis, 2003; Thompson, 1984) were used. These threats are usually very small, however, and mostly of academic interest. According to Hinman (2002), students usually trust faculty. Thus, clearly stating a privacy policy as suggested by Neal (2004) or Educause (1998) is an easy and effective step to align privacy expectations with the reality of employed e-learning systems. The platform for privacy preferences (P3P; Hochheiser, 2002; Reagle & Cranor, 1999) is a protocol to exchange a privacy policy between a Web browser and a Web server. The privacy policy is specified using XML (extensible markup language) so that the user's Web browser can automatically decide whether the user is willing to accept the policy based on his or her preferences. P3P, however, offers no way of guaranteeing that the server really honors the policy. Users simply have to trust that the policy is implemented as stated.

Anonymizers based on Chaum mixes (Chaum, 1981) or Dingedine, Mathewson, and Syverson's (2004) Tor system can be used to obfuscate traces at ISPs and Web servers. Chaum's system implements anonymity so that eavesdroppers do not know who is communicating with whom at what time. Tor is an improvement of the original Onion Routing system that routes each request encapsulated in encrypted packages via several nodes to make traffic analysis impossible. At the client side, however, privacy expectations can still be violated by locally installed software such as keystroke loggers.

Dourish and Redmiles (2002) clearly distinguished between *theoretical* and *effective* security. Theoretical security refers to the maximum level of security that can be achieved using a given technology. The level of security that is effectively achieved in daily routine tasks is usually much lower, however. Because many people are unable to determine the security implications of their decisions, easy-to-understand gouges can be used to visualize relevant parameters.

Case Study: Moodle

Moodle (2004b) is a course management system that is based on social constructionist pedagogy. The online help thoroughly explains to teachers not only how to use certain functions from a technical perspective but also illustrates pedagogical concepts. The explanations are brief and concise addressing also technical and science faculty that usually dislike "soft education mumbo jumbo."

Moodle's design is centered on *communicating* with students. It offers different styles of forums, chats, journals, and workshops.

Privacy Concerns

We found that several teachers expressed concerns about their students' privacy even before conducting a systematic security risk analysis when using Moodle. As mentioned in subsection "Teaching and Learning," students might refrain from openly expressing their thoughts on controversial political and societal issues if electronic copies of their discussions are stored.

Moodle logs each user action and stores it in a database. For teachers, this feature is quite useful to analyze which pages are visited how often, and which students spend a lot of time in the system or who never logs on (Figures 7 and 8).

Anonymity in Moodle

Moodle logs all user actions in one central place. To avoid that the users' actions are written to the log file, we modified the logging function to log a dummy user ("anonymous user"). This approach is better than not making any log entries at all because anonymized usage statistics are still available.

Anonymous posting, however, does not imply that everyone can post a message. Access to the course's discussion site is still protected with a login requiring user name and password. Nonetheless, the notion of trust is weakened because the identity of the author is unknown. On the other hand, this can be used as a pedagogical advantage: Students often trust postings from the faculty as true without critically challenging them. In anonymous discussions, readers need to decide whether to trust the content based on the cited references.

Making the user anonymous in the forum is a little trickier, because the user has to remain identified to be able to edit his or her own entry. Moodle allows editing entries for a limited time after which they can no longer be modified. The first approach we implemented was to set the user to anonymous only after this initial period of time in the database. To avoid displaying the user name during this period, we introduced a flag that prevents the name from being displayed even though it is stored in the database.

Although users thought they posted anonymously, their contributions could be identified during the first 30 minutes after the posting by looking directly into the database. Because during this time frame backups can be made, we decided that this approach was dangerous because *users thought they acted anonymously even though they did not*. Therefore, we eventually decided to allow completely anonymous posts. As a trade-off, these postings cannot be edited or deleted by the author. If authors cannot be identified, it might be more difficult to follow the discussion as to who said what. The easiest approach to reduce this problem is to encourage the use of quotations and the treelike organization of discussion threads.

Known Limitations

As mentioned earlier, it is on the application layer that the most detailed logs are available. We modified the

Figure 7: Each action by every user is stored in a database.

application so that users can switch to an anonymous mode. Nonetheless, our approach has some limitations. Because we mainly addressed privacy-related functions on an application level, there are still usage traces in other layers, for example, the Web server's log. Because these logs are usually only stored for a couple of weeks or months, there is little risk that the data will be available in the distant future. The main privacy concern in teaching is not so much the near future but long-term archiving. With in-class teaching, for example, the attending

students remember discussions anyway, so that short-term archives of discussions introduce little additional threat to privacy. In contrast, out-of-context quotations decades later can be a threat. Just imagine that a candidate running for president in the United States is reported to have argued pro-communist when he was in college. Belotti and Sellen (1993) proposed a framework for designing feedback and control mechanisms in computing environments. The main idea is that users can *control* which information is captured, what it is used for, and

Jacob [Vienna, AT] : (XX . XX .35.77) is located in Vienna, Austria. (48.22, 16.37)

who has access to it. In addition to control, users receive *feedback* on who uses which data for which purpose.

OUTLOOK: SECURITY IN M-LEARNING

Before analyzing security requirements of mobile users in a teaching-learning environment, this section briefly looks at the way mobile devices are used in an educational setting. Walker, Rockman, and Chessler (2000) provided an overview of how mobile technology influences education. Weippl (2004) provided additional details on how some of the related security issues might be addressed. Throughout this section, when referring to mobile devices or mobile computing, it means devices such as personal digital assistants (PDAs) or cell phones.

In-Class Teaching

Mobile devices are used to support the traditional in-class learning process by providing supporting information such as lecture schedules and venues. Both pull and push technologies are used: *pull* refers to information that students actively seek, whereas *push* means that students automatically receive it, such as cancellation of classes.

Sharples, Corlett, and Westmancott (2002) suggested that PDAs will improve learning outside of class (contextual learning) because they are easier to carry along and can thus be used in different situations compared with PCs. They describe a prototype system of a mobile learning device that is targeted at children aged 9 to 11 years. Being able to use the devices anytime leads to a deeper learning experience that can be considered a form of life-long learning. Sharples et al. (2002) based their idea on Walker et al. (2000), who noted that students use laptop computers more efficiently to learn than desktop PCs because of their mobility.

The eClass project (formerly Classroom 2000; Abowd et al., 1998) supports in-class learning with mobile devices. During class time, the lecture is recorded electronically, including notes, and captured onto digital media. This makes the creation of e-learning content easier. Instead of creating a digital course on the author's desk, the course is created while a teacher gives a lecture—something that takes place in every university and requires no additional effort. Pimentel, Ishiguro, Abowd, Kerimbaev, and Guzdial (2001) connected in-class activity, in the form of captured lectures that are later made available on the Web, with collaborative discussion spaces. Based on the collaboration of students and teachers during lectures, digital content can easily be created.

We now briefly look at the most common risks to m-learning identified at security risk analyses. When mobile services support in-class teaching, this normally includes the publication of sensitive information such as grades and time-relevant notification services for changes of venue. Because potentially large groups of students could receive wrong information, message integrity and nonrepudiation are essential.

Notification Services

Notification services are useful to reduce time lags of asynchronous communication such as e-mail and news

groups. Students frequently use bulletin boards to discuss class assignments and solutions. Just before the hand-in deadline, students often nervously await answers to their open questions. Mobile devices are used to send short message service SMS notifications to a user's cell phone as soon as an answer to her posting has been received.

Notification services depend on availability by their very nature. Students expect to be notified within minutes once an answer to an important question has arrived. Secrecy of data is relevant because recipients may want to remain anonymous. Natural language messages contain redundancy so that unintentional changes can be detected easily. Intentional modifications could point to a wrong event (i.e., posting) that caused the message to be sent. As soon as the message arrives (availability), the user simply has to check all his or her newsgroup postings that might have triggered the message. Thus, integrity and nonrepudiation are generally not considered important in this application context.

Registration Service

Students need to register for courses on a regular basis. Before registration, they often attend information sessions offered by teachers or want to talk to their lecturer personally. During this period of time, registration (or pre-registration) and de-registration via mobile devices may be a useful application. Using mobile devices to register for courses only makes sense at large universities and for large courses. In this case, teachers do not know students personally and rely on electronic records generated by the application used for registration. Registrations should be binding for students. In addition, students need to be certain that their registration was correctly received and that no one else can unregister them—for instance, a fellow student who was not able to register because the course was fully booked.

Field Data

In science classes, students occasionally need to collect data outside of labs. Mobile devices have been used a lot for this application scenario. Okoada, Tarumi, Yoshimura, and Moriya (2001), for instance, used mobile devices to incorporate learning of theoretical knowledge into field learning. Courses on environmental education allowed users to access background information while outside.

Gathering data in the field requires that data are stored correctly and that their integrity is preserved. The protection should focus mainly on unintentional modification. Availability is essential as well, because numerous measurements might be taken resulting in a high volume of data. In overload situations, measurements might be stored incorrectly (integrity) or not at all (availability).

Solutions for Authentication

Research in computer science offers a plethora of solutions for the aforementioned security requirements. Nonetheless, it has been established (Sharples et al., 2002) that the human factor is the weakest link in most application environments.

The first step for all mobile security issues is to establish securely the identity of a user and to verify his claimed identity. This process is called authentication (Sandhu & Samarati, 1996). In this context, we focus on the user's authentication via his or her device to other services and not how he or she may authenticate to the device itself. Depending on the application scenario, different forms of mobile authentication can be distinguished (Weippl et al., 2002).

Mobile identification is a service that implements identification without authentication. This is useful for services with low security requirements. It is useful, for example, to automatically sign in on class attendance lists; the equivalent "traditional" paper-based lists are also used without proper ID check. *Mobile authentication* requires the correct identity of the accessing person, for instance, when a student registers for a course. *Mobile pseudonymous authentication* is used to identify oneself with a fake name. This fake name should be reused every time when the user logs onto the same service. For different services, different identities can be claimed to prohibit profiling across services. Nonetheless, other people should not be able to claim the (fake) identity. Thus, some form of authentication is required.

Using mobile *anonymous authentication*, users may remain anonymous even if the service requires authentication. For example, a newsgroup server may require identification such as a unique user name and a password. To make it easier for users to protect their privacy, they will want to generate anonymous accounts automatically.

CONCLUSION

This chapter showed how to conduct a security risk analysis for e-learning projects and presented typical threats that people perceived before and after such a workshop. Focusing on two security requirements, the third section analyzed typical threats for common activities such as creating content or teaching online. Subsequently, it was shown how two major security requirements (secrecy of data, privacy) can and have been addressed in theory.

Based on these findings, the implementation described here illustrates that the required changes to existing platforms such as Moodle are not extensive. Picking up our approach other researchers and commercial e-learning providers can implement similar function in other platforms.

In the future, e-learning will most likely be enriched by m-learning features. However, new technology almost always introduces new threats. The main security threats identified here as relevant for m-learning were summarized.

GLOSSARY

Computer-Based Training (CBT) A term that encompasses the use of computers in both instruction (computer-assisted instruction; CAI) and management (computer-managed instruction; CMI) of the teaching and learning process (Learning Circuits Glossary, 2003). Training where a computer program provides

motivation and feedback in place of a live instructor is considered to be computer-based training regardless of how the content is delivered (ELearners Glossary, 2003).

E-learning Dating back to the hype of the term e-commerce, e-learning is widely used in different ways; for instance, LineZine (2003) understands e-learning as ranging from the convergence of the Internet and learning, or Internet-enabled learning, to the use of network technologies to create, foster, deliver, and facilitate learning, anytime and anywhere, or the delivery of individualized, comprehensive, dynamic learning content in real time, aiding the development of communities of knowledge, linking learners and practitioners with experts. *ELearners Glossary* (2003) defines e-learning as any form of learning that utilizes a network for delivery, interaction, or facilitation. According to *ELearners Glossary* (2003), e-learning covers a wide set of applications and processes, such as Web-based learning, computer-based learning, virtual classrooms, and digital collaboration. It includes the delivery of content via Internet, intranet-extranet (LAN/WAN), audio- and videotape, satellite broadcast, interactive TV, and CD-ROM. I prefer the last definition because of its broadness. The "e" in e-learning stands for electronic and thus all forms of learning that involve electronic components should be considered to be e-learning in the broadest sense; obviously e-commerce mainly refers to commerce conducted via electronic networks, and e-learning therefore has strong ties with communication networks. Because computers no longer exist without networks, however, these stand-alone learning applications will eventually cease to exist. For instance, today, even the simplest CD-ROM courses contain links to the Web.

Instructor-Led Training (ILT) This term often refers to traditional classroom training, in which an instructor teaches a class to a room of students (Learning Circuits Glossary, 2003). With the rise of virtual classes, ILT can also be conducted using WBT or e-learning platforms. Teleconferencing software, for instance, can be adapted to support ILT.

Web-Based Training (WBT) The delivery of educational content via networks such as the Internet, intranets, or extranets. Web-based training is characterized by links to other learning resources including references and supporting material. Moreover, communication facilities such as e-mail, bulletin boards, and discussion groups are also often included. WBT may also be instructor-led, that is, a facilitator provides course guidelines, manages discussion boards, delivers lectures, and so on. Nonetheless, WBT also retains the benefits of computer-based training. Web-based training is considered a synonym of Web-based learning (Learning Circuits Glossary 2003).

According to *ELearners Glossary* (2003), WBT learning content is delivered over a network and may either be instructor-led or computer-based. The term WBT is often used as a synonym for e-Learning, but the term *training* implies that unlike education, this type of learning takes place on a professional or corporate level.

INTRODUCTION

Although there is widespread interest in the topic, e-government lacks a common definition. The American Society for Public Administration (ASPA) and United Nations (UN) Division for Public Economics and Public Administration have defined e-government as “utilizing the Internet and the World Wide Web for delivering government information and services to citizens” (UN/ASPA, 2001, p. 1). Marche and McNiven (2003, p. 75) define e-government as “the provision of routine government information and transactions using electronic means, most notably those using Internet technologies.” The U.S. General Accounting Office (2003, p. 1) has also operationalized e-government as referring to “the use of information technology (IT), particularly Web-based Internet applications, to enhance the access to and delivery of government information and services to citizens, to business partners, to employees, and among agencies at all levels of government.” Finally, e-government is often summarized as a process revolutionizing the business of government through the use of information technology (IT), particularly Web-based technologies, which improve internal and external processes, efficiencies, and service delivery.

WHAT E-GOVERNMENT IS AND HOW IT IS USED

E-government has evolved from the IT revolution, particularly the proliferation of the World Wide Web. Information technology in government has long been acknowledged as a method for improving efficiency and communication (Kraemer & King 1977; Norris & Kraemer, 1996). The advent of the Internet has led to developments such as electronic mail (e-mail) that have had profound organizational consequences through the perceived erosion of limitations such as time and geography (Rahm, 1999). The main concerns of e-government move beyond the benefits of automating processes and employing new public information technologies and concentrate more on reinventing processes to exploit fully the potential of information technology. E-government involves government to citizen (G2C), government to government (G2G), government to

business (G2B), and government to employee (G2E) interactions.

According to some proponents of e-government, it is more than just a shift in communication patterns or mediums. Theoretically, e-government involves a transformation of the organizational culture of the government. According to Fountain (2002), the cultural transformation that can be achieved through e-government resides in the elimination of redundancy and duplicity of service provision. These shifts in culture are not without difficulty, however. To reorient government culture successfully away from the stovepipes and limited integration and interoperability, data must be shared both vertically and horizontally. By creating a distributed data environment, the system will create winners and losers in terms of control over data. This battle, both political and bureaucratic, will hinder the cultural shifts associated with the promises of e-government.

Despite the issues associated with cultural reorientation, recent authors argue that information technology facilitates new governmental structures and parameters as demanded by citizens and businesses (Heeks, 1999; Ho, 2002; Osborne & Gaebler, 1992). These demands require services that cut across traditional departmental and agency lines, which in turn require government to improve communication and interaction (Alexander & Grubbs, 1998). These new requirements, which fundamentally alter the nature of government, are made possible through the strategic use of information technology. As Fountain (2001) noted, the reinvention process requires overcoming the rigidities and limits of traditional bureaucracy. Specific objectives may include the centralization of public data and the improvement of internal processes and communications (Alexander & Grubbs, 1998). This delivery of services and information also involves the integration of government networks and databases to allow for cross-agency communication and interaction (Moon, 2002). Again, the turf issues associated with the cultural context of government may preclude some of these efforts from reaching maturation. However, the impact of the information era in government can be witnessed in the increasing governmental movement to Web-based information, services, and transactions, as evidenced by recent national surveys (ICMA, 2002; West, 2000). Before looking

at specific data about the expansion of e-government in the United States, we examine the history of federal legislation regarding public information technology and e-government.

HISTORY OF E-GOVERNMENT AT THE U.S. FEDERAL LEVEL

The U.S. groundwork for e-government at the federal level was laid in the 1980s. The Paperwork Reduction Act of 1980 (PRA) mandated an information resources management (IRM) approach to federal data, thereby for the first time establishing a single policy framework for information resource management at the federal level. The director of the Office of Management and Budget (OMB) was given responsibility for developing an IRM policy and for overseeing its implementation. A major revision of the PRA in 1995 mandated strategic planning for IRM.

At the same time this administrative structure was created, the infrastructure for the Internet was being developed. ARPAnet, a network project of the Department of Defense, had been implemented in 1969, uniting some 23 defense-related military, university, and research laboratory sites by 1973. It was the funding of NSFNet by the National Science Foundation in 1986, however, that really marked the beginnings of the modern Internet. This long-haul backbone network was placed under a cooperative agreement with IBM, MCI, and Merit Network, Inc., the following year and by the end of 1987, there were 10,000 Internet hosts. By 1989, there were 100,000. By the time Tim Berners-Lee developed the World Wide Web in 1992 and Mosaic software was released to surf the Web, the number of Internet hosts exceeded 1 million. One of these was the server, which housed the first White House home page, launched on the Web in 1992.

Up to 1992, access to the Internet backbone was limited by the NSF's Acceptable Use Policy, which prohibited commercial traffic on the Internet. With the support of Congressman Rick Boucher (D-VA), chairman of the Science Subcommittee of the House Committee on Science, Space, and Technology, legislation was passed, and in November 1992, President George H. W. Bush signed new legislation that repealed the Acceptable Use Policy, replacing it with language that permitted commercial traffic on the Internet backbone. In 1993, federal funding of the Internet ended and the Internet became a private sector entity.

With the full advent of the "Internet Age" in the early 1990s, early efforts that might be seen as part of building e-government centered on educational functions. The Information and Technology Act of 1992 sought to ensure technology development in public education, health care, and industry. It called on NSF to fund efforts to connect K-12 classrooms to the Internet. In 1993, the National Information Infrastructure Act was passed, targeting federal research and development funding to the accelerated development of high-performance computing and high-speed networking services at the university and research laboratory level.

An important part of the administrative background of e-government in the early to mid-1990s was the National Performance Review (NPR) created March 3, 1993, under

the leadership of Vice President Al Gore, himself a strong technology advocate. NPR reflected the Clinton administration's emphasis on information technology as a tool to reform government. Its report, *Creating a Government That Works Better and Costs Less: Reengineering Through Information Technology*, was an important document of the "reinventing government" mandate. This administrative movement originated with a focus on traditional forms of decentralization, devolution, and privatization. "Reinvention" advocates quickly came to see, however, that e-government was a major reform thrust facilitating and implementing their own goals of a results-oriented, client-centered, market-reliant approach to government. In 1993, the Government Information Technology Services Board was created to help implement NPR in information technology areas.

As the momentum for e-government grew, so did awareness of a major impediment: the skew of access to the Internet toward the well-to-do, and lack of access for America's "have-nots." The Commerce Department's 1994 report, *Falling Through the Net*, brought public attention to the issue of the "digital divide." In response, the Telecommunications Act of 1996 provided for a Universal Service Fund fee (a telephone tax, also known as the "e-rate" fund or fee), part of which the Clinton administration used to provide modem-based Internet access to schools, libraries, Indian reservations, and other "digital divide" target groups. By the end of the decade, however, the digital divide problem had receded due to falling hardware and software prices, making Internet access affordable to the great majority of citizens.

Some credit must also be given to another Clinton administration initiative, openness in government. The Electronic Freedom of Information Act Amendment of 1996 (EFOIA) extended the right of citizens to view executive agency records to include access to electronic formats and online opportunities for access information.

Also in 1996 came a piece of legislation that provided the basis for centralizing in the OMB the authority to enforce implementation of e-government (as well as other IT practices) across the federal government. The Clinger-Cohen Act of 1996 (originally named the Information Technology Management Reform Act of 1996, an amendment to the Paperwork Reduction Act of 1980) established a chief information officer (CIO) in every agency, making agencies responsible for developing a plan that relates IT planning with agency missions and goals. The oversight role of the director of the OMB was strengthened, and later, when e-government became a priority, the existence of the CIO strategic planning structure was an important element facilitating e-government implementation at the federal level.

A variety of agency-centric developments extended e-government in the late 1990s. In 1997, the U.S. Department of Agriculture became the first agency to engage in e-rulemaking, soliciting Web-based comments on rules for organic foods. This initiative won the 1998 Government Technology Leadership Award and became the basis for one of the major projects of the e-government efforts of the current Bush administration (see the President's E-Government Strategy, available at <http://www.whitehouse.gov/omb/inforeg/egovstrategy.pdf>). The 1998

Amendments to the Rehabilitation Act required federal agencies to make their information technology and electronic information available to people with disabilities. The IRS Restructuring and Reform Act of 1998 promoted electronic filing of tax returns, requiring the IRS to establish that all forms, instructions, publications, and other guidance are available via the Internet. It also provided for taxpayer electronic access to their accounts by 2006.

In some ways, the official “start” of federal e-government might be traced to the Government Paperwork Elimination Act of 1998 (GPEA), which authorized the OMB to acquire alternative information technologies for use by executive agencies; support for electronic signatures; electronic filing of employment forms, with a deadline set for most forms to be in place by October 21, 2003. The GPEA was the legal framework for accepting electronic records and electronic signatures as legally valid and enforceable and also represented congressional endorsement of the e-government strategy (Fletcher, 2002).

In a Presidential Memo of December 17, 1999, titled *Electronic Government*, President Clinton endorsed the concept of a federal government-wide portal (later to be *FirstGov.gov*). In 2000, the President’s Management Council adopted digital government as one of its top three priorities. On June 24, 2000, President Clinton made the first presidential Internet address to the nation, again calling for establishment of the *FirstGov.gov* portal. *FirstGov.gov* was launched September 22, 2000, as a Clinton management initiative. It is the official U.S. government portal, designed to be a trusted one-stop gateway to federal services for citizens, businesses, and agencies. At launch, it was a gateway to 47 million federal government Web pages. *FirstGov.gov* also links to state, local, District of Columbia, and tribal government pages in an attempt to provide integrated service information in particular areas, such as travel. The Office of Citizen Services and Communications, within the General Services Administration, manages *FirstGov*.

In Election 2000, both candidates (Gore and Bush) advocated digital government concepts. After the election, President Bush made e-government one of his central management reform themes (although opposing most “digital divide” funding advocated by Clinton and Gore). The President’s Management Agenda, issued in August 2001, committed the Bush administration to five major management objectives, one of which was electronic government.

In June 2001, the OMB created the position of associate director for Information Technology and E-Government. This gave the OMB a key point of contact to force higher priority to IT initiatives, particularly the goal of creating a citizen-centric government. In essence, this position had a mandate to provide leadership to all federal IT implementation, including a special emphasis on e-government. The first incumbent was Mark Forman, who quickly took strong actions to implement e-government throughout federal agencies. On July 25, 2002, the first chief technology officer (CTO) for the federal government was appointed, responsible for overseeing implementation of e-government policies. The first incumbent was Casey Coleman, heading up the General Services Administration’s Office of Citizen Affairs.

Table 1 Overview of U.S. Federal E-Government “Quicksilver” Projects

Government to Citizen (G2C)

- USA Service (GSA)
- EZ Tax Filing (Treasury)
- Online Access for Loans (DoEd)
- Recreation One Stop (Interior)
- Eligibility Assistance Online (Labor)

Government to Business (G2B)

- Federal Asset Sales (GSA)
- Online Rulemaking Management (DOT)
- Simplified and Unified Tax and Wage Reporting (Treasury)
- Consolidated Health Information (HHS)
- Business Compliance One Stop (SBA)
- International Trade Process Streamlining (Commerce)

Government to Government (G2G)

- E-Vital (SSA)
- E-Grants (HHS)
- Disaster Assistance and Crisis Response (FEMA)
- Geospatial One Stop (Interior)
- Wireless Networks (Justice)

Internal Effectiveness/Efficiency (Government to Employee [G2E])

- E-Training (OPM)
- Recruitment One Stop (OPM)
- Enterprise HR Integration (OPM)
- Integrated Acquisition (GSA)
- E-Records Management (NARA)
- Enterprise Case Management (Justice)

The OMB issued the cornerstone document, *E-Government Strategy*, on February 17, 2002. This document set forth Bush administration e-government principles: citizen-centric, results oriented, and market based. It also called for increased cross-agency data sharing. Some 34 specific projects were identified for funding, including those in the “Quicksilver Initiative” announced in October 2001, as noted in Table 1.

Among other recent developments in e-government at the federal level has been the implementation of e-procurement. The GSA and OFPP (Office of Federal Procurement Policy), with involvement from the Department of Defense, National Aeronautics and Space Administration, and National Institutes of Health, advanced e-procurement by establishing Past Performance Information Retrieval System (PPIRS) to give online access to past vendor performance records in 2002. Another development is the Dot Kids Implementation and Efficiency Act of 2002, passed in December 2002. This act created a new domain, like .com and .edu. Every site designated .kids will be a safe zone for children and will be monitored for content, for safety, and all objectionable material will be removed.¹

The Electronic Government Act (EGA) of 2002 was passed by Congress November 15, 2002, and signed by

¹ Many civil liberties proponents have criticized this act as allowing government censorship, thereby reducing transparency.

the president on December 16, 2002. The act was sponsored by Senator Joe Lieberman (D-CT). It is intended to promote e-government in all federal agencies. The EGA establishes an Office of Electronic Government within the OMB. The head of this office is to be appointed by the president and is to report to the OMB director. In essence, this formalizes the administrative setup established by the OMB in 2001 under Mark Forman. It requires regulatory agencies to publish all proposed rules on the Internet and to accept public comments via e-mail as part of "e-rulemaking." All information published in the Federal Register must also be published on the Web. The federal courts must publish rulings and other information on the Web, and there are numerous other provisions. The EGA makes \$45 million available for e-government projects in the current fiscal year 2003 and \$345 million over 5 years. (This compares with \$5 million for Forman in fiscal year 2002.)

Clearly, the legislation and mandates of the U.S. federal government indicate the importance of e-government. Other countries have even more sophisticated laws and procedures to guide e-government adoption. For example, Singapore has developed long-range strategic plans for e-government, incorporating the eCitizen Center as the one-stop shop for all G2C interactions. The United Kingdom also demonstrates one of the highest levels of executive commitment to e-government. The Office of the E-Envoy has been created to oversee the transition to e-government for all services by 2005. Many other examples from around the globe further demonstrate the shift toward e-government.

E-GOVERNMENT ADOPTION IN THE UNITED STATES

Following the detailed review of U.S. federal commitment to e-government, it is important to assess the levels of e-government adoption at the local government level, as well as to illustrate usage by citizens. This description focuses on the United States; however, other sources provide more international coverage (Demchak, Friis, & La Porte, 2001; UN/ASP, 2002). By analyzing data obtained from the 2002 E-Government Survey conducted by the International City/County Management Association (ICMA), the adoption rates of e-government at the local level can be assessed. The survey was conducted to evaluate the involvement of local governments in e-government activities, including Web site development, electronic services, geographic information systems, changes associated with e-government adoption, and barriers preventing such adoption. The survey was sent to 7,844 municipal and county governments with populations over 2,500; 4,123 surveys were completed and returned, a response rate of 52.6%.

For the purposes of this analysis, the municipalities and counties have been divided into three population categories. Small jurisdictions contain less than 50,000 inhabitants. Medium jurisdictions contain 50,000 to 249,999 inhabitants, and large jurisdictions contain 250,000 or more. The responding jurisdictions represent all four geographic regions, Northeast, North-Central, South, and West, as defined by the ICMA.

The presence of local government Web sites, as gathered during the ICMA survey, is significant, with 74.2% of responding counties and municipalities having an official Web site. In terms of the municipalities, 71.1% of small jurisdictions, 97.9% of medium jurisdictions, and 100% of large jurisdictions have official Web sites. Furthermore, 58.8% of small counties, 92.8% of medium counties, and 98.4% of large counties have an official Web presence. The high rate of Web presence demonstrates the movement of local governments to the e-government model; however, static Web presence is not sufficient for true e-government.

To assess more effectively the required interactive component of e-government, the presence of Web-enabled transactional processes via governmental Web sites was analyzed. The ICMA survey queried respondents about several categories of transactions, including online payments of taxes, utility bills, fines and fees, form completion and submission, business license application and renewal completion and submission, online requests for records, online delivery of records, online requests for services, online registration for facility usage, online voter registration, online property registration, downloadable forms, and online communication with elected and appointed government officials. In the aggregate, few local governments are using Web-based transactions. Table 2 demonstrates the offering of transactions by municipalities, based on the population categories previously denoted.

The positive effect of size on the rate of transaction offerings is important to note. For example, only 1.8% of small municipalities offer online payment of taxes, whereas 5.3% of medium and 24.0% of large municipalities offer the same online service.

A similar trend regarding the increased offering of Web-based transactions based on population size is found in the counties. Table 3 highlights the percentage of counties offering specific transactions, by population grouping.

Although electronic transaction offerings are limited in local governments, there is increasing citizen and business demand for such Web-based services. A national survey conducted by the Pew Research Center during September 2001 demonstrates the widespread usage of governmental Web sites and their interactive services. The 2002 Pew Internet and American Life Project indicates that 58% (68 million people) of U.S. Internet users have accessed at least one governmental Web site (Larson & Rainie, 2002). Furthermore, 68% of Internet users indicate that government Web sites improve their interaction with at least one level of government. Approximately 63% of those surveyed have downloaded government forms, 16% have filed taxes online, and 12% have renewed automobile registrations online. The 2002 Pew Internet and American Life Project highlights the citizen interest in and use of the Internet to enhance standard interactions with government.

Although governments' use of the Internet is increasing, there is still a significant lag time compared with private sector adoption of new technologies. Both structural inertia and risk aversion, commonplace in the public sector, foster governments that are slow to adopt and

Table 2 Percentage of Transactional Offerings by Municipalities, by Population Grouping

Service	Small Municipalities (%)	Medium Municipalities (%)	Large Municipalities (%)
Online payment of taxes	1.8	5.3	24.0
Online payment of utility bills	3.0	13.5	15.4
Online payment of fines and fees	2.1	12.4	23.1
Form completion and submission	7.7	16.1	33.3
Business license application/renewal completion and submission	4.4	8.0	14.8
Online requests for records	26.4	31.9	38.5
Online delivery of records	16.2	21.4	25.9
Online requests for services	31.3	41.0	44.4
Online registration for facility usage	12.1	20.3	36.0
Online voter registration	1.5	1.7	9.5
Online property registration	2.1	5.0	5.3
Downloadable forms	50.2	75.3	92.0
Online communication with elected and appointed officials	68.7	84.2	96.0

implement new technologies. The inherent tension between the need for reliability and accountability contrasted with reliance on maintaining organizational status quo leads to the increased adoption lag time in governmental organizations. For government information technology adoption and implementation, the inertia that exists within the public sector means that organizations are often less willing and able to engage new technologies (Bretschneider, 1990). This inability to adapt to the rapidity of the information age creates a disconnect between the movement toward e-government and the need to consider all citizen requirements and needs. The most common example of this problem is demonstrated by the creation of governmental Web sites that are organized by administrative structure rather than by service

orientation, which is more intuitive to constituents. To understand more fully the issues associated with e-government adoption, including challenges and benefits, it is crucial to understand the theory and typology associated with e-government.

THEORY AND TYPOLOGY OF E-GOVERNMENT

Using the theoretical frameworks of e-government of decentralization–democratization and normative–dystopian, as outlined by Garson (1999), one can begin to assess the benefits and challenges associated with e-government. The decentralization–democratization

Table 3 Percentage of Transactional Offerings by Counties, by Population Grouping

Service	Small Counties (%)	Medium Counties (%)	Large Counties (%)
Online payment of taxes	9.2	25.0	40.0
Online payment of utility bills	1.0	8.2	9.4
Online payment of fines/fees	1.9	9.2	11.1
Form completion and submission	5.6	13.6	21.1
Business license application/renewal completion and submission	1.9	5.2	16.1
Online requests for records	23.1	43.2	65.0
Online delivery of records	12.0	35.9	53.6
Online requests for services	7.6	17.9	25.9
Online registration for facility usage	6.7	10.6	21.4
Online voter registration	4.7	7.0	7.4

Downloadable forms	42.1	72.6	87.7
Online communication with elected and appointed officials	63.6	77.1	82.1

framework of e-government revolves around the progressive nature of technology and highlights governmental advances resulting from e-government. Essentially, decentralization–democratization highlights the fundamental restructuring of government interactions with its constituents through the strategic use of information technology, that is, greater efficiency, effectiveness, and increased participation. On the other hand, the normative–dystopian framework uses the high rates of conflict and failure associated with information technology applications and offers a pragmatic, even skeptical view of e-government. The normative–dystopian framework is associated with the notion that e-government is another medium for communication between constituents and the government; however, it does not support the concepts of reinvention of government often associated with e-government. Although neither framework can be considered fully descriptive, taken together they provide a useful delineation of the theoretical literature on e-government.

Decentralization–democratization theory is the traditional view of e-government, beginning with Bozeman and Bretschneider's seminal article in 1986, which highlights the transformational, progressive nature of technology adoption in the government sector. Furthermore, Reschenthaler and Thompson (1996) contended that the power of public information technology, a prerequisite for e-government, lies in its ability to level the playing field for all sizes and types of governments. They viewed the basis for reengineering the business of government, refocusing its work on the needs of the citizens, and returning government to its core functions residing under the technology umbrella.

Another decentralization–democratization approach for examining the e-government model involves comparing and contrasting traditional bureaucratic design with the evolved e-government design. The traditional bureaucratic model of public service delivery (the Weberian model) focuses on specialization, departmentalization, and standardization (Ho, 2002). This traditional model has created departmental “silos” that resist functioning across agency boundaries, in the name of equitable and efficient governmental interactions. In the 1990s, however, the reinventing government movement sought to shift the core focus of government, moving from departmentalization and centralization to citizen-centric decentralization (Osborne & Gaebler, 1992).

The e-government paradigm, which emphasizes coordinated network building, external collaboration, and customer services, is slowly replacing the traditional bureaucratic paradigm and its focus on standardization, hierarchy, departmentalization, and operational cost-efficiency (Ho, 2002). In this view, the development and deployment of technology networks, shared databases, and Web-based interactions are the necessities that will facilitate seamless integration of government services. Although this shift to the e-government paradigm has not been fully realized, the Internet is a key enabler to this transformation because it provides government with the ability to use technology to impact customers directly, instead of simply reengineering internal processes (Scavo & Shi, 1999).

Decentralization–democratization proponents use e-government adoption rates as proxies for gauging the success of e-government. As the adoption and implementation rates increase, e-government technologies will enjoy increased legitimacy (Fletcher, 1999). Increasing citizen and business demand for e-government applications, which have permeated to the local government level, are central to greater adoption across all levels of government (Norris, Fletcher, & Holden, 2001). Response to the changing environment with improved service delivery, increased efficiency and reduced costs is key to e-government success (West, 2000). Beyond the optimistic prospects of the democratization–decentralization theorists, there is a concrete reality of governmental technology and e-government failures, which are explained in the normative–dystopian framework.

Issues of privacy, security, and the digital divide fall under the normative–dystopian model, which offers a critical approach to evaluating e-government. This view entertains concepts of dehumanization and isolation, resulting from the proliferation of information technology. The normative–dystopian theory addresses ethical issues that surround e-government. Recent concerns about the “digital divide,” the technology gap that exists between distinct groups in the United States, highlight the issues associated with the move to e-government as a mode of service delivery because of the potential consequences for unconnected or underserved populations. Several studies note racial, regional, educational, gender, and age disparities among Internet users and technology owners (e.g., Norris, 2001; Novotny, 1998). These gaps are of great concern for public administrators, who must serve efficiently, effectively, and equitably to fulfill their public charge.

Using the normative–dystopian framework, Bovens and Zouridis (2002) examined the inherent problems associated with the shift toward an e-government paradigm. The emerging emphasis on information technologies as the medium for citizen interaction with government fundamentally alters the role of the bureaucrat. The traditional Weberian model uses street-level bureaucrats to interact with citizens and to determine the proper services and service levels to assist these citizens (Lipsky, 1980). This method allows for expertise, judgment, and practicality to be engaged in the decision-making process. In the e-government model, computer programs are used to interface with clients, assess eligibilities, and decide on proper levels of service (Bovens & Zouridis, 2002). This model suggests that the street-level bureaucrats are losing their discretionary power, which can have deleterious effects on the clients. Bovens and Zouridis (2002) use the normative/dystopian framework to highlight the potential arbitrariness and threats to the legitimacy of governmental actions at the street level in the e-government model. Both frameworks for assessing e-government are valuable and valid; however, the rising citizen demand and increasing governmental use of e-government components indicate that e-government will only progress.

Stages 1–5 of E-Government

Several models have been developed to explain the progression of e-government (Layne & Lee, 2001; Moon, 2002). Nonetheless, the stages or iterations of

e-government do not follow a linear progression. Often, e-government applications are developed for utility, an ad hoc approach, instead of according to a master project plan, a systematic approach. For example, one local government may offer the ability to pay property taxes online through an application service provider but still have a basic informational Web site without interactive enhancements. Furthermore, the various models to be described offer a broad categorization of each stage or iteration. These are arranged in a continuum in which governments can be within the same stage while having diverse service capacities or functionalities.

According to the UN and ASPA (2001), there are five main stages of e-government, which are precipitated by the recognition that some form of presence exists for the given locality. Stage 1, the emerging Web presence, presents static information and is often considered to be "brochure-ware" (UN/ASPA, 2001, p. 16). The main goal of this stage is to provide an online dissemination of general information about the government. Often, a Stage 1 Web site visually represents the "stovepipes" that exist within agencies and does not allow for continuity across various departmental pages.

The association of the Web site denotes enhanced Web presence, Stage 2, with information on services; however, it is still organized by departments. This stage often offers e-mail as a method of two-way communication. It offers limited communication and greater information about the services of the government but is not consistent with the citizen-centric approach that has been advocated for e-government (UN/ASPA, 2001, p. 17; Layne & Lee, 2001; Moon, 2002).

Stage 3, interactive Web presence, does offer some of the citizen-centric methods as advocated by e-government proponents (UN/ASPA, 2001, p. 18). Information is presented in intuitive groupings, rather than by departmental or agency association. Often, portals are used as a single point of entry into various departments and service areas. Major groupings in the portal design might include business, new resident, seniors, children, or other standard groups. Subsequently, end users would control their Web destination based on the grouping they select. Each sublevel under the group headings offers commonly requested services, information, and assorted items of interest to the particular group. Again, a specific agency or department does not designate the services and information contained within each group; they are offered as a bundle of interests to the target population. Stage 3 sites also have downloadable forms with online submissions, e-mail contact for various governmental employees, and links to other governmental Web sites.

Stage Four, transactional Web presence, allows secure online transactions (UN/ASPA, 2001, p. 19). User needs dominate the organization of this Web presence and the information presented is dynamic. Potential transaction offerings include online payments of taxes, utility bills, fines and fees, form completion and submission, business license application and renewal completion and submission, online registration for facility usage, online voter registration, and online property registration. As evidenced by the ICMA 2002 E-Government Survey, less than

15% of responding counties and municipalities offer these services. Furthermore, only 4.6% of the respondents offer online payments.

The final stage, Stage 5, involves seamless government. This stage represents an ideal, and no real example of its application is available. Stage 5 ideally involves a cross-agency, intergovernmental approach that only displays one front, regardless of service area (UN/ASPA, 2001, p. 20). For example, a portal may offer a compendium of local, state, and federal government services without user recognition of what level of government provides the service. A Stage 5 site would offer vertical and horizontal integration and would require true organizational transformation with respect to administrative boundaries (UN/ASPA, 2001, p. 20).

Drawing on the UN and ASPA typology, current literature indicates that the majority of local governments are in Stage 2, with enhanced Web presence. Moon's (2002) analysis of 2000 ICMA E-Government Survey indicates that a majority of municipalities with populations over 10,000 are not offering transactional Web sites. Furthermore, based on the 2002 ICMA E-Government Survey, only 62 (1.7%) municipalities offer online payment of taxes, 113 (3.1%) offer online payment of utility bills, and 91 (2.5%) offer online payment of fines and fees. The percentages for counties are only slightly higher, with 69 (16.3%) offering online payment of taxes, 17 (4.0%) offering online payment of utility bills, and 21 (5.0%) offering online payment of fines and fees. More robust transactional services can be found at the state and federal levels of government, as would be expected.

Using Ho's (2002) methodology for assessing municipal Web sites, a different dimension of e-government typology can be discerned. He centers on three primary orientations designed to demonstrate the shift from the Weberian bureaucratic model to the e-government paradigm. The first orientation is administrative-oriented Web sites, organized along departmental lines, which represents the traditional bureaucratic paradigm (p. 437). The second orientation is information-oriented, crossing departmental lines to provide a one-stop shopping experience to the user (p. 437). The final orientation is user-oriented, which categorizes information in intuitive groupings that offer end user control and rapid access to predetermined information (p. 437). This orientation also crosses traditional departmental lines in an attempt to provide an all-encompassing experience to the end user. Ho's analysis of the 55 largest municipalities' Web sites indicates that a majority has moved toward varying degrees of user-orientation (p. 438).

Further alternative approaches to defining the e-government typology use various levels of communication, applications of technology, and citizen participation in democratic forums to define its stages. One example of this approach is found in Moon's typology (2002), as adopted from Hiller and Bélanger. This framework also uses five stages, but its focus is on the communications between various stakeholders, including government to government (G2G), government to employee (G2E), and government to citizen (G2C). Stage 1 involves information dissemination and uses basic Web authoring tools and

bulletin boards as methods of communication (p. 426). Two-way communication, utilizing e-mail and electronic data exchange (EDI), is found in Stage 2. Stage 3 highlights service and financial transactions, along with technologies such as EDI, electronic filing systems, digital signature, and public key infrastructure. Stage 4 centers on the concepts of vertical and horizontal integration of the technologies found in Stages 1, 2, and 3. It is similar to Stage 5 of the UN/ASPA model in its seamless outward appearance. Political participation is the mainstay of Stage 5 in moon's typology. It involves online voting, e-democracy, and e-participation. Few local governments have evolved to Stage 5, evidenced by the fact that only 2.1% of respondents to the 2002 ICMA E-Government Survey are using online voter registration. This alternative approach to the typology of e-government still acknowledges the importance of the user's view of e-government but extends the model to include digital civic engagement and enhanced electronic democracy.

The various models of e-government allow for broad comparisons across the various governmental Web sites, using similar benchmarking criteria. Such comparisons are useful to the extent that they can highlight the critical success factors associated with individual experiences, which can be generalized to the general population. One of these critical success factors is training for e-government. Issues of training are directly related to the need to move along the e-government continuum because training fosters greater understanding of the processes and applications and provides a method of eliciting user support. By examining the current training practices of governments with regard to e-government, one can begin to understand the need to bridge e-government expansion and training in order to create a holistic, enterprise approach.

SECURITY AND PRIVACY

Issues of security and privacy in the post-9/11 era are of grave concern to the majority of government constituents. Yet only a small minority of governments are actively addressing security and privacy issues. According to the 2002 ICMA E-Government Survey indicates that 15% of the survey respondents have or will make significant changes to their existing security practices as a result of 9/11. Additionally, over 10% indicate that they have removed information from their Web site for security reasons. Clearly, the issues of security and privacy are more salient than ever and governments must address constituent concerns if e-government is to achieve high levels of adoption and usage.

Security

Although security is important to citizens, the majority of security literature for the public sector revolves around intraorganizational security. In terms of the complexity of security, the issue is really one of trade-offs. For example, higher levels of security required increased costs, lower levels of privacy, and decreased functionality. Despite the trade-offs that must be made, attention to security for public sector technology is at an all-time high. In fact,

leading technology think-tanks, such as the Harvard Policy Group, and federal agencies have produced major reports outlining the critical components of public sector IT security. Based on the work of these organizations, this article offers a high-level overview of security policy best practices.

Given the increasing numbers of computers, networks, hardware, and software in the public sector, it is critical for a security policy to be developed to protect the organizational investments. As such, the security policy should state that information resources are essential organizational assets and should be protected. Furthermore, top management must be involved in the security process to ensure adequate support and funding (see GAO, 1998; Harvard Policy Group, 2001).

The security policy should mandate that the team adopt standards for availability, confidentiality, authentication, integrity, and repudiation. These standards will be employed enterprisewide. It should recommend practical risk assessment procedures that create goal alignment between security concerns and organizational needs. Additionally, the security policy should security training mandate for all employees and should hold program and business managers accountable for breaches in security.

The policy should mandate that risk be managed on a continual basis via various security methods. One of the methods is physical security. The policy will include standard security measures such as locked doors and use of identification badges for staff and visitors. The policy should also mandate simple computer policies, such as locked terminals with password-protected screensavers, mandatory password rotation, consent to monitoring, and installation of antiviral software on all department computers. For example, one password policy may be that each password must be eight characters long and include one special character. The passwords must be changed every 90 days. At no time should passwords be written down or shared among employees, one of the most common security lapses.

The security policy should establish a central group to carry out departmental security training and enforcement. This group should be designated funding and staff sufficient to cover its needs. Another strategy for inclusion in the policy is enhancement of staff skills, both generic security measures and technical security advancements. All security policies established by the central group will be codified and included on the employee Intranet. Beyond placement on the Intranet, the security policies will be reviewed individually at group meetings to ensure that users understand risks and methods for combating them.

Finally, the policy should indicate that the central group responsible for security should use constant monitoring and frequent attack methods to ensure that security is being upheld. By monitoring the factors that contribute to security breaches, the team can create alternative policies to mitigate problems within the organization. Finally, the team should employ current security monitoring devices to prevent undetected intrusion. These devices must be proven before purchase, but there should not be a lag in technology between the public

sector and private sector counterparts. It is evident that security is one of the highest priorities of the public sector. As such, a given security policy should lay the foundation for the establishment of a security team, as well as articulate guidelines for achieving high levels of security.

Privacy

Moving into the privacy arena, there is significant citizen concern about establishing and maintaining privacy rights. In the 1950s, the Freedom of Information movement, spurred on by McCarthyism, mobilized people to protect their right to know about governmental affairs, in particular, information collected by the government about the individual. The Freedom of Information Act was passed in 1966, but it had little impact because of lack of compliance regulations and lack of punitive structures. During the mid-1970s, the Freedom of Information Act was amended to address some of the grievances, such as limiting costs for access to information, and attaching penalties for noncompliance. By 1996, the act had been amended again to encompass electronic information and transmission. This amendment requires the agencies to offer electronic copies of traditional paper-based documents. The lack of real resources to complete the tasks required in the legislation has significantly reduced the value of the amendment, however. The Freedom of Information Act and Electronic Freedom of Information Act created a venue for obtaining information about government operations, but they also brought to light issues of personal privacy rights, which are the common context of today's privacy conversations.

Attention to privacy in terms of public sector information technology often involves Web site privacy and its relationship to website visitors. As such, high-level guidelines for Web site privacy policies are offered, based on a survey of best practices literature (see Berman & Bruening, 2001; Kent & Millett, 2002; O'Neil & Dempsey, 2000). First, the policy should state that the public sector organization is open to the public and its Web site is a vehicle for providing the desired openness and transparency as sought by citizens. It also should note that the organization only uses collected personal information for the purposes stated prior to collection. The policy should also indicate that information collected will not be disclosed, unless mandated by law.

The policy must define "personal information" such as name, address, e-mail, and so on. In terms of collection of personal information, the policy should indicate that information collection is limited to the requirements of the law and will not be collected for superfluous reasons. Furthermore, the individuals will be apprised as to how their information will be used prior to collection. As previously noted, personal information will not be shared or disclosed unless authorized by law. Individuals will also be allowed to access their personal information to ensure its correctness. The organizational policy must also state that security measures are strictly enforced in order to ensure the security of personal information. Finally, the privacy policy should note that electronic and nonelectronic information are afforded the same levels of privacy protection.

In terms of Web site collection of information, the privacy policy should note the types of information collected, as well as the manner of collection and storage. For example, if the Web site automatically tracks incoming Internet domains, browsers, operating systems, pages visited, or other such items, the users of the Web site should be informed about this collection via a link to the privacy policy. In addition, if the Web site collects "cookies," the user should be informed. Cookies are text files stored on a user computer to enable user recognition by the Web site. The Web user should be informed that their Web browser can be configured to refuse cookies or to notify the user when a site attempts to send a cookie.

Finally, the privacy policy developed by the subcommittee should mandate the use of privacy impact assessments (PIAs) for all technology projects. PIAs are designed to help the department determine whether new technology projects or initiatives meet set privacy requirements. PIAs also help to mitigate risks to privacy by identifying alternative solutions. PIAs involve four basic steps:

1. Project initiation—During this stage, the goal is to determine the scope of the PIA and to adapt the tools provided in the guidelines to the context.
2. Data flow analysis—This involves describing and analyzing the business processes and data flows to identify information transmission.
3. Privacy analysis—This step examines the data flows compared with accepted privacy policies and legislation.
4. Privacy impact analysis report completed—This is a written evaluation of privacy risks, implications, and alternative solutions for risk mitigation.

This model, although time-consuming, allows for standardized decision making about distribution of personal and, potentially, sensitive information.

Clearly, security and privacy are important concerns in the public sector technology arena. They create many challenges for public sector organizations and require significant attention and regulation to appropriately manage them. Regardless of the trade-offs, security and privacy are critical to maintaining citizen trust in government and efforts should be institutionalized in order to address these issues.

CONCLUSION: THE FUTURE OF E-GOVERNMENT

The march toward e-government has not been without setbacks, notably in the areas of universal access and governmental openness. Presidents Bush's 2003 budget proposed to eliminate two critically important community technology programs related to diminishing the "digital divide": the Technology Opportunities Program (TOP) and the Community Technology Center (CTC) initiative. A study by Brown University's Center for Public Policy studied 1,265 federal and state Web sites and found only six% had restricted areas requiring a password to enter. Likewise, the Environmental Protection Agency has removed

risk management plans and other information pertaining to hazardous waste sites from its Web site, citing risk of terrorism outweighing the right of citizens to know hazardous waste risks near their homes, workplaces, and schools.

Nonetheless, the setbacks are far overshadowed by the remarkably rapid expansion of e-government. The Pew Internet and American Life Project, in the Larsen and Rainie (2001) report cited earlier, stated, "The rise of e-government has been one of the most striking developments on the Web" (p. 5). Because of citizen demand for things such as e-access to building permits, dog licenses, and birth certificates, the bandwagon effect for implementing e-government is strong (Moulder, 2001). There is now considerable momentum for government change along the e-government model. Governments are competing to be seen as being on the leading edge, not laggard adopters (Sprecher, 2001).

Many cities are moving away from traditional bureaucratic emphasis on standardization, departmentalization, and operational cost-efficiency, toward the "e-government" paradigm, which emphasizes coordinated network building, external collaboration, and customer services (Ho, 2002). In this way the reinventing government movement is tied to the e-government movement.

Many municipal governments have adopted e-government, but it is still at an early stage and has not obtained many of expected outcomes (cost savings, downsizing, etc.) that the rhetoric of e-government has promised² (Moon, 2002). There has been general progress in online services, privacy policy statements, and standardized navigational features but much less progress in disability and foreign language access. Most agencies used Web for one-way communication with no provision for two-way interaction with citizens (West, 2001). The desire to transcend limited progress is one motivation behind the push for public-private partnerships in support of e-government initiatives (Holmes, 2001).

It is still too early to assess e-government in terms of effect on democracy. Clearly, there are great hopes that e-government will provide new opportunities for widening civic engagement and participation (Milward & Snyder, 1996). In principle e-government increases the reliability and accountability of public organizations, but in Santa Monica, California, home to PEN, one of the first major community computing experiments, whereas city officials were eager to participate in a community computing experiment in its first year, by the sixth year most had ceased participation, citing lack of substance if e-forums and too much "flaming" and personal attacks by a minority of network participants (Docter & Dutton, 1998). The Electronic Government Act of 2002 has now mandated e-rulemaking, a critical aspect of e-democracy, and there are other e-democracy experiments, such as the fact that all hearings and committee sessions of the Michigan legislature are now broadcast in streaming video, live over nine channels. Although e-government may have a much less profound effect on e-democracy than it is already having

² This "rhetoric of e-government" promises cost savings and other benefits, which arguably are not realistic outcomes of e-government.

in the provision of governmental e-services, at the very least new channels of two-way communication between citizens and their government are being enabled.

GLOSSARY

Citizen-Centric A new approach to organization of government information and dissemination of government services that focuses on citizen needs and desires instead of traditional bureaucratic functions. For example, a citizen-centric Web site may combine various services, provided by different departments or agencies, under a common heading based on life events.

E (electronic)-Democracy A new method of engaging citizens in political participation, including e-rulemaking, e-voting, and various means of communication with elected and appointed government officials.

E (electronic)-government A strategy for revolutionizing the business of government through the use of information technology (IT), particularly Web-based technologies, which improve internal and external processes, efficiencies, and service delivery.

E (electronic)-Procurement The online provision of goods and services by government agencies. E-procurement includes online requests for proposal (RFPs), online request for bids (RFB), online bid acceptance, and online monitoring of contracts.

E (electronic)-Services The provision of government services via the Internet, including online information, online forms, online transactions, and online referral processes.

Portal A one-stop, cross-department/business unit, and cross-jurisdictional Web site that serves as aggregation of government services in a given functional area or based on user needs.

"Stovepipe" The traditional orientation of government departments or business units, in which each department or business unit acts independently and autonomously. Lack of integration and interoperability and issues of duplication of efforts characterize "stovepipe" organizations.

E-GOVERNMENT INITIATIVES

Definitions of E-Government

E-government, a contraction of “electronic government,” refers to the use by government agencies of information technologies (such as the Internet) to conduct interactions with citizens, with businesses, and with other arms of the government. E-government initiatives seek to improve delivery of government services to citizens, improve interactions with business and industry, empower citizens through access to information, and improve government management efficiency. E-government can potentially result in less corruption, more transparency, greater convenience, revenue growth, and cost reductions (World Bank Group, n.d.).

General

Traditionally, the interaction between a citizen or business and a government agency took place in a government office. With emerging information and communication technologies, it is possible to locate service centers closer to the clients. Such centers may consist of an unattended kiosk in the government agency, a service kiosk located close to the client, or the use of a personal computer in the home or office.

E-government is analogous to e-commerce, which allows businesses to transact with each other more efficiently and brings customers closer to businesses. E-government aims to make the interaction between government and citizens, government and business enterprises, and interagency relationships more friendly, convenient, transparent, and inexpensive.

U.S. Government-Specific

Within the United States, under the “e-gov” initiatives, e-government is to use improved Internet-based technology to make it easy for citizens and businesses to interact with the government, save taxpayer dollars, and streamline citizen-to-government communications. A major motivator for e-government within the U.S. government was the Government Paperwork Elimination Act (GPEA) of October 21, 1998, which required federal agencies, by October 21, 2003, to provide for the options of (a) electronic maintenance, submission, or disclosure of information, when practicable as a substitute for paper, and

(b) use and acceptance of electronic signatures, when practicable. Implementation of the GPEA provides the management framework for electronic government. Office of Management and Budget (OMB) Memorandum M-00-10, dated April 25, 2000, provides procedures and guidance on implementing the GPEA. OMB’s guidance, in addition to procedural guidance for Paperwork Reduction Act reporting, requires that an agency’s implementation plan relate to strategic information technology planning in the budget process. If an agency needs additional resources to implement the plan, its budget request under OMB Circular A-11 should reflect that need, and agency GPEA reports should address progress in implementing the act and e-government initiatives. The E-Government Act of 2002 builds on the U.S. government’s expanding e-government initiative with a comprehensive framework for information security standards and programs and uniform safeguards to protect the confidentiality of information provided by the public for statistical purposes. The act also assists in expanding the use of the Internet and computer resources to deliver government services, consistent with the principles of a citizen-centered, results-oriented, and market-based government.

The goal of these initiatives is to eliminate redundant systems and improve the government’s quality of customer service for citizens and businesses. E-government does not just mean putting scores of government forms on the Internet. It aims to use technology to its fullest to provide services and information that are centered around citizen groups (E-Gov Web Site: http://www.whitehouse.gov/omb/egov/about_backgrnd.htm).

Examples of E-Government Program Types

There are a number of taxonomies of e-government service types. Some are based on functional relationships (e.g., government to citizen, government to business, government to government, and internal effectiveness and efficiency). Others focus on functional processes content and degree of interaction inherent in the services provided. For purposes of this security discussion, the services provided by e-government program are categorized with respect to functional processes as (a) publishing, (b) interactive processing, (c) transaction processing, and (d) service delivery.

Publishing

Publishing involves simply posting information on a publicly accessible Web site. The primary automated interaction of the public with e-government publishing services is limited to navigation around the Web site. The public should have no ability to modify government Web content.

The major challenge associated with e-government publishing is content management: the process of creating, updating, distributing, and publishing information on a Web site. Content management involves creating a central storage area for files, templates, images, and other material used to build a Web site. Content management templates support conformance of government Web pages to government standards. Content management systems also support review and approval of Web page content being published. Content management processes are also vehicles for periodic review and update of agencies' online information. Content work flow includes the following elements:

- Contribution—Content is written and placed in the Web page.
- Approval—Content is reviewed and approved or rejected.
- Publishing—Content is sent to the live site.

At each step in the work flow, someone must sign off. These sign-offs help to ensure accountability for content. No unauthorized modification of Web site content should be permitted.

To date, most e-government activity has centered on publishing.

Interactive Processing

E-government interactive processing involves private citizens or other user entities reading instructions published on agency Web sites and following those instructions to submit reports, applications, or other service requests (e.g., submit tax returns, apply for licenses or other services, renew licenses, order products or services, or provide notification of address or other status changes). Here, citizens or other private entities need to be able to write and modify some data files with which they are associated on the government Web site. No user entity, however, should be able to read or modify data files associated with another user entity, be able to read or modify data files restricted to agency use, or modify any Web page content (other than that entity's own data) or underlying program. In addition to dealing with content management issues associated with Web-based publication, agencies that host interactive Web sites need to be able to provide citizens and other customers with assurance that privacy, integrity, and binding to the originator will be preserved for information that is submitted to interactive government Web sites. Furthermore, the effective management of an interactive Web site also requires some mechanism for identifying the originator of Web-based reports, applications, and other requests with the information provided by the originator. Inputs to interactive e-government sites should not be permitted without prior completion of the following process:

- Application—The user identifies himself to the agency and requests an interactive account.
- Approval—The application is approved or rejected.
- Credentialing—The agency provides the user with an electronic credential (e.g., personal identification number, password, public key certificate) that can be used to associate information with the possessor of the credential.

Once in possession of the appropriate access credential, a user is able to access an e-government Web site, navigate to the appropriate form, enter the requested information, and submit the form. The Web site should be capable of invoking processes that receipt for the submission, including notification that the submission complied with rules regarding information format and completeness.

Interactive government Web sites are less numerous than sites limited to publication but are becoming more common.

Transaction Processing

Transaction processing includes processing of information submitted via interactive e-government Web sites, providing notification of approval for actions to be taken on the basis of that information, and activation of implementation processes (e.g., billing, payment, licensing, permit issuance, contract awards, invoice approvals, etc.). Transaction processing generally involves distributing data received from users to multiple databases and multiple processes and includes interactions with third parties. This characteristic multiplies the distribution of privacy and integrity mechanisms. It also requires a process for dissemination of the decision notification and any associated authorization information in a manner that binds the content of the notification to identity credentials associated with both the e-government originator and the user recipient. Government-issued interactive access credentials need to include some information that can be used to verify the origin and content integrity of information allegedly received from an e-government source. Cryptographic mechanisms are usually employed for this purpose.

Service Delivery

Service delivery goes beyond the transaction approval component to transaction processing, including the actual execution of actions approved on the basis of e-government interactions. Examples of such actions include acceptance of credit card payments or electronic funds transfers, execution of government payments (e.g., benefits, grants, refunds, or payments for services or products) by electronic fund transfers, and delivery of licenses or permits. Because service delivery can be difficult, expensive, or even impossible to repudiate, assured invocation and effectiveness of source authentication, destination authentication, authentication of any third-party authorization, and verification of the integrity and correctness of the information contained in the service delivery communication are essential.

SECURITY ISSUES ASSOCIATED WITH E-GOVERNMENT

Taxonomies of security issues associated with e-government usually include three to five major elements. Examples of major security categories include confidentiality, privacy, integrity, authentication, authorization, and nonrepudiation. For purposes of this discussion, the taxonomy employed by the E-Government Act of 2002 will be used. The E-Government Act of 2002, Section 3542(B), defines integrity, confidentiality, and availability attributes of security.

Threats to the security of information in an e-government environment can include natural and accidental events (e.g., flooding, fire, storms, human error, environmental problems) and deliberate threats (e.g., sabotage, fraud, information theft, Trojan horses, hacking, viruses, logic bombs). Deliberate attacks may come from criminals, hackers, terrorists, disenchanted employees, curious or mischievous users, journalists, state-sponsored or industrial spies, or state-sponsored or industrial saboteurs. The primary focus of this chapter is on threats and countermeasures affecting remote connections to e-government resources rather than on insider and other threats involving physical access to servers and other storage and processing facilities. It focuses also on the potential for denial, unauthorized alteration, and unauthorized disclosure of information rather than on some of the purposes for which successful compromise of information security can be employed. For example, the focus might be on *potential* for unauthorized access to information regarding an individual (e.g., Social Security numbers and mother's maiden name) rather than the use of that information to commit a crime such as identity fraud.

Availability

The E-Government Act of 2002 defines availability as "ensuring timely and reliable access to and use of information." Availability concerns affect publishing, interactive processing, transaction processing, and service delivery e-government activities. Availability concerns include those resulting from system faults, those intrinsic to the technologies employed to provide e-government services, and malicious activities intended to prevent access to or use of information (denial of service attacks). Although fault-related availability and intrinsic availability concerns are not usually treated as security issues, they can significantly affect access to and use of e-government services, and countermeasures that are employed against denial of service and integrity threats can often mitigate system fault and intrinsic availability concerns.

Fault-Related Availability Concerns

System faults that can affect availability of services include hardware faults, changes in program or data structures due to transients or design errors, and failures in other system facilities that are not computer based. An extensive literature addresses fault concerns (e.g., National Institute of Standards and Technology's [NIST, 1995] *A Conceptual Framework for Systems Fault Tolerance*,

references listed in the *Selected Bibliography of Fault-Tolerant Computing at Hopkins* [Sullivan, 1996], and references listed in the *Bibliography on Byzantine Fault Independence* [Martin, 2004]).

Intrinsic Availability Concerns

Intrinsic availability concerns include obsolescence of storage and recovery mechanisms, deterioration of magnetic media, ephemeral continuity of access channels such as addresses and protocols, and loss of facilities due to physical damage or support infrastructure problems. Continued availability may require not only maintenance of backups and archives, but also migration to new media and formats for the backups and archives. Service availability concerns include reduced responsiveness of processes where provision is not made for, e-approval by alternate authorities (e.g., deputies, acting managers or functionaries) in the temporary actual or virtual (non-functioning automation component) absence of an approving authority resultant processing delays cannot be mitigated by "hand carrying" or other expediting mechanisms available for paper-based processes.

Obsolescence of storage and recovery mechanisms is a concern that is likely to become more acute as paperless records and transactions begin to predominate. The media (e.g., punched cards, magnetic tapes, floppy disks, CDs, DVDs, memory sticks) and formats (e.g., CP/M-, DOS-, Unix-, and Windows-) on which and in which information and information retrieval programs are stored are constantly evolving. New generations of data retrieval hardware and software tend to be incompatible with those of only a few years before. Organizations that stored volumes of information on 5¹/₄-inch floppy disks often have failed to copy the information onto 3¹/₂-inch disks or more modern media and no longer possess either the hardware or software applications necessary to read or interpret the stored information. Where large databases are concerned, the recurring need to copy the data onto current storage media in currently accessible formats can be expensive and time-consuming. Failure to copy the information can result in loss of availability of the information.

Magnetic storage media can deteriorate over time due to oxidation, compression of plastic or metal housing components, or other causes. Again, copying the information may be necessary to maintain availability.¹

E-government information access often involves links to related sites. Web sites are constantly changing, coming into existence, and being disestablished. If the links are not adequately maintained (e.g., maintaining currency and awareness of the status of linked sites and databases), information on which advertised e-government services are dependent may become unavailable.

In the case of cryptographically protected databases, the loss or corruption of keying material can result in loss of availability of information on which e-government services are dependent.

¹ For further information, see National Archives of Australia, Archives Advice 5, "Protecting and handling magnetic media," revised June 2002. Retrieved from <http://www.aa.gov.au/recordkeeping/rkpubs/advice5.html>

Denial of Service Concerns

Government sites are attractive targets for malicious activities intended to prevent access to, or use of, information (denial of service attacks). These can range from relatively unsophisticated assaults that result in temporary degradation of service response times to crippling attacks that corrupt or destroy system resources. Denial of service attacks can be launched from a variety of sources and can take a number of forms.

Sources

The source of a denial of service attack can affect (a) the scale of the attack (available resources); (b) the efficiency with which large-scale attacking resources are employed; (c) timing of attacks in the context of maximizing impact on system resources and maximizing the number of e-government clients affected or criticality of services affected; (d) the intelligence information available to facilitate an attack and focus it on specific e-government services, the denial of which will cause maximum harm; (e) the degree to which the source of the attack can be obscured or otherwise shielded from countermeasures and retaliation; and (f) scale of compensation that can be extracted from or retaliation that can be invoked against an attacker.

Individual or Informally Organized Hackers

Most denial of service attacks against e-government services have been launched by individuals or informally organized groups of hackers. Some of these have resulted in significant disruption and expense to the taxpayer. Individuals have penetrated and “captured” large numbers of computers, without the knowledge or consent of their owners and used these captured computers to launch Internet-based attacks against government sites or against service providers on which e-government services are dependent. The “captured” computers employed by some individuals number in the thousands, or even tens of thousands. The computers employed often are not even in the same country as the individuals who launch the attacks.

In some cases, groups of individuals who share a common cause (e.g., religiously or politically motivated grievances against the government) cooperatively launch attacks against resources on which e-government resources are dependent. The degree to which the attacks can be coordinated tends to be limited when such groups are informally organized and their constituent individuals employ clandestine methods to avoid being identified and arrested.

Individual hackers do tend to share information. Whether they operate independently or cooperatively, they may share information regarding techniques, successes, and failures. Some of the hackers are extremely sophisticated and often are more technically capable than the government and government-sponsored personnel who are charged with defending against them. The most sophisticated designers of attacks are often not the individuals who launch them. They often simply share the attacks with other, much less sophisticated and less prudent individuals, who then launch the attacks. Historically, there is a delay between the posting of a potential attack by a designer and its launching by an attacker. This

delay has often permitted detection by defenders and deployment of countermeasures in time to mitigate the effects of attacks (e.g., through distribution and implementation of software patches). However, the delays experienced between posting of potential attacks and launching of attacks has been decreasing.

Efficient allocation of defensive and law enforcement assets is relatively difficult in the case of individuals and informally organized groups. The target environment is excessively diffuse.

Nonstate Organizations

Attacks by formally organized groups can pose a much more serious threat than attacks by individuals and informally organized groups. This can result in increased efficiency with which large-scale attacking resources are employed and improved timing of attacks to maximize impact on system resources and the number of e-government clients or criticality of services affected; likewise, it can lead to improved availability and efficiency in exploiting intelligence information available to facilitate an attack and focus it on e-government services, the denial of which will cause maximum harm. On the other hand, many of the brightest hackers are individualists who have, so far, not tended to become subordinate to institutional management. Also, concentration of hacking resources into a formal organization permits more efficient employment of law enforcement and other resources charged with defending e-government systems. Although an organization may have resources to shield perpetrators of denial of service attacks, it presents an identifiable and resource-rich target against which defensive, law enforcement, and compensation assets may be employed.

State-Sponsored Attacks

State-sponsored denial of service attacks have long been a major concern for e-government activities. Very large sets of resources can be brought to bear on design and execution of attacks, and the state can (to some extent) shield the actual perpetrators from individual identification, capture, and retaliation. On the other hand, so far, many of the most effective hackers are individualists who have not tended to subordinate themselves voluntarily to government oversight. Also, if an attack can be demonstrated to be state sponsored, a range of remedies is available to discourage future attacks and extract compensation (e.g., economic sanctions, retaliation in kind, military action). State-sponsored denial of service attacks remains a largely unrealized concern.

Classes of Attacks

Denial of service attacks against e-government resources has been extensively defined and discussed in security literature. Examples include *Distributed Denial of Service (DDoS) Attacks/Tools* (Dittrich, 2004), *Denial of Service Attacks* (CERT Coordination Center, n.d.), and the Denial of Service Database. Denial of service attacks can take physical or logical forms.

Physical

Although physical attacks on e-government resources can have catastrophic and relatively enduring consequences,

they usually involve significant risk exposure for the perpetrators and have a relatively uncertain prognosis. For example, the 2001 attack on the World Trade Center affected some e-government services, but some potentially catastrophic outages were avoided by chance. Some important service provider hardware remained in service in a heavily damaged building. In most cases to date, impacts on e-government services have been by-products rather than primary objectives of physical attacks.

It is possible for an individual or small organization to carry out significant attacks on e-government resources. The bombing of the Murrah Federal Building in Oklahoma City is an example of a large-scale attack on federal assets. However, the larger physical threat may still be posed by nation-states, state-sponsored organizations, and large nonstate organizations.

Logical

The simplest and so far most common denial of service attacks, logical attacks keep e-government servers so busy with fake data traffic that they can't employ their resources to provide services to their legitimate users. Most of the more common attacks take advantage of network protocol characteristics and are termed "flooding" attacks. Some flooding attack scenarios follow:

- An Internet control message protocol (ICMP) message to a server (also known as a "ping" on a server) produces an echo response to confirm the server's presence. When enough pings are sent, the target server can do nothing but respond to the requests.
- User datagram protocol (UDP) diagnostic services generate characters that are echoed back from the receiving end to the host, swamping the network with useless data.
- Multiple spoofed requests for transmission control protocol (TCP) connections force the server to keep ports open, waiting for responses.
- Some attacks (i.e., "Smurf" attacks) appear to originate from the target server's own Internet protocol address or somewhere else on the target's network. Targeted correctly, the attack can flood the network with pings and multiple responses.

Distributed denial-of-service attacks employ multiple computers across the Internet against a single target server. Most serious attacks today orchestrate the use of hundreds of machines and take the target server out of commission for the duration of the attack.

Integrity

The E-Government Act of 2002 states that the term integrity "means guarding against improper information modification or destruction, and includes ensuring information nonrepudiation and authenticity." Integrity concerns affect publishing, interactive processing, transaction processing, and service delivery of e-government activities. If published information, requests for information received from users, or authorizations or payments issued to users are improperly modified or destroyed, routed, or ascribed, then damage to confidence in the government, to user or customers, or to government assets can result.

Data Content Integrity Issues

Data content integrity issues are associated with unauthorized modification or destruction of e-government information content. This can involve modification or destruction of

- information electronically published by the government;
- information associated with reports, applications, or other service requests provided by private citizens or other user entities (e.g., submit tax returns, apply for licenses or other services, renew licenses, order products or services, or provide notification of address change or other status changes);
- notification to private citizens or other user entities of approval actions or activation of implementation processes (e.g., billing, payment, licensing, permit issuance, contract awards, invoice approvals, etc.); and
- information executing actions approved on the basis of e-government interactions (e.g., credit card payment information or electronic funds transfer information, electronic fund transfer information, and licenses or permits).

Loss of data content integrity can result from error-based integrity faults or from intentional modification or destruction of data. The consequences of loss of integrity from either cause can range from inconvenience or financial loss to users to unintentional violation of public laws or regulations by users. Impaired confidence in e-government systems is a likely consequence in any case.

Error-Based Integrity Faults

Although most error-based integrity faults (i.e., accidental losses of integrity) are not, strictly speaking, security concerns, they can have consequences similar to those of maliciously induced faults, and a number of the countermeasures to intentional modification of data are effective in mitigating the consequences of error-based faults. Note also that many fault-tolerance measures are also effective in mitigating the consequences of error-based integrity faults.

Intentional Modification of Data

Data may be modified or destroyed within e-government processors (e.g., Web servers) or in transit. In the case of the former, an attacker must gain write-access to the processor and to the desired data file or process within the processor. Penetration may be accomplished by defeating identification and authentication mechanisms or by inserting malicious code into a legitimate transaction. In some cases, information transits more than one government processor in the course of interactive or transaction processing or service delivery processes. In such cases, it may be sufficient to penetrate only one processor in the path between the originating process or database and the connection to external communications. Information transiting an intermediate processor can be modified or destroyed in that processor. In some systems, Web servers outside the security perimeter (e.g., outside the firewall)

make attractive penetration targets. If the configuration of their access control mechanisms is inadequate, it may be possible for attackers to destroy, forge, or modify e-government information in these external processors (e.g., maliciously modifying Web pages).

Modification of information in transit can mean dynamic modification of information on a communications path, but it can also mean modification of information in an intermediate processor (e.g., a server belonging to an Internet service provider). It may be possible using either approach to forge or intercept and change legitimate e-government publications or transactions.

Connection Integrity Issues

Successful implementation of e-government services requires some degree of confidence on the part of private citizens or other user entities that information being read originated only with the assumed government source and that information being provided goes only to the appropriate government destination(s). Similarly, it is important to government electronic service providers that reports, service requests, and applications actually originate with the user entity claiming to make the submission and that service delivery transmissions and private or proprietary information go only to authorized destinations. Modification of header or routing information (see previous section, Intentional Modification of Data) can potentially result in distribution of information or service delivery instruments to unauthorized parties. The consequences can include simple violation of laws and regulations regarding privacy or proprietary information, identity theft with financial or legal consequences, erroneous or fraudulent issuance of permits or licenses, and diversion of services or funds.

Nonrepudiation Issues

Nonrepudiation involves proof of the origin and content integrity of data (including the property of not having been forged) in a form that can be verified at any time by a third party. Nonrepudiation most commonly applies to requests and reports from private citizens and other user entities, but there are cases in which user entities expect protection from repudiation of government-originated information or responses to requests. The following properties need to be satisfied to support nonrepudiation of e-government services:

- Publications and transaction information must be tightly bound to their claimed sources.
- Transactions must be difficult to forge without the forgery being detected.
- Transactions must be difficult to alter without the alteration being detected.
- Transactions must be verifiable.

Particularly in the case of reports required by law or regulation, it is important to the government that there be nonrepudiation with respect to both originator and content. Particularly with respect to approval actions and publication of regulations and requirements, it is important to user entities that there be nonrepudiation

with respect to both originator and content. Neither the originator nor the recipient of information or a transaction request must be able to claim falsely and convincingly that the information or transaction request actually originated from a different source, was posted at a time different from when it was actually posted, or had different total content from that which was received. Particularly in the case of service delivery, the recipient must not be able to claim falsely and convincingly that information or transactions received were misdirected or not received for other reasons.

As the level of e-government service progresses from publication through interactivity and transaction processing to service delivery, the importance of nonrepudiation increases.

Confidentiality and Privacy

The E-Government Act of 2002 states that the term *confidentiality* “means preserving authorized restrictions on access and disclosure, including means for protecting personal privacy and proprietary information.” E-government publication services involve primarily dissemination of information authorized to be in the public domain. Interactive e-government services may include communication to government facilities of information that is subject to laws or regulations restricting dissemination of private or proprietary information. The volume and frequency of occurrence of privacy and proprietary information increase in the cases of e-government transaction services and services delivery. In all cases, it is necessary to protect against use of e-government portals for unauthorized access to government information that has not been released into the public domain.

Distinguishing Confidentiality and Privacy Issues

The terms *privacy* and *confidentiality* are often used interchangeably. The U.S. Congress Office of Technology Assessment (OTA) has observed that “neither term possesses a single clear definition, and theorists argue variously that privacy and confidentiality (and the counterpart to confidentiality, secrecy) may be concepts that are the same, completely distinct, or in some cases overlapping” (U.S. Congress, Office of Technology Assessment, 1993). For purposes of this e-government discussion, confidentiality protection is protection against disclosure of information without the implicit or explicit consent of an entity that legitimately possesses the information, whereas privacy protection also includes protection against dissemination of information by an entity that legitimately possesses the information in violation of laws and regulations restricting the dissemination of that information.

Threats to Confidentiality and E-Government Vulnerabilities

Although intercept of transmissions between e-government facilities and user entities can be employed to achieve unauthorized disclosure of information, adversaries more commonly employ legitimate access facilities to gain unauthorized access to information (e.g., Internet connections, electronic mail, self-service kiosks and

terminals, simputers² and other wireless devices). The adversaries can employ a variety of means to defeat system identification, authentication, filtering, and authorization mechanisms (e.g., legitimate messages that contain malicious code enclosures, password dictionary attacks, transmission of protocol messages or other control function sequences) to access information stored in government devices or alter (change or add to) address information and misdirect information transfers. The more flexible and user-friendly the e-government service, the more opportunities are usually presented to adversaries. For example, use of connectionless protocols (e.g., UDP) eliminates most effective firewall configuration options. Penetration of an e-government security perimeter often gives adversaries extensive opportunities to browse confidential, private, or proprietary files.

Impacts or Consequences of Unauthorized Exposure

The consequences of unauthorized exposure of information via e-government resources depend in large part on the specific information that is exposed.

Loss of Confidence in Institutions and Service Delivery Mechanisms

Public disclosure of e-government confidentiality breaches can result in loss of public confidence in e-government mechanisms and in the institutions that they serve. The future of e-government will be determined in large part by public acceptance of e-government mechanisms as a dependable approach to doing business with governments.

Impacts on Operations

Impacts of confidentiality breaches on government operations can include disruption of ongoing plans and operations, legal actions against government organizations, financial impacts on the public, or even public safety consequences. The U.S. National Institute for Standards and Technology's *Guide for Mapping Types of Information and Information Systems to Security Categories* (Barker & Lee, 2004) describes the impacts or consequences of unauthorized disclosure of 145 types of U.S. government information. It also identifies Executive Orders, Executive Directives, and federal laws mandating protection for various confidential, private, and proprietary information types. Probably the most damaging breach of confidentiality is unauthorized access to cryptographic variable information that would permit an adversary to pose as a legitimate user who is authorized access to sensitive or critical information (including transaction data).

Legal Issues

Government institutions are bound by law to protect confidential, private, and proprietary information from unauthorized disclosure. Consequences for government personnel can range from reprimand to fine and imprisonment, depending on the nature of the information that is disclosed and the degree to which the compromise is willful or negligent. Particularly, in the case of

e-government transactions and service delivery, the legal consequences for government institutions can include breaches of contract and other bases for recovery from the government of compensatory and punitive damages.

SECURITY MEASURES FOR E-GOVERNMENT

Mechanisms and Techniques

Security mechanisms and techniques for countering availability, integrity, and confidentiality threats are described in detail in Parts 2 and 3 of this volume. The countermeasures information provided in this chapter focuses on e-government-specific considerations for application of security mechanisms and techniques.

Availability

Availability assurance features can include design characteristics (e.g., component or path redundancy, survivable design, isolation of resources), policy and procedural characteristics (e.g., access control policies, system certification and acceptance plans and procedures, recovery and continuity plans, data and program back-ups), and access mechanisms (e.g., reliable communications protocols, identification and authentication mechanisms). E-government mission requirements limit the application of some of these assurance features. For example, because public access is central to the purpose of e-government systems, physical isolation (e.g., of kiosk or terminal devices) and logical isolation of e-government assets must necessarily be limited. Use of surveillance devices and physical hardening and alarming of terminal logic components may be possible to raise the levels of difficulty and risk associated with unauthorized installation of mechanisms to capture key strokes or information in electromagnetic form within the terminal. However, significant residual risk is probably unavoidable. Terminal penetration can permit an adversary to bring down a system to which it connects and even use that system's interfaces to launch denial of service attacks against other systems. Similarly, ease of use is a major consideration for e-government applications. This includes ease of sign-on, user-friendly interfaces (graphical user interfaces), and support for a broad range of Web page development and support and mission-support applications. In the world of Web-based network services, the same properties that support user-friendly interfaces and a multiplicity of applications tend to offer more opportunities for penetration of the system and complicate security analysis beyond the point at which reasonable assurance can be achieved. As an example, network protocols necessary to support some widely used database management applications must be connectionless, thus preventing secure configuration of firewalls (see earlier section, Protocol and Operating System Mechanisms).

Integrity

Integrity mechanisms can include operating system-based (see chapter of this *Handbook*, "Operating System Security"), protocol based (see chapter of this *Handbook*, "Firewall Basics"), or cryptographically based mechanisms.

² The simputer is a low-cost personal computer with multiple connectivity options; see dmoz.org/Computers/Systems/Handhelds/Open_Source/Simputer/

Protocol and Operating System Mechanisms

Firewalls are front-end processors that employ primarily protocol-based screening mechanisms to protect internal systems and networks that may contain sensitive or critical information from exploitation from external sources (e.g., from Web servers accessible by the public). A primer on firewalls is provided by chapter of this *Handbook*, “Firewall Basics.”

Operating system–based access control mechanisms are employed to protect e-government components outside the firewall(s) from modifications that alter either their content or their functionality. They are also used to protect the firewalls themselves from exploitation and components on internal networks from insider threats (including from unauthorized “back-end” connections to external networks or the public switched telephone network). Too often, security configuration of components outside the firewall is given insufficient attention. A number of highly embarrassing, and even damaging, unauthorized modifications to e-government publications and processes have resulted.

Ideally, processors employed to provide e-government services should have been evaluated as conforming to at least the EAL-4 level of the *Common Criteria* (CC).³ However, most government agencies are required to employ commercial off-the-shelf (COTS) computer and communications components. It is commercial practice to modify systems regularly and replace current systems with new “improved” versions. Patches to software are constantly being made available to correct flaws or enhance capabilities. In this COTS environment, it is proving extremely difficult to maintain security configuration control. An initial CC rating (e.g., EAL-4) can mean little once the system has been patched or upgraded. Regression testing to ensure that critical security properties of systems have not been impaired can mitigate this problem.

Cryptographic Mechanisms

Digital signature (see chapter of this *Handbook*, “Digital Signatures and Electronic Signatures”) and message authentication are the most commonly employed cryptographic integrity protection mechanisms. Time stamping and establishing a reliable chain of trust for the public key certificates used in digital signatures are also critical elements for providing nonrepudiation services. Public key systems rely on a chain of trust for source authentication of PKI (public key infrastructure) certificates that are used to distribute public keys (Federal Public Key Infrastructure Steering Committee, 2000). Although a PKI⁴ has been developed by and is becoming standardized within the federal government, many government agencies currently contract public key management for nonnational security systems from the private sector. In this case, federal certificates that are used to transport the public keys employed to check the validity of digital signatures are generated and signed by a certification authority that is a private company. In addition, the private keys that are used to sign information (to provide source authentication and

data content integrity) are also generated by, known by, and distributed by the private sector. In some cases, agencies generate the private keys and public key certificates employed within their own agencies. There is currently no common public key management system in use within the Federal government and no common chain of trust for e-government.

A complicating factor for e-government is maintenance and use of certificate revocation lists (CRLs). A CRL is a list of revoked public key certificates created and digitally signed by a certification authority. Policies and procedures regarding high-integrity distribution of notices listing revoked certificates in e-government applications are needed to achieve the level of assurance necessary to support high-value and mission-critical transactions and services delivery functions.

Currently, quantum computing (West, 2000) is in the early stages of research and development. However, if large-scale quantum computing becomes available, public key methods in current use are likely to become obsolete. Message authentication encoding based on symmetric key (secret key) cryptography will remain viable. However, distribution and management of secret keys for authenticating information is problematic, and message authentication alone does not provide the full range of digital signature services. Furthermore, there is no current infrastructure to support key notarization and other measures that would be necessary to replace public key cryptography-based digital signature. Also, there is no symmetric key infrastructure for unclassified government operations. Integrity of e-government transactions is likely to remain dependent on the security of PKI for the foreseeable future.

A final issue affecting employment of cryptographic integrity mechanisms in U.S. E-government is availability, use, and interoperability of mechanisms that meet federal standards. Federal agencies are legally bound to employ only government-approved cryptography. In the cases of unclassified systems, approved algorithms are the digital signature algorithm (DSA), the Rivest, Shamir, and Adelman (RSA) algorithm (American National Standards Institute [ANSI], 1998a), and elliptic curve DSA (ECDSA; ANSI, 1998b) as specified in the *Digital Signature Standard (DSS)*.⁵ Minimum key sizes approved through the year 2010 are 1024-bit DSA, 1024-bit RSA, and 160-bit ECDSA. After 2010, 2048-bit RSA and DSA and 224-bit ECDSA will be the minima. Hash functions used in e-government digital signature processes must conform to the NIST *Secure Hash Standard* (NIST, 2002). After 2010, the 160-bit secure hash algorithm 1 (SHA-1) hash function may no longer be used in digital signatures to protect U.S. government information. It is incumbent on e-government service providers to ensure that digital signature mechanisms conform to these standards and that plans accommodate transition to the higher assurance requirements that will be in force after 2010.⁶ In the case of message authentication encoding, either the triple data encryption algorithm (TDEA; Barker 2004) or the advanced encryption standard (AES) may be used, and encoding schemes employed in U.S. e-government

⁴ See chapter of this handbook, “PKI (Public Key Infrastructure).”

⁵ Soon to be superseded by FIPS 186-3, same title.

⁶ Note that SP 800-57 will require still larger key sizes after the year 2030.

operations must conform to NIST's *Recommendation for Block Cipher Modes of Operation* (Gasser, 2004).

Confidentiality and Privacy

Access to e-government information and processes is dependent primarily on the identification and authentication processes that support e-government access control mechanisms (see Availability earlier in this section). If e-government information is intercepted in transit, or accessed in storage (e.g., following penetration of system access control mechanisms), it can still be protected by encryption. (See Volume II, Part 3: "Foundations of Information, Computer, and Network Security.")

Encryption is necessary to protect confidential information that is subject to intercept or access while stored or being processed in e-government systems.

Protocol and Operating System Mechanisms

Because e-government facilities generally need to be accessible by the general public to fulfill their missions, they are subject to a broad range of hacking and other penetration attacks. Front-end security processors (e.g., firewalls, screening routers as described in chapters "Digital Signatures and Electronic Signatures", "E-mail Security", "Security for ATM Networks", and "VPN Basics", of this *Handbook*) can be used to isolate those elements of e-government facilities that are publicly accessible from those that contain confidential, private, or proprietary information. These mechanisms separate internal government networks from publicly accessible e-government facilities. They can provide identification and authentication functions, access control functions, limit the protocols that are accepted (thus limiting adversaries' opportunities to tunnel into system compartments that contain confidential information). As noted in earlier, (see Availability), there tends to be an inverse relationship between flexibility and ease of use on one hand and strength of security mechanism on the other. U.S. e-government systems should conform to *Guidelines on Firewalls and Firewall Policy* (Wack, Cutler, & Pole, 2002).

Operating system-based access control mechanisms are employed to protect e-government components outside the firewall(s) from disclosure of configuration information or other information that can assist an adversary in making modifications that alter either the content or functionality of these components. Similarly, operating system-based access control mechanisms are employed to protect the confidentiality of government systems inside the firewall (as discussed earlier; see Protocol and Operating System Mechanisms).

Cryptographic Mechanisms

Several factors complicate encryption of e-government information. First, public key (asymmetric) cryptography is sufficiently computation-intensive that encryption of large volumes of data, or of data where high throughput is required, is undesirable. Second, because of threats of exposure over time and limitations on the volume of data that should be encrypted under a single key, encrypted information needs to be decrypted, then re-encrypted under a different key. This is excessively expensive

for large databases. Third, protection of secret keying material in a publicly accessible system is technically challenging. Finally, there is no common government symmetric key management infrastructure for unclassified systems.

As in the case of digital signatures, the encryption algorithms employed in e-government must be government-approved. Currently, only TDEA and AES are approved for encryption of U.S. government information. Encryption schemes employed in U.S. e-government operations must conform to NIST's *Recommendation for Block Cipher Modes of Operation*.²³ Through the year 2010, either two-key TDEA or three-key TDEA may be used (see NIST's *Recommendation for the Triple Data Encryption Algorithm (TDEA) Block Cipher*, Special Publication 800-67). After 2010, only three-key TDEA may be used; and after 2030, TDEA may no longer be used for protection of U.S. e-government information.¹⁸ To avoid transition problems, use of AES rather than TDEA may be prudent.

Database Design

Some e-government services include provision of data that are derived from aggregation or analysis of information that is subject by law to privacy protection, are proprietary, or for which confidentiality must otherwise be maintained (e.g., provision of statistical information based on Privacy Act-protected data). A number of database design and management approaches have been developed to address this problem (e.g., *A Near-Term Design for the SeaView Multilevel Database System* (Lunt, 1998). This continues to be an active research topic.⁷

Implementation and Management

Interdependency of Measures/Mechanisms

Significant interdependency exists among the various countermeasures that may be employed to mitigate e-government security concerns. At the level of individual security mechanisms, computer security mechanisms (e.g., firewall and operating system⁸ access control mechanisms) may play a role in protecting secret or private keys. At the same time, cryptographic processes used by authentication elements of access control mechanisms may employ one or more of the secret or private keys. At a "system of systems" level, source and data content integrity may depend on the aggregate performance and security of a private sector PKI certificate authority, an Internet service provider, the configuration of the e-government server that manages interactions with the public, the design and configuration of the firewall between the e-government server and the government processors inside the security perimeter, and the design and configuration of those internal government processors that process confidential or private information. Security of e-government systems is a total systems problem, and managers responsible for system security must address the adequacy of security

⁷ See archive.infopeace.de/msg02567.html

⁸ See the discussions of operating system security found in chapters "The Common Criteria", "Internal Security Threats", "Physical Security Threats", "Fixed-Line Telephone System Vulnerabilities", "E-Mail Threats and Vulnerabilities", "E-Commerce Vulnerabilities", "Hacking Techniques in Wired Networks", and "Hacking Techniques in Wireless Networks".

features and assurances associated with each subsystem and component mechanism.

Program Requirements

The Federal Information Security Management Act of 2002, the Paperwork Reduction Act of 1995, and the Information Technology Management Reform Act of 1996 (Clinger-Cohen Act), explicitly emphasize a risk-based policy for cost-effective security. In support of and reinforcing this legislation, the OMB through Circular A-130, Appendix III, *Security of Federal Automated Information Resources*, requires executive agencies⁹ within the federal government to

- *plan* for security;
- *ensure* that appropriate officials are assigned security responsibility;
- *review* the security controls in their information systems; and
- *authorize* system processing prior to operations and periodically thereafter.

These management responsibilities presume that responsible government officials understand the risks and other factors that could adversely affect their missions. Moreover, these officials must understand the current status of their security programs and the security controls planned or in place to protect their information and information systems to make informed judgments and investments that appropriately mitigate risk to an acceptable level. The ultimate objective is to conduct the day-to-day operations of the agency and to accomplish the agency's stated missions with what OMB Circular A-130, Appendix III, defines as *adequate security*, or security commensurate with risk, including the magnitude of harm resulting from the unauthorized access, use, disclosure, disruption, modification, or destruction of information.

Policies, Procedures, and Infrastructures

E-government systems must establish security policies and procedures that address the access rights of the public, requirements for protection of the privacy of its users, requirements for protection of the confidentiality of government information contained in e-government systems and government systems connected to those systems, necessary service assurances, integrity and nonrepudiation requirements, and the laws and federal regulations on which these requirements are based. Systems managers must also establish operating procedures that permit compliance with these policies while satisfying e-government mission requirements. Finally, e-government managers must identify or establish the necessary processing, communications, and security (e.g., key management) infrastructures necessary to implement system policies and procedures.

⁹ An executive agency is (a) an Executive Department specified in 5 U.S.C., Section 101; (b) a Military Department specified in 5 U.S.C., Section 102; (c) an independent establishment as defined in 5 U.S.C., Section 104(1); and (d) a wholly owned government corporation fully subject to the provisions of 31 U.S.C., Chapter 91.

Certification and Accreditation

As stated in the *Guide for the Security Certification and Accreditation of Federal Information Systems* (Johnson, Katzke, Ross, Stoneburner, & Swanson, 2004), the E-Government Act requires each federal agency to develop, document, and implement an agencywide information security program to provide information security for the information and information systems that support the operations and assets of the agency. An e-government information security program must include

- periodic assessments of risk, including the magnitude of harm that could result from the unauthorized access, use, disclosure, disruption, modification, or destruction of information and information systems that support the operations and assets of the agency;
- policies and procedures that are based on risk assessments, cost-effectively reduce information security risks to an acceptable level, and ensure that information security is addressed throughout the life cycle of each agency information system;
- subordinate plans for providing adequate information security for networks, facilities, information systems, or groups of information systems, as appropriate;
- security awareness training to inform personnel (including contractors and other users of information systems that support the operations and assets of the agency) of the information security risks associated with their activities and their responsibilities in complying with agency policies and procedures designed to reduce these risks;
- periodic testing and evaluation of the effectiveness of information security policies, procedures, practices, and security controls¹⁰ to be performed with a frequency depending on risk, but no less than annually;
- a process for planning, implementing, evaluating, and documenting remedial actions to address any deficiencies in the information security policies, procedures, and practices of the agency;
- procedures for detecting, reporting, and responding to security incidents; and
- plans and procedures to ensure continuity of operations for information systems that support the operations and assets of the agency.

It is essential that e-government officials have the most complete, accurate, and trustworthy information possible on the security status of their information systems to make timely, credible, risk-based decisions on whether to authorize operation of those systems. The information and supporting evidence needed for security accreditation is developed during a detailed security review of an information system, typically referred to as security *certification*. The results of a security certification are used to reassess the risks and update the system security plan, thus providing the factual basis for an authorizing official

¹⁰ Security controls are the management, operational, and technical controls (i.e., safeguards or countermeasures) prescribed for an information system to protect the confidentiality, integrity, and availability of the system and its information.

to render a security accreditation decision. Security accreditation is the official management decision given by a senior agency official to authorize operation of an information system and to accept explicitly the risk to agency operations, agency assets, or individuals based on the implementation of an agreed-on set of security controls.²⁹

SUMMARY

E-government shows great promise for use of improved Internet-based technology to make it easier for citizens and businesses to interact with the government, save taxpayer dollars, and streamline citizen-to-government communications. With these potential benefits come real risks to the privacy of information provided by citizens and businesses, to the confidentiality of government information contained in e-government systems and systems connected to e-government systems, to the long-term availability of records stored only in electronic form by the government, and to the integrity of citizen-to-government transactions and government-to-citizen delivery of services. These risks are based on intrinsic technical characteristics of storage and processing systems, on the potential for accidents or system faults, and on the attractiveness of e-government systems as a target for malicious activity. A variety of countermeasures are available to mitigate these risks (e.g., fault-tolerant design, disaster recovery procedures, information backups, access control logic in front-end processors and e-government service systems, digital signature for transactions, encryption of sensitive information, and database design and management that permit use of privacy-protected data without divulging the privacy-protected elements to unauthorized sources. Law requires that the security mechanisms conform to federal standards and be evaluated in accordance with a federally mandated certification and accreditation process prior to the e-government systems being placed into operation. These policy requirements, together with the projected consequences of loss of public confidence in both e-government and government institutions in general, suggest that the process of converting paper-based services to e-government services cannot be accomplished without careful planning and systems-based oversight.

GLOSSARY

Asymmetric In the context of cryptography, a type of cryptographic system in which a participant publishes an encryption key and keeps private a separate decryption key. These keys are respectively referred to as public and private. RSA and D-H are examples of asymmetric systems. *Asymmetric* is synonymous with *public key*.

Authentication A process that establishes the origin of information or determines an entity's identity.

Availability The property of ensuring timely and reliable access to and use of information.

Confidentiality Preservation of authorized restrictions on access and disclosure, including means for protecting personal privacy and proprietary information.

Cryptography The discipline that embodies principles, means, and methods for the transformation of data

to hide its information content, prevent its undetected modification, or prevent its unauthorized use.

Digital Signature The results of a cryptographic transformation of data that, when properly implemented, provides the services of origin, authentication, data integrity, and signer nonrepudiation.

Encryption The process of rendering a message (a *plaintext*) into a data string (a *ciphertext*) with the aim of transmitting it privately in a potentially hostile environment.

Integrity Guarding against improper information modification or destruction, which includes ensuring information nonrepudiation and authenticity.

Interactive Processing Service that permits private citizens or other user entities to read instructions published on agency Web sites and to follow those instructions to submit reports, applications, or other service requests.

Nonrepudiation A service that is used to provide assurance of the integrity and origin of data in such a way that the integrity and origin can be verified by a third party as having originated from a specific entity in possession of the private key of the claimed signatory.

Privacy Protection against disclosure of personal information in violation of laws and regulations restricting the dissemination of information.

Private Key In an asymmetric or public-key cryptosystem, the key that a communicating party holds privately and uses for decryption or completion of a key exchange.

Public Key In an asymmetric or public-key cryptosystem, the key that a communicating party disseminates publicly.

Publishing As used in this chapter, posting information on a publicly accessible Web site.

Secret Key A cryptographic key that is used with a symmetric cryptographic algorithm that is uniquely associated with one or more entities and is not made public.

Service Delivery Actual execution of actions approved on the basis of e-government interactions (e.g., acceptance of credit card payments or electronic funds transfers, execution of government payments by electronic fund transfers, and delivery of licenses or permits).

Symmetric In the context of cryptography, a cryptographic algorithm that uses one shared key, a secret key.

Transaction Processing Processing of information submitted via interactive e-government Web sites, providing notification of approval for actions to be taken on the basis of that information and activation of implementation processes. Transaction processing generally involves distributing data received from users to multiple databases and multiple processes and includes interactions with third parties.

INTRODUCTION

The previous chapter in this *Handbook* documents the rise of e-government and its transformative effects. The digital representation of government activities leads to a wider spread of information and decision making, both vertically and laterally. This challenges hierarchical bureaucratic procedures and established agency roles. Responses include requirements to make key documents available electronically and the development of standards for electronic consultation, or e-rule making. This effect is apparent at every level of government, from the smallest local council to the largest nation state. At the same time, the issues governments deal with are also outgrowing traditional boundaries. Sometimes the issue expands outward, as when a regional government builds a dam that decreases the water flow to neighbors. Other times issues are imposed inward, for example if decisions made in another country affect the price of a local product.

E-government is evolving to deal with transborder issues. Government responses to these supranational issues become an element in emerging forms of global governance, but it cannot be assumed that the emerging systems will serve democratic goals. It is not even clear what global forms of democracy might mean or what they might 'look like' for citizens. It is, however, certain that patterns of digital representation and decision making will impact on the overall security of peoples in today's very insecure climate. Increasingly, the security and accuracy of the information being shared globally underpins the effectiveness of governmental response, and thus affects citizen safety. This applies to a myriad of socio-political-scientific issues, from climate change to terrorism to new disease vectors.

This chapter considers the overall context in which e-government is evolving and the importance of both administrative and democratic accountabilities. It then considers some issues for which information management and security cannot be contained within national borders. These include the global information infrastructure itself, which may be thought of as a global information "commons." Global e-governance is the complex of administrative, technical, and policy arrangements that collectively form a default pattern of governance on a particular international issue. The electronic representation is embedded in the human systems that give rise to them. Transborder issues are generally subject to different constraints than are localized issues and information. The role of nongovernment players in international information arenas is outlined, along with their influence on both physical and informational security with illustrative examples from particular areas of concern. Lastly, suggestions are offered for research and modeling global e-governance as a complex adaptive system. This issue is inherently transdisciplinary and is informed by a large body of work on complex adaptive systems in human behavior.

E-GOVERNMENT EVOLUTION

From local councils through state legislatures and national programs, electronic efficiencies are altering the pace and processes of government. Typically, electronic government addresses services, administrative procedures, and transactions. A current analysis of digital government (Pavlichev & Garson, 2004) documents the issues and current state of play of digital government at the national level and some of the aspects that overflow into international dimensions. The previous chapter

in this *Handbook* describes the stages of digital government from information presentation through seamless access across agencies. Much of the literature on e-government focuses on the United States or may only consider local, state, and national governments. Writers on international relations, technology, and global governance, on the other hand, may not concern themselves with the digital representation of these issues. The extension of e-government to the international sphere is, however, the subject of much speculation, and the focus of this chapter. Both the administrative and democratic dimensions of emerging forms of international e-government are relevant to global information management and security.

Technology and the State

It is common to view information technology in government as an advanced expression of technocratic efficiency. However, information system design, management, and funding are also an expression of their socio-political-economic context. In a study of U.S. government information policies, Hernon and McClure (1993) found there was inadequate public involvement in this area, although it often involved fundamental issues about how society operates and the role of government. Not surprisingly, they found overlapping impacts, fragmentation, and difficulties of categorization in complex areas. There is a gulf between the theory of wide public involvement as a democratic ideal and the practice of e-government development.

Inevitably, information systems serve the political, economic, and social systems that fund them. Beniger (1986) showed the importance of information in all forms of evolution and control, including biological evolution. Feenberg (1991) provided a critical theory of technology and revealed how the democratizing potential of information technology makes it a site for ongoing power struggles. Sclove (1995) considered the need to embed democratic assumptions in technology design. Zuboff's (1988) concept of "informating" within organizations provided an adaptive learning element, which leads to complexity theory and the developmental role of democracy and policy. A key assertion of this chapter is that information and communication systems need to be considered as manifestations of governance. The implications compound when comparing information systems across national boundaries.

Current Dimensions and Limitations of E-Government

This section considers the dominant focus of digital government at the national level as a basis for extrapolation to the international level. From local councils to national agencies, governments have focused their technology efforts on service delivery and information provision. There has been less emphasis on citizen communications with government, input into policy making, or citizen-to-citizen communications. This trend has been identified in a survey of member nations of the Organisation of Economic Cooperation and Development (OECD;

Gualtieri, 1998), at local government level in the United States (Musso, Weare, & Hale, 2000), and within agencies of the Australian government (Geiselhart, 1999). Because these patterns are observable at different scales, they may be seen as fractal. If supported by data and modeling, this insight from the field of complex adaptive systems could assist in the analysis of global technology systems and patterns. The possibility of modeling governance from a normative democratic perspective suggests how the linkages between local and global activities might be integrated. While commonplace for physical data such as climate, this has not yet been fully explored in the human sciences.

The study of information technology in government has tended to focus on developed democratic states, partly because they have been the trend setters that other nations emulate as they implement digital procedures. The United Nations provides a statistical index of e-government for member states based on infrastructure and access (see <http://www.unpan.org/egovernment2.asp>) but does not go into qualitative detail of information on governance in relation to transparency or online citizen engagement. Most analyses have an implicit understanding that electronic applications will support democracy as the more privileged nations understand that term. This assumption is questionable, however, as specific examples throughout this chapter illustrate. The World Bank, among others, is exploring the potential of new communication technologies to assist in democratic reform. One hypothesis of this chapter is that global information and physical security will be supported most effectively by emerging forms of global e-governance that facilitate digital equity and minimize democratic deficits within and between nations. A second hypothesis is that the patterns of technology use are determined by the values of the stakeholders, and these may not always favor wider social stability or equity. In a system driven by the values of the actors and the rules for their interaction, the patterns will reflect the overall democratic information 'value chain,' and highlight the weak links as gaps in transparency and accountability. The value chain, as in business applications, consists of the linkages and transferrals of goods and data between intermediaries. For democratic information purposes, this chain contains data but not goods, although it might also consist of services, such as monitoring and evaluation. It is truly a value chain, as every link gives actors options for passing along or withholding information. The degree to which all stakeholders are included also forms part of the pattern. For example, Clover (2004) argues that in most nations fishing policy caters to a relatively small industry, without mechanisms for including the public interest.

Branscomb (1994) identified at least four types of information needed by governments and their citizens: to fulfill voting obligations; to comply with legislative and judicial decisions; to be informed about environmental, welfare, medical, and other developments; and to manage government tasks effectively, for example, census and economic data. She noted that in meeting these requirements, governments must juggle their accountabilities to operate cost-effectively, maintain maximum access, and also encourage private sector development. A report by Accenture (2004) identifies five trends in e-government,

including tangible savings, improved take-up by citizens, a continuing challenge of integration, and gradual personalization of online services. Neither of these catalogues adequately capture the need for democratic accountabilities in information management.

Information technology has been an important focus for public sector reform, both for the instrumental collection and processing of information and for the government's developmental obligations to promote participation by an informed citizenry. A client focus together with web technologies have vastly increased the amount of information available to the public. The pursuit of cost-effectiveness has also encouraged electronic access. Pressures for the cost recovery of information create inevitable trade-offs between equity and efficiency. At every stage of the policy process—agenda setting, planning, implementation, and evaluation—information is a key ingredient. International standards for electronic data interchange have, with some struggle, gradually evolved for greater interoperability. But similar standards for democratic transparency of data and information access remain a battleground both within and across jurisdictions. Political globalization increases the pressures for harmonization of data flows on matters of democratic interest and public concern.

Localized Accountabilities of E-Government

Not all aspects of e-government have international ramifications. Some issues for governments can be understood and managed with reference primarily to their own jurisdiction. At the most local level, this includes rates, services such as schools and garbage collection, planning, and development. Fully responsive local governments also promote cultural activities, heritage awareness and protection, responsible business growth, and environmental sustainability. When local e-government works well, these matters are represented transparently on a web site, with provision for citizens to engage with each other and their government. This helps to complete the loop by providing ongoing feedback. It can also provide a higher level accountability by ensuring that policies are effective. Early steam engines had a "governor" that kept the engine from exploding by keeping its function within the norms needed to run efficiently. E-rule making can avoid the worst of bad policy decisions by offering a normative and iterative "governor" to stabilize government activities. A carefully planned approach to citizen consultation, supported by appropriate use of digital communications, can help manage the democratic obligations of government. This pluralistic alternative to hierarchical decision making is described by Richard (2000). She elaborates on the ways a network model, actively enabled through appropriate digital techniques, can help achieve the transformative promise of e-government.

At a local or even regional level, achieving awareness and engagement is facilitated by geographic proximity to the issues. The site for a proposed toxic dump may be visited, and community discussion can take place casually. Corruption or nepotism may be difficult to conceal. These direct and analog sources of evidence provide a form of accountability for the information that is publicly presented. If people are getting sick or the roads are

in bad repair, then those who provide data to the contrary can be questioned. The checks and balances can be immediate and provide a level of information security that is probably unsurpassable.

Problems of Scale for Information Accuracy and Security

Once the systems for information collection and display exceed what can be verified by the senses, a level of abstraction is necessary. Zuboff (1988) provided a powerful description of the changes technology brings to tasks that were previously capable of being physically monitored. Workers in a factory who could once go directly to a vat to see, hear, and smell its processes become dependent on gauges and displays to tell them what is happening. The abstractions of analog gauges are compounded by even purer digital representations.

For e-government, distance from both the sources of information and decisions about how it is represented become concerns for its verification. As the scope of government covers more territory, either encompassing more issues or over a wider area, the accuracy and integrity of the information can become attenuated, and therefore less secure.

Because government process is, virtually everywhere, underpinned by information, these issues of information security and integrity grow apace with the size of the government jurisdiction. The problems that scale poses for democracy as a particular form of government were raised by Dahl (1989), along with the possibilities of telecommunications in addressing these problems. The importance of democratic protocols to drive fractal patterns of technology governance was discussed in Geiselhart (1999). Figure 1 illustrates how fractal patterns can provide alternative systems of behavior. In the case of the famous Lorenz attractor, it is the weather system, but similar analyses have been provided for human systems of government (for example, Kiel, 1994).

For a complex adaptive system such as the weather, an attractor is a pattern that recurs with minor variations, such as wet winters. In human systems, all kinds of behaviours can settle into attractor patterns. From individual investment choices to mass movements of stock dumping, human behaviour can also display fractal patterns that repeat at several scales. Democratic attractors may be thought of as those that use negative or normative feedback loops to keep the system from spinning out of control, like a runaway thermostat. Sensitivity to the direction of change is a critical monitoring activity. A reasonable assumption for democratic process is that a dynamic of increasing inequality indicates a system moving further from democratic norms. This is because, given a level playing field of information and a fair voting process, most people would presumably not vote for benefits to flow from themselves. Managed and relatively stable inequality is assumed to be the "basin of attraction" for democratic systems.

Information management, in a broad sense that encompasses verification and communication, is analogous to the problem of infrastructure in a very large building. Bigger buildings, particularly very tall ones, require increasing amounts of resources and space devoted to

Figure 1: Lorenz Attractor, courtesy Paul Bourke, Centre for Astrophysics and Supercomputing, Swinburne University.

moving water, waste, energy, and people efficiently around the building. Likewise, as the size, scope, and scale of government expands, a proportionately large amount of resources are needed to ensure that the information necessary for good government is secure, accurate, useful, available, and democratically accountable. Of course, a dictatorship or a corrupt regime will not need to verify its information in the same way. For the purposes of this chapter, however, it is assumed that, at least theoretically, the goals of e-government aim to support democratic process. The next section outlines some of the factors affecting the management of the global information commons.

E-GOVERNMENT BEYOND NATIONAL BORDERS

Whether it involves buildings or information, efficient management has implications for both infrastructure and administration, which we may think of as a superstructure. For the global information infrastructure, it might be preferable for these to be determined on a practical basis, independent of political concerns. The realities of our globalized world mean, however, that inevitably, there will always be friction between the practical and the political. This leads to considerations of governance as a broad system of management, rather than government as a process of political control. This broader perspective also allows comparison and possibly modeling between government, nonprofit, and corporate systems.

The processes, possibilities, and problems accompanying e-government, as outlined in the previous section, do

not recognize borders. Information has become central to exchanges between governments, as well as the currency of international commerce and communications. Global dynamics influence both the development of information technology and the evolution of e-government. Security in the broadest sense is now a key issue for all governments and is intimately entwined with the ways information is created, presented, distributed, and evaluated. It has become commonplace to think of the global information and communications infrastructure as a virtual neural system. This metaphor encourages consideration of the locus of control for this system. Unlike human neural networks, the networks of e-government do not access a centralized "brain."

Current manifestations of the overlap between international forms of governance and information security and management are the systems for protecting the information infrastructure. Groups such as the Communications-Electronics Security Group (<http://www.cesg.gov.uk>) in the United Kingdom, AusCERT in Australia, and the OECD Working Party on Information Security and Privacy (WPISP) represent high-level networks that bring together governments for collaboration and information sharing on key infrastructure security issues. Each national level group links to subnational groups and non-government players who communicate, negotiate, liaise, diffuse, and take responsibility for various aspects of information infrastructure security.

In Australia, the subnetwork is the Trusted Information Sharing Network for Critical Infrastructure Protection (TISN is at <http://www.tisn.gov.au>). TISN is a forum in which the owners and operators of critical infrastructure work together to share information on security issues which affect critical infrastructure. There are advisory groups for key industry sectors, such as banking, communications, emergency services, food chain, water services, etc. They share information on shared threats and vulnerabilities and appropriate measures and strategies to mitigate risk.

It is, in effect, a diffuse form of governance and management of the critical infrastructure. This infrastructure includes, but is not limited to, information. There is implicit acknowledgment that the wide range of security threats listed are linked through the information infrastructure and that defense of these assets and supplies is dependent on the quality of the information exchanges that monitor them.

Further on this chapter outlines other international issues that are subject to similarly diffuse forms of management. In each case, their effective management is dependent on the governance arrangements for their information networks. Thus, management and security of information necessary for global citizenship is emerging as a form of governance in its own right, but without a unified or democratically accountable locus of control.

Taxation and Representation

One of the triggers of the American Revolution was colonists protesting against taxation without representation. In the 21st century, the protests come from both former colonies and nations who feel that their interests are not represented in international decision making and

revenue gathering. Much consumer, citizen, and corporate activism is spurred by the lack of adequate participatory mechanisms. This presents an enormous challenge for all aspect of global e-governance. Clearly, the ability to amass revenue underpins the legitimacy and therefore also the sovereignty of governments everywhere. Perhaps less widely acknowledged is the way profit aggregation functions as a de facto form of taxation, particularly in trans-national contexts. Systems that allow information relevant to revenue collection to operate securely are as essential for international forms of governance as for existing governments. Corporations that amass and move enormous resources and revenues are increasingly subject to challenges to their legitimacy and calls for greater participation by those subject to their actions. Other dimensions of these twin issues of taxation and representation are discussed later in relation to information equity and the democratic deficit. The requirement for both resources and legitimacy is a key issue for all forms of information management, but particularly for those information security measures that are necessarily global in scope. Challenges of information governance are critical at all scales but are relatively uncharted waters for global issues.

E-Governance of Global Information Commons

At a global level, the telephone system and the Internet can only be managed through collaborative international effort. Short of a global empire or dictatorship, all nations are dependent on each other's good will to enable global communications. Global governance has been defined as "political management at the global level of a given area of human existence in the absence of global government" (Meyer & Stefanova, 2001).

This *Handbook* discusses the security aspects of these issues in depth. The routers and switches of the Internet are linked through an elaborate system of physical and administrative infrastructure. The human networks that manage the Internet include the Internet Engineering Task Force (IETF), but that is just the tip of the iceberg of organizations and agencies that develop and support the protocols that allow information to be transmitted securely. The domain name system of Internet addresses is managed by an international nonprofit corporation with appointed and elected members, the Internet Corporation for Assigned Names and Numbers (<http://www.icann.org>). Attempts to manage the global information commons multilaterally, for the good of all peoples, can be seen in the process for the World Summit for the Information Society, the WSIS (<http://www.itu.int/wsis/>).

In each of these examples, a set of players maps out agendas and actions. Even highly technical areas, such as mobile devices and protocols, have advocates of alternative approaches, standards, reporting mechanisms, and so on. The totality of infrastructure and networks for the establishment, maintenance, and accountability of a particular area constitute its governance. These may overlap, intersect, interfere, or conflict. Ultimately, however, all the pieces form a system, and it may be possible to map the overall patterns as an attractor. It may be functional in

some ways and erratic in others, but the system altogether, changing and amorphous, makes up the global information commons. For democratic governance systems, the direction of change is as critical as the current state of the system. Identifying the patterns or attractors could aid predictability. It might be possible to see the outcomes of information systems with greater or less transparency and participation, by adjusting the number of nodes and rules for interaction between nodes.

The mutable networks that govern the global information commons have some resemblance to biological actors. For example, lawyers arguing about piracy may not be concerned about TCP, and the IETF may have little interest in intellectual property issues when they are developing wireless transmission protocols. Nonetheless, these separate groups might find themselves suddenly involved in negotiation over a common issue that involves all their expertise, such as identify theft. In such a case, a new network can appear, have a role, and fade away again. Although only some of the agencies or individuals might have a formal role, the cluster of actors becomes, at least for a time, an element in the global governance of the Internet. A recurrent theme is that governments are not always the key players in these patterns of global information management. As has been done for biological agents (see Kauffman, 2000), it should be possible to step back from these specifics to model the wider patterns through a normative democratic lens, and determine what outcomes result from existing rules and players.

Management of the collective set of infrastructure, resources and rules that comprises the global information systems is subject to the "tragedy of the commons." First described in relation to overgrazing of herding lands, this term refers to any resource in danger of being destroyed by undisciplined overuse and exploitation. Clover (2004) describes the impending collapse in many areas of fish stocks due to overfishing and the role of actors and governance structures (or rules) at many levels and globally. This issue dramatically illustrates how the failure of governance safeguards for the accuracy of the information, the integrity of the reporting systems and their transparency and accountability are major factors in tilting the system into unsustainability. The pattern formed by the not particularly democratic information value chain for this issue shows a sad but predictable tragedy of the commons in the making. Clover's solution includes the ultimate information-driven transparency: satellite monitoring over the Internet, live and public, of fishing boats. Transparency is a sine qua non of accountability, but cannot ensure it without other elements in the democratic information value chain.

Spam is another example of a failure to manage part of the global information commons. The uncontrolled use of this marketing tool, most of it originating from the United States, illustrates the danger when information resources are not managed in the best interest of the widest group. This imposes costs on everyone, but particularly in a country such as Australia, which has volume-based Internet pricing. Intergovernmental arrangements for controlling this abuse are clearly inadequate, and individual businesses and consumers have little direct ability to influence their governments to enact stronger laws or

interventions. Rather, a wide array of antispam activists, organizations, software solutions and networks at various levels and with varying degrees of formality have been set up to place control in the hands of users. Responses to spam show how power can seep into the gaps to create forms of management, action, and de facto governance where governments have proved inadequate.

Many information security issues are caught up in similar internationalized governance concerns. Legal matters such as identify theft, money laundering, and digital rights management (DRM) are dependent on the wide support of governments. Other aspects, such as standards and protocols for security architecture and products, require the cooperation of corporate players at least as much as governments. In the case of DRM, strong corporate lobbying on governments is countered by assertive activism by individuals and groups. Some elements, such as password protection and antivirus technology, cannot achieve widespread effectiveness unless individuals are adequately informed and motivated to take necessary precautions. The roles of nongovernment players in information security and management is expanded below.

Responsiveness, Monitoring, and Adaptation of Global Information

In addition to the difficulties of authenticating information, timeliness and quality of response also give rise to risk in a globalized world. These inadequacies have the potential to provide dysfunctional feedback patterns because power structures “circle the wagons” to deny or undermine attempts to learn from error. This deliberate political blindness to scientific information is a recurring theme in Clover’s book on overfishing. A recent report from a coalition of nonprofit groups revealed that the U.S. government spent \$6.5 billion in 2003 on preventing new documents from reaching the public domain. The report found that government secrecy is increasing and that secrecy between security agencies is stovepiping information, hindering the war on terrorism (Epstein, 2004).

A dynamic of diminishing access to information also makes it more difficult for the public to get the information people need to make their families safe from environmental hazards, such as the impact of toxic chemicals in the food chain. This is a direct example of information as security. Over the longer term, governance of information affects the capacity for reflectiveness and learning. If the ability to adapt is dampened, information can become not just less reliable, but dangerous. Governments that disguise risk from citizens soon find their legitimacy called into question, and these calls can come from both within and outside jurisdictional borders.

Skolnikoff (2001) outlined some of the pressures accompanying globalization that relate to technology and governance. He noted that domestic and international affairs are two parts of a whole. Governments have become ever more dependent on technology for their information, while the time for response has shrunk. Officials suffer from time scarcity, while the issues they must deal with have grown in scope and complexity. In this framework, they must make decisions which require urgent action, but whose consequences will be felt far into the future.

Often the risks are high, and there may be multiple and perhaps disastrous unintended outcomes. Technical complexity of issues makes officials more dependent on specialists and experts and less able to communicate with their publics. Domestic agencies are drawn into international arenas, often inadequately prepared. Responses are caught up in bureaucratic entanglements with diplomatic offices, and cooperation with other states must be filtered through similar constraints within those nations. Skolnikoff predicted that greater autonomy may eventually be conceded to international organizations, driven by crises and system breakdowns.

Some of those who have been most successful in bypassing or undermining global security systems are the groups that are most able to mutate quickly and adapt to changed circumstances. These survival skills are as essential for legitimate regimes and industries as they are for biological viruses. For governments to survive, they need to adopt principles for information structuring, sharing, and security that mimic the most adept life forms. These approaches have been outlined in some detail for the corporate sector in relation to innovation (Tuomi, 2003) and also governmental and organizational adaptation (Kiel, 1994; Pascale, Millemann, & Gioja, 2000). These sources draw strongly on complex adaptive systems and non-linearity as a new paradigm.

Consistency and Coordination of Global Information

The lack of uniform systems is one of the key features of information flows for international issues. Governments vary so greatly in their capacity to implement secure systems that consistency across nations is difficult to achieve. Coordination of systems suffers from not just technical discrepancies but human resource differences. Coordination is not easily outsourced to an international agency, for both practical and political reasons. A few high level institutions such as the World Bank, International Monetary Fund, and the United Nations have coordination roles, defined by their charter. Such institutions are limited by their bureaucratic distance from the individuals affected by the issues. Only a small subset of international agreements are truly enforceable, and these tend to be those relating to trade. Enforcement of the Kyoto Agreement on greenhouse emissions is limited, whereas the World Trade Organization and the World Intellectual Property Organization seem to have more potent enforcement mechanisms because strong stakeholders support them. As a result, WTO and WIPO agreements are more likely to have procedures for secure information documentation and storage and retrieval.

For most issues, there is no single global authority to direct or manage global information flows. Moreover, there is no direct representation of individuals’ interests. Instead a plethora of amorphous and mutable institutions representing governments, corporations, clusters of organizations, and international entities all act on particular issues, often without coordination between them. Their lack of formal legitimacy and resources hampers their effectiveness. An example of great concern worldwide is cyber crime. Although many groups and levels of

government have a strong interest in both defining and addressing cyber crime, a fully effective coordinated response is inhibited by the wide range of jurisdictions involved and the reticent cooperation of companies such as banks and Internet service providers (ISPs) to divulge commercial information or voluntarily bear associated costs. Furthermore, a government or jurisdiction that secures cooperation from its relevant industry sectors cannot guarantee that local solutions will be effective, as cyber crime, in its many manifestations described in this *Handbook*, is clearly an internationalized issue. As well as being a fundamental issue for information security and management, this problem overlaps with related areas, such as privacy, copyright protection, and electronic commerce. The tangle of approaches to this hydra-headed problem becomes, in effect, another imperfect governance system.

Citizens as well as governments incur blockages when dealing with issues that may affect them profoundly but lie beyond their legal entitlements. Hypothetically, how might a Malaysian obtain information about Indonesian plans to dump nuclear waste in common waters? There is no international provision for freedom of information, for example, to other countries. Citizens often have very limited rights to find out what is being planned, either by corporations or sometimes their own governments. This is one of many information black holes for issues that transcend national boundaries. Professor Alasdair Roberts's Web pages offer a starting point for international freedom of information issues, but there is a long way to go before freedom of information becomes a secure aspect of human rights in cyberspace. Pursuit of information generally has to go through often weaker international bodies with little enforcement capacity. There is little redress for nations, much less individual citizens. Nations can opt out of international agreements and treaties or simply not honor them. Enforcement depends on the cooperation of individual states, whereas within one country, standards for information, services, and reporting can be legislated on a national basis. Digital representation and interactivity also vary enormously among nations, reflecting an international digital divide based on another suite of infrastructure, skills, and attitudinal differences.

Under current arrangements for representation, the institutions for global governance are several links removed from citizen participation. Many countries also lack the democratic institutions and practices that foster effective participation. This has been observed in Asia, where lack of civil society structures delimits participation in the organization that manages the global Internet addressing system (Kang, 2003). However, even countries that rank well on Transparency International's assessments of corruption are subject to a democratic deficit, often in the form of more subtle undermining of democratic process. This is discussed in relation to Australia by Hindess (2004).

At a local or even a national level, it is possible to set priorities that lead to programs and systems to collect and manage the information that underpins government performance. These typically include policing and defense, health and education, but also social and economic goals. The accepted role for government leads to

the services and transactions that are the bread and butter of e-government. Roads and hospitals, schools, and resource management all form part of the commons that governments exist to develop and protect. On an international level, the public goods are not so easy to reach agreement on or to quantify. One country may see its strategic goals in exactly the areas of resource development that may lead to environmental and social upheaval in another country. Even when there is accord on a universal right or a standard, there is contention over the who and how of enforcement. The involvement of non-government agents further complicates the ability of governments to negotiate equitable outcomes. World Bank studies have shown the link between good governance and economic development (Kaufman, Kraay, & Zoido-Lobaton, 1999, 2000). A corollary of this is that when government mechanisms for accountability shrivel, economic implosion may not be far behind.

Many international issues do not have clearly defined stakeholders. By their nature, they lack both geographic grounding and structures for distributed representation. Therefore, questions about the type and presentation of information, services, transactions, forms of communication, and so on tend to be answered according to importance placed on them by those with influence or resources. In the absence of uniform protocols for participation, transparency, and accountability, the establishment and monitoring of best practice in digital representation is difficult to determine and is often more driven by the relevant community of practice and influence than either public need or information technology enthusiasts.

Deterrents to Global E-Governance

The digital and democratic divides that separate nations and organizations present a huge hurdle for both global governance and managing the information commons. Highly developed countries will have organizations that are capable of advanced communications and information management. Countries and regions with few resources or minimal infrastructure will be unable to match these standards. Both their citizenry and their public institutions will be at a disadvantage in negotiating or implementing good information systems. To the extent that monitoring or evaluating a range of agreements or situations depends on information handling, these countries will be unable to exercise effective responses. If non-government players become the primary determiners of information security and control, national sovereignty is correspondingly compromised.

The gap between the "info rich" and "info poor" has long been a concern for many observers of the information society (Lyon, 1988). On a global level, this may be thought of as a scaling up of the digital divide that exists within communities. Areas at greatest disadvantage are likely to be Africa and remote areas of Asia and Latin America. Countries without adequate information infrastructure will not be able to compete economically, and this will further inhibit their ability to participate in shaping the information infrastructure to their advantage. This is also true of rural and remote areas of developed countries. In Australia, the ongoing drive to privatize fully the

telecommunications carrier is being held up by the continuing inadequacy of rural infrastructure. This could become an information-as-security issue, given the vast and vulnerable northern coastline and repeated attempts at illegal landings by people smugglers. Research by the author found that remote electronic points of presence already provide a valuable service in providing information essential for the preparedness, management, response, and evaluation of natural disasters in outback Australia (Geiselhart, 2004b).

In keeping with the concept of a global information commons, the less developed countries may also be the ones whose information is critical for the well-being of the rest of the world. The challenge is to provide them with both the incentives and the ability to participate fully in information management and sharing. Countries are unlikely to be receptive to plans for globalized control of information or its infrastructure while they remain economically disadvantaged. Muslim nations might not be enthusiastic about systems for biometric identification of travelers, for example, if they thought this would place their citizens at risk of intrusive searches and delays. Some organizations claim that a global registration and surveillance infrastructure is being assembled to assist the US in anti-terrorism activities, but with profound implications for privacy and individual security (ICAMS, 2005). This could have implications for cooperation on other information issues, such as health and environment, discussed below.

The democratic deficit that exists even in the most highly developed nations offers a substantial obstacle to effective management of both the local and the global information commons. This, too, may be seen as a pattern that can be modelled and that repeats at several scales. Failures of democratic information process have much greater potential to undermine global security than inadequacies of technical standards and protocols. The democratic deficit embraces at least three interrelated aspects of governance: low voter turnout that reflects public disengagement in and cynicism about the political process; a lack of accountability in government; and the need for international governance in a globalized economy (Axworthy, 2003, 2004).

These problems with democracy that Axworthy described with reference to Canada can directly affect the security of information, as with the U.S. example on increasing government secrecy cited earlier. The democratic deficit can take many forms. A recent report indicates Australian politics is not free from corruption (McLennan, 2004). Sins of both omission and commission via information manipulation, together with the politicization of the public service, have led to debate but not much action. Endorsement of overseas intelligence claims about weapons of mass destruction, leading to commitment of Australian troops against popular opinion, and the subsequent reelection of the government that made those claims, indicates that democratic process is a complex beast indeed. Of course, the public is also part of the value chain of democratic accountability.

The democratic deficit highlights the relationship between security of information and the processes for its verification and transparency. This is particularly pertinent

to global aspects of scientific decision making. Thousands of scientists in the United States, including 48 Nobel Prize winners, have signed a letter claiming political interference in scientific issues. These claims, even if only partly true, indicate how fragile knowledge can be, and the importance of checks and balances for its verification. There may not be much point in sharing information if the authentication and interpretation of that information is compromised. As with electronic financial data exchanges, scientific information needs to be free from both political and technical tampering en route, as it proceeds through policy channels. Climate scientists claim that vital information about global warming is not finding its way into government documents. This indicates the population's right to know is compromised, further weakening the entire chain of decision making. The governance dimensions of information can overtake scientific bias or error as sources of insecurity.

Another dimension to the democratic accountability of public information is the role of the media. It is only possible here to refer to the extensive literature on the role of the mass media in managing public opinion and determining what information is publicly available. A starting point for this research is McChesney (1999). This somewhat vague relationship to information security comes into sharper focus when linked to government procedures for freedom of information. Neither the "free" media nor interested individuals and organizations can easily leap the hurdles that accessing information can pose in even the most open societies. This encourages the informal networks that bypass government channels. The next section expands on the types and roles of nongovernment actors in relation to managing the information infrastructure and networks.

NONGOVERNMENT ACTORS AND GOVERNMENT INFORMATION

Actors outside governments are important influences on the overall flow of information. They are also critical players in the management of the information infrastructure and in the emerging forms of e-governance on specific issues. Networks of varying density and intensity connect nongovernment actors and stakeholders with each other and with governments. Like governments, these actors are also subject to the globalizing pressures of complexity, urgency, unquantifiable risk, time scarcity, and dependence on technological sources of information described by Skolnikoff (2001).

Each of the following sets of actors has the capacity to act and interact with the others and with governments, to form new and unexpected alliances, networks, and patterns of behavior. These can become the seeds of new regimes that support or undermine existing governments. They can also provide de facto forms of transnational e-governance through communities of practice and affiliation. The following perspective draws on Rosenau's "spheres of authority" analysis (including Rosenau, 1997) and Earnest's (2001) discussion of international relations and the changing role of the nation state. The underlying theory is a complex adaptive systems approach applied

to governance, described in titles listed in the Further Reading section at the end of this chapter and in Geislerhart (1999, 2004a).

Corporate Sector

The global corporate sector has a double influence on both national and international aspects of e-governance. As systems and software contractors, they are both the subjects and the providers of digital information. They are strong lobbyists for information policy—for example, stronger IP and patent laws in areas such as biotechnology, entertainment, pharmaceuticals, and genetics. Consistent with the view presented earlier that technology design reflects its sociopolitical context, the systems design and architecture available for e-government are likely to support corporate interests and limitations.

The larger groups are relatively well resourced and often linked to global media systems. As a result, their voices tend to be clearly heard. Their role is to maximize profits, and this can lead to negative externalities. Good governance helps to manage their externalities and avoid tragedies of the commons. Their voice, like that of the public, is not homogeneous, but varies depending on the issue and where their interest lies. Some companies may be less than forthcoming when dealing with privacy invasion, pornography, software security issues, and so on if they are profiting from it. Others will be lobbyists for stronger protections and government intervention on issues that negatively affect them. All stakeholders (except perhaps cyber terrorists) seek stability, consistency, and appropriate forms of coordination.

On many issues, global corporations may band together to solve common problems of e-governance. For example, the development of electronic commerce is taking place through representation by industry bodies as well as intergovernmental panels. The International Telecommunications Union (<http://www.itu.int>), founded on the principle of cooperation between governments and the private sector, is active as part of a set of organizations involved with electronic commerce standards through a number of working groups, memoranda or understanding, and subprojects. Membership across the broad field of telecommunications generally includes policymakers and regulators, network operators, equipment manufacturers, hardware and software developers, regional standards-making organizations, and financing institutions. The ITU overtly states that its “activities, policies and strategic direction are determined and shaped by the industry it serves.” (<http://www.itu.int/aboutitu/overview/role-work.html>, accessed May 13, 2005). Thus, although not formally structured to provide democratic accountabilitys of representation or public good provision, the overall direction is nonetheless part of a sphere of authority that includes governments and their regulatory agencies as partners. It is a mutable, fast-evolving area, and like many organizations, the ITU aims for responsiveness and adaptation as their norm. The ITU has also been running the World Summit on the Information Society, as yet another aspect of their role that overlaps with many other dimensions of e-governance, digital divide and equitable development, and the engagement of civil society.

Another cooperative corporate project relating to e-governance is the Global Reporting Initiative (GRI). Although not directly related to information infrastructure or security, the GRI, like many global projects, makes good use of the Web’s universal interface for its activities. The GRI (<http://www.globalreporting.org/>) is a set of consistent accounting standards used to track social, economic, and environmental outcomes. This is known as triple bottom-line accountability and illustrates how global information management of a particular form of data can occur without formal government or legal obligation. As compliance with these standards spreads, the GRI may become a valuable resource for nations as well as corporations. The impact may flow into the government sector, rather than governments attempting to impose it on the private sector. Accountabilitys of the corporate sector extend beyond the nations where they have headquarters or pay taxes. Even small companies can have global reach, with global responsibilities that are often incompletely defined or enforceable.

Local Nongovernment Agencies

Many local government issues are informed by events elsewhere. Water management, urban design, drugs and crime as social concerns, best practice in early childhood development—the list is extensive. Local government authorities often need assistance in keeping up with this information. Community interest groups are often the best placed to capture and interpret additional information needed by governments. When suitably informed, they can lobby more effectively. Sometimes they can enlist the assistance of wider groups to their cause. A visiting expert with pertinent insights can cause a local welfare group to change direction abruptly in its approaches to a local government. Both success and failure can now be instantly conveyed, leading to reverberations in other localities.

This is not to underestimate the difficulties of transmitting information and gaining the benefits of local experience from around the globe, or even across the district. This is why many projects aim to facilitate networks for learning and sharing across geographic areas or communities of interest. The information networks and patterns of distribution are structural elements along with the actors that access and feed them.

International Nongovernment Agencies

These are an increasingly influential aspect of de facto global e-governance. The number of nongovernment agencies has mushroomed in recent decades. These organizations have the potential to achieve levels of trust that are often no longer available to the nation state, and thus they can speak quasi-independently to the media and over the Internet.

The larger international agencies, such as the Red Cross, Greenpeace, Human Rights Watch, Amnesty International, and Transparency International become respected players on the global relations circuit. Their reports, actions, and spokespersons often have high status at international conferences. They are supported by dispersed publics, their allegiances all the more valuable for being voluntarily given (Ernest, 2001). As part of their

activities, they often contribute to, comment on, and distribute government information and reports. For example, groups such as those involved in antispam activism are players and stakeholders on issues with a direct input to information security. Thus, RIPE (<http://www.ripe.net>) is the regional internet registry for Europe. This independent, not-for-profit membership organisation supports the infrastructure of the Internet through technical coordination in its service region. It looks at issues of wide area IP networks but has formed an antispam working group to assist Europeans and others in combating this Internet plague. Its members, mainly Internet Service Providers (ISPs), telecommunication organisations and large corporations located in Europe and the Middle East, are part of the invisible web of cooperation that helps manage the Internet as a network of networks.

Some groups do not have a formal Web presence. For example, Al Qaeda's information is presented via other fundamentalist Web sites, including video footage of beheadings that has reverberated around the globe. The Chechen resistance is represented through the Web site <http://www.kavkazcenter.com>, which offers news and information about this Islamic uprising in three languages. They have designed the site so that media and others can easily keep up-to-date on their activities and relay this information to wider audiences.

Actors of all persuasions use networked strategies to assert their values and gain dominance. These include social activists as well as criminal and tax evasion syndicates. Extensive networks of information exchange and planning have underpinned, for example, the antiglobalization rallies that have become a feature at high-level international meetings. Indymedia (<http://www.indymedia.org/>) is just one prominent site for alternative news. Another activist group has been involved in the Civil Society gatherings of the WSIS process (<http://www.wsis-cs.org/>).

Political groups that embrace violence will have no compunctions about attacking information resources online to meet their ends. As a form of warfare, their skills are sophisticated and highly committed (Ronfeldt & Arquilla, 2001). Again, these tactics can be difficult for formal government processes to address, partly because they are more flexible, decentralized, and adaptive than bureaucratic structures. Even though they may be part of terrorism and be linked to cyber crime, money laundering, and attacks on infrastructure, their activities can be inadvertently protected by measures to protect identity and privacy online. Their very unaccountability to formal governance processes leaves them free to act and undermine information security globally.

Citizens Without Borders

Less ominously, citizens have responded to globalization with their own transborder activities. One of the best known features of electronic commerce is the ability to reach out to markets internationally. Likewise, activism now is more possible and more effective beyond national limits. Not all of this is mediated through organizations. Some is simple consumer choice that operates on the marketplace, often without political intent. Other dimensions, however, are overtly about creating a voice or change as

diverse members of a diffuse public. One example is birdwatchers flocking together to count birds and incidentally become part of a global scientific project (Garreau, 2001).

Another area of individual (and group) activism concerns the maintenance of predigital rights. As noted earlier, digital rights management, or DRM, has become polarized between strong, almost coercive intellectual property protection versus those who want to protect "fair use" and the open exchange of ideas, information, and artistic expression. The Creative Commons project (<http://creativecommons.org/>) offers an alternative approach to the intense and expensive legalism of copyright law. Piracy and appropriate free use of digital material is one of the most contested areas of global e-governance.

On a formal political level, groups reach out to find the likeminded, regardless of where they might be. Parties set up convenient Web sites so expatriates can enroll to vote. The diaspora of many communities use electronic communications to inform and seek support. When disaster hits (such as a cyclone) or victory arrives (such as being awarded the privilege of staging the next Olympics) the international phone and Web links run hot for days, with congratulations, enquiries, and, if necessary, financial support. Some resource flows become semipermanent, as those in more economically advanced countries feed the organizations and movements of their choice. Inside repressive regimes dissidents continually change Web hosts and utilize all the tricks of online anonymity to get information and stories out.

Individuals need the protection of their identity, money, information, privacy, and so on when dealing within their own borders. This is usually provided by governments through legislation, policing, and so on. These protections are much less available for citizens roaming internationally, either as activists or consumers. This is where globalization gets personal, not just for nuisances such as spam and the notorious Nigerian e-mail fraud, but also for extensions of criminal behavior that endanger lives and livelihoods. Emerging forms of e-governance will need to respond to these concerns.

In enterprises such as Amazon.com, eBay, and myriad others, the inputs from many participants provide the data to shape the system. In advanced forms, the participants actually patrol and regulate the system. For example "eBay vigilantes" help flush out dishonest traders (Cronaca, 2004). Central to this approach is the ability for leaderless action, driven by intent and individual initiative. In human systems, the rules of interaction are generated by the values of the actors (Kiel, 1994; Pascale et al., 2000; Theys, 1998). Conflict between the values of various sets of actors inhibits harmonization of the global democratic information value chain and systems.

The outline just provided highlights the nature of today's globalized information interdependence. It is dispersed, mutable, and often uncontrollable and unpredictable. The following section of this chapter discusses some specific areas of high information security risk where governments are trending toward greater integration of global information systems. These reinforce earlier claims in the chapter about the critical role of information systems and their governance in wider security and sustainability concerns. In nearly all of the areas where

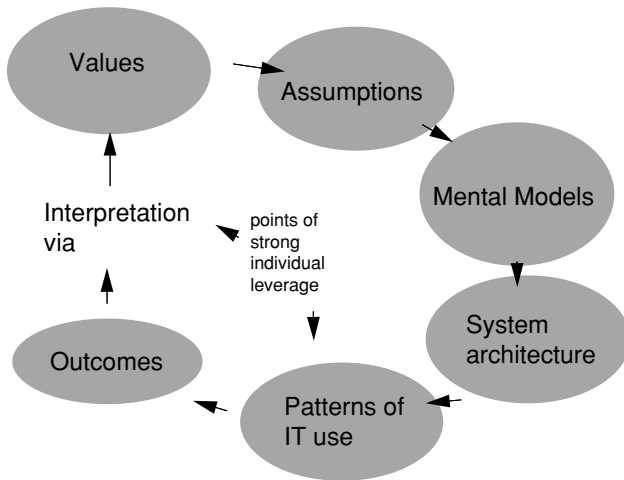

Figure 2: The IT system design value chain (Geiselhart, 1999).

formal governments operate, the processes that manage and integrate transnational information flows have a direct impact on personal, public, and national security. Figure 2 illustrates the cycle of information systems development and the role played by values in shaping these systems. At no point are patterns of governance independent of the values and mental models of the actors who shape them. This highlights the need to articulate and embed democratic values in systems of e-governance.

GLOBAL INFORMATION—AREAS OF HIGH RISK

These areas are indicative of the overlap between national and international information systems and the links between these and global security. For each of these, a long list of actors contribute to the information creating a dynamic sphere of authority, with smaller similar (fractal) patterns at national and local levels, frequently with implications for individuals. Each sphere also overlaps and is interdependent on the others, as illustrated in this section. For each, the key to information as a dimension of security lies in the patterns being created at all levels and how they interact, along with the information flows and their checks and balances. Each sphere of authority contributes to global e-governance on that issue.

International Information: Economic and Financial

The world economy is perhaps the most obvious manifestation of globalization, and the area where global e-governance is most highly coordinated. It consists of industries, flows of goods and services, resource manipulation, advertising and marketing, and consumption by governments, organizations, and individuals. Trade laws and sanctions of various kinds, unilateral, multilateral, and global, enforce and reinforce alliances or enmities. The largest industries, such as energy and agriculture, are subject to fluctuations and crises. These issues affect the ability of less well-developed nations, regions, and individuals

to participate in the global economy because knowledge about innovation is also manipulated through legal and administrative controls, pricing regimes, and so on.

Where representation issues have been resolved, e-governance can be effective. For example, SWIFT (Society for Worldwide Interbank Financial Telecommunication, <http://www.swift.com>) is an industry-owned cooperative that provides the information infrastructure for much of global banking and finance. The banking industry is a “virtual community,” with the capacity to design and manage their information systems to the mutual advantage of stakeholders. As a cooperative, its governance structures have commonalities with democratic representation. International financial and commercial transactions have rigorous requirements for digital documentation. The forms of information security include nonrepudiation, verification, and authentication. The governance role of many hybrid government and industry organizations in setting standards and norms is a theme of this paper. Similar patterns or attractors of representation, negotiation, and collaboration are repeated for many other aspects of the information superstructure.

For many forms of communication between sovereign nations, clarity about information structure, content, transparency, and security is much more elusive. Diplomatic communications, for example, are not likely to travel on public networks without strong encryption. Likewise, documents relating to the negotiation of treaties cannot be entrusted to public systems. Many reports and much research commissioned with public money will be provided to other governments for purposes of negotiation without being made available to citizens of either country. Further, the procedures by which such information might be made public are continually subject to contestability by relevant stakeholders, often on a subject by subject basis. The potential for a unified framework for disclosure, even within one country or jurisdiction, is restricted by political pressures and the bureaucratic artifacts of fragmentation and compartmentalization.

Legal and Administrative Information

Legal matters include taxation, treaties, and intellectual property, along with judicial and criminal issues relating to extremes of behavior from innovation to terrorism. Collecting tax becomes more difficult when individual and corporate actors can move and conceal their money and transactions. Some nations actively provide tax havens, and others seek global sanctions to eliminate them. Some corporate players position themselves to aid and abet tax avoidance as a market opportunity. Individuals as well as companies seek gaps in taxation monitoring and take advantage of the limited cooperation on reporting to shield their income from governments (Geiselhart & Singh, 2001). Addressing these taxation issues is a major concern for nations and relates closely to information security issues relating to support for terrorism. Transparency is the other side of the representation coin for e-governance. As global integration increases, questions of who will guard the guardians of information will intensify.

Again, there are national and nonstate actors, public organizations, and underground groups that seek influence

in each of these spheres. The issues are notoriously entwined. One legal-economic example is the superannuation industry. Individual citizens have accounts and accumulate funds from various employers, in addition to their own contributions. This has a government element because the government agency sets the rules by which citizens can enter or withdraw as well as taxation limits and a whole range of administrative and legal issues. There is also a powerful corporate element because there are companies, both for profit and not for profit, that manage and administer the investments of these funds. Finally, there is also a substantial international dimension because the funds regularly invest both on- and offshore, thus bringing the superannuation fund into communication and perhaps negotiation with international governments, other legal systems, concerns about possible human rights or environmental practices, corruption, and so on.

A random sampler of other legal aspects of global e-governance includes the use of biometrics at national borders; the regulation of radio frequency identification tags on consumer goods; and spim, or the next generation of spam, which is unwanted text messages sent over mobile phones. In addition to their legal and regulatory aspects, each of these has a consumer dimension and a set of privacy concerns, in addition to the purely technical dimensions of standards and transmission. It is not clear where the representation of global citizens' interests falls in each of these. This is one function of modelling, to develop maps of how the parameters interact and identify their sources.

Environmental Information

A growing area is disaster planning, response, recovery, and evaluation. Natural and human events can disrupt the global communication system, precisely when and where coordination of information and response is most needed.

The broader field of secure information relating to environmental communications encompasses details of climate variation and communications about short-term events and medium and longer term dynamics, along with species identification, documentation and preservation, water resource allotment and management, air quality monitoring, and many other issues. Information on these matters is important not only for the ability to preview and model scenarios, but also to adopt precautions and preventive strategies where possible. Information sharing in response to catastrophe, both human and natural, as well as recovery and evaluation to promote learning, are other dimensions of global environmental management. There is an increasing risk of rogue states endangering the planet with chemical or nuclear weapons. One approach to minimizing these risks is international standards for reporting, documentation, and information sharing and enforcement on the total life cycle of materials with the potential to become weapons of mass murder. Many current systems for reporting do not include the full value chain of information to include democratic stakeholders.

The outstanding global example of the environmental dimensions of information as security is climate change. Information on this topic is highly debated. The overlaps with economic, legal, and also health and transport are

self-evident. Alliances are forged along interest lines, and each faction produces copious information to support its stand. The level of risk is extreme, and potential for harmonization is limited by the relative power of key actors. This information cascades to every level of global structure because there is virtually no place on earth that is outside this sphere. Here, too, individual actors have to make risk assessment decisions based on the information available to them locally and their level of confidence in wider sources of information. Many writers are documenting the potential for a global form of 'open source politics' (Sifry, 2004) that compels the kinds of ultimate transparency and citizen monitoring that Clover (2004) has described for fisheries and that he sees on a smaller scale in Iceland.

Other aspects of environmental information reveal why some writers suggest environmental degradation will be the main security risk in this century (Kaplan, 1994). These issues are intimately entwined with the other spheres of authority. Thus concerns about security and quality of water are coupled with globalizing pressures to privatize supply, and increasing dependence on fossil fuels is coupled with uncertainty about reserves. According to Thomas (2001), the greatest undermining factor to security in a globalized system of trade, finance, and ecology is poverty. This may be seen as the weakest link in the democratic information value chain, creating vulnerabilities where disease or terror can fester.

Health Information

Health is a critical integrating area, where forms of information are inextricably caught up in their political context. Health crises are by nature complex and often defy state-centric approaches (Lee & Dodgson, 2000). Nations seeking to go it alone during an outbreak of a new disease, for example, can endanger multiple other populations beyond their borders.

Clearly, this is closely related to environment, but health issues are associated with additional information components that require global information sharing: epidemiological patterns and patterns of antibiotic resistance, new disease vectors, promulgation of best practice, and economically viable approaches.

Lee and Dodgson (2000) have documented the ways in which the patterns of cholera have reflected those of globalization. They maintain that the systemic ills of globalization itself are reflected in health challenges. They observe an erosion of spatial, temporal, and cognitive boundaries. They also note a failure of the rationalist thinking that says these problems can be solved by simply adding more information, when it is the patterns of interconnection that need to be addressed. This is another way of stating the importance of management and governance procedures for existing information.

Health and administrative-legal matters are closely related because the intellectual property arrangements for pharmaceuticals are a key focus for trade liberalization. Bilateralism can dampen plurality and transparency and result in essentially "a covert form of private governance" (Drahos & Henry, 2004). In such cases the information systems are likely to reflect the degree of covertness.

Consider a situation of a biological infestation in an exporting country's wheat crop. This can diminish food supply in one country and national income in another, as well as create hunger and stress at both end points. These large-scale dynamics are mediated at both ends by relevant national bureaus, industry groups, farmer organizations, welfare agencies, and unions. Every point of possible action is a node in a complex array of actors and rules for information transmission. There may be little or no direct communication between the end points of producer and consumer in the two countries. These groups will be more or less dependent on the quantity, quality, and timing of the information made available to them. The security of their livelihood or sustenance may, in the extreme case of famine, be as tenuous as the weakest link in these global flows. Equally important is the chain of accountability for the information that determines whether they will know that information has been withheld or distorted. This chain is only as strong as the civil and political institutions and values that generate the democratic information value chain.

This scenario of interdependence is repeated for other spheres of the global economy. The steel industry would have parallel sets of government, industry, and local worker and consumer groups. These spheres intersect through groups that have an overall role of coordinating economic development, or trade, or occupational health and safety, or biological safety, in the case of wheat. The information systems servicing these diverse actors and agencies can be secure, but closed to scrutiny, or they may be porous and open to review to a greater or lesser extent to those with an interest in holding them accountable. The urgency of each economic strand will depend on its role in the national and global economy and the current dynamics of its production. There is probably little current interest in, for example, the international paper clip industry, except as a very minor product in global steel production and exports.

Transport Information

Our last issue is transport, again connected with the others. The carriage and smuggling of dangerous materials is one aspect, including radioactive substances, chemicals, machines, and equipment of warfare and weapons of mass destruction. Legal and administrative matters overlap, for example, in the insurance arrangements that affect oil tankers and the consequences for spills.

The transport of people is also now a large international trade, both legal and illegal. These people bring not just disease vectors, but challenges to cultural, welfare, political, religious, and legal situations. Tourism is not an unmixed blessing for the host nations, particularly if it encourages terrorist attacks, as in Bali when Australians and Balinese met a common fate. There were claims that the Australian government had knowledge of the impending threat but did not provide warnings. Around the world, more travelers are paying closer attention to whatever information sources they think can provide a margin of safety through information about such matters.

CONCLUSIONS

This chapter has argued that democratic governance processes sit at the centre of information security issues, rather than on the periphery as a desirable but distant goal. It has shown that e-government is now more diffuse, particularly for the many issues that overlap national boundaries. In examining the drivers of e-government that flow beyond the nation state, many examples have demonstrated the other side of the information security coin: information as security. The author suggests that a democratic information value chain enhances transparency and participation and therefore accountability. In this scenario, government information becomes a tool to identify, manage, and defuse risk. The alternative is information as weapon and control, ultimately destabilizing when governments are unable to harness the new integrating dynamic. Yet another possibility is information out of control, where lies, misinformation, and hatred can infect both computers and minds. More optimistically, new forms of organization are emerging that provide "citizens sans frontiers" with the information tools to help shape and manage the global information commons. All these scenarios are the subject of intense debate and speculation. Figure 3 illustrates how actors at various levels or scales of influence might combine to determine the processes of information exchange. This figure is part of important work now being done on the role of open standards and social networks in developing trust relationships for Internet governance (see Reed, Le Maitre, Barnhill, David, & Labalme, 2004).

Given the paradigm shift toward a complex adaptive systems approach in recent years, it is likely that this perspective will inform modeling the protocols for a democratic management of the global commons. It is hoped

Figure 3: Representation of the ways groups can form membership in other groups in fractal patterns at many levels of complexity (from Reed et al., 2004).

that international e-governance and democratic information systems may eventually converge as part of a triple bottom line to address current environmental and political crises.

For all the issues discussed in this global context, the security of information is only as good as its distribution, management and governance. This chapter has provided a brief overview of the international dimensions of government information, and the implications for security. Information security and measures for transparency and accountability are an integral part of the risks associated with each issue. Issues with greatest acceleration are subject to the greatest risk, as these have the potential for sudden bifurcations. The compression of time makes pattern recognition more urgent, as does the interaction between issues and regimes to manage them. Government collection, creation, and dissemination of information is always and intensely a matter of national security. It is likely that modeling and simulations of governance, based on patterns for information creation, verification, transmission and access will become as common as economic and climate modeling is today.

Future research on international dimensions of e-government is needed to determine the forms of information sharing and management that will be most productive of protecting the global information commons. These may eventually take the form of protocols, growing out of such processes as the WSIS. There have been many attempts to codify the design features of democratic information systems, including Sclove (1995) and Geiselhart (1999). These principles for electronic democracy are based on a report from the OECD (2003) and may suggest the following avenues for research into specific information projects with global dimensions:

- create new public spaces for political interaction and deliberation
- provide for multidirectional, interactive communication flow
- integrate e-democratic processes within broader constitutional structures and developments
- facilitate and summarize public inputs
- ensure information is of high quality and trustworthy
- recruit the widest range of public voices
- provide equal access to the democratic process.

Another possibility is the development of an international charter of rights relating to the global information commons. Preliminary work on this has been done by Cameron and Geiselhart (1997). Work on the effects of information transparency and availability should help to establish which patterns are most productive of both information security and democratic process.

GLOSSARY

Attractor A state, condition or pattern that a system tends to stabilise in

Complex Adaptive System A system based on agents and rules for interaction, typified by evolution and unpredictability.

Democratic Deficit The gaps between formal democratic processes and government functioning and accountability.

Digital Divide The gap in communications technology knowledge, skills, and use between different groups.

Global E-Governance The electronic dimensions of emerging mechanisms for managing transnational issues and resources.

Global Information Commons The total human and physical infrastructure that supports the flow of information globally.

Globalization The process of increasing interdependency among countries, accompanied by convergent patterns of economic development and technology use.

Fractal Patterns that repeat at different scales, such as a coastline, or behaviors and institutions.

Triple Bottom Line Accounting procedures that include economic, environmental, and social elements.

INTRODUCTION

The Internet consists of millions of digital passages that carry signals all over the world. These conduits, which connect us to the World Wide Web, come in many shapes, sizes, and modes. The bewildering assortment and seemingly endless conduits, more commonly referred to as communication media, that are used to connect computers together can be boiled down to two types: conductive cable and wireless. Conductive media is simply a hard-wired connection, which requires someone to physically join network devices with some type of cable. The three major types of cable are coaxial, twisted pair, and fiber optic. The focus of this chapter is on conducted communications media. Wireless communication is the alternative to conducted communications media. This is accomplished using a variety of broadcast transmission technologies, including radio, terrestrial microwave, and satellite communications.

To aid in understanding conductive communications media, a short explanation of network transmission basics is discussed, followed by a detailed exploration of the three major types of media, mentioned earlier. In addition, a presentation of the similarities and contrasts between these media is provided. Finally, the suitability and application of each type of conducted media along with security concerns are discussed.

OVERVIEW OF NETWORK TRANSMISSION BASICS

Network Transmission Basics

When computers communicate over the Internet or on private networks, they must follow certain communication protocols. In short, each computer that connects to a network must follow rules that govern the type of hardware and software that is used for access to the network. These protocols consist of signal types and speeds, cable layouts, and communications access schemes.

Baseband and Broadband

Bandwidth is the range of frequencies that a particular network transmission media can carry. It also reveals the

maximum amount of data that can be carried on the medium. A baseband transmission is a single, fixed signal that uses the entire available bandwidth. Baseband signals use a single channel to communicate with devices on a network, which allows computers to transmit and receive data on one cable (Tittel & Johnson, 2001). Baseband communications are typically used for local area networks (LANs). When LANs expand into a metropolitan area network (MAN) or a wide area network (WAN), baseband systems do not provide the bandwidths that are adequate for these larger networks.

Network connections that attach several LANs together, such as MANs or WANs, or that allow remote access from external users or networks to local servers often require multichannel bandwidths because of increased traffic flow. Broadband transmissions help to meet these needs. In contrast to the discrete digital signals produced in baseband communications, broadband transmission generates an analog carrier frequency, which carries multiple digital signals or multiple channels. This concept is much like cable television systems that carry many channels on one cable.

The decision to use baseband or broadband is determined by the application. If the network consists of a single LAN, baseband would be the best choice. If an organization has computer networks that spread over several geographic areas, multiple channels of communications between locations may be needed, which can be achieved only through broadband applications. Note that it is the network type and the particular network device that determines whether a signal is baseband or broadband, not the transmission media.

Cable Access Methods

A cable access method is how data are placed on the transmission media. Data are formatted into small pieces called packets. A packet contains header and trailer information about the contents, destination, error checking, and the actual data. A packet typically contains a specific amount of information, normally 1 to 2 Kbytes that is defined by the particular network protocol being used. It is a lot like an envelope used to hold a letter to be mailed. The outside of the envelope contains a destination address along with

Figure 1: Star topology.

sender information. This information is used by the postal service to deliver the mail to its destination. When a wrong destination address is used, the postal service can notify the sender by means of the return address. Network packets are handled in a similar way (Tittel & Johnson, 2001).

Packets are placed on the communications line in several ways. Typically, the communication media used in a LAN will be shared by all network devices. In most cases, only one device can transmit information on the communication media at a time. This will often be in the form of a broadcast. A broadcast by a computer will be received by all of the devices connected to the particular network segment. For example, Ethernet, a widely used LAN protocol, uses a cable access method called carrier sense multiple access with collision detection (CSMA-CD). This method is a lot like a two-way radio broadcast, which allows only one person to talk at one time. CSMA-CD requires each participating network workstation to first listen to the communication line to determine whether it is clear before attempting to broadcast a packet of information, because it is possible that two or more workstations will begin broadcasting their packets at almost the same time. If this occurs, the collision detection (CD) feature of CSMA-CD will instruct the conflicting workstations to cease transmissions and assign a random delay before they are allowed to attempt to send another packet of data. Without a random delay, the colliding workstations would continue to rebroadcast at the same time, causing more collisions. Occasionally, a defective network interface card (NIC) may cause excessive collisions by constantly broadcasting packets. This is called a broadcast storm (Tittel & Johnson, 2001).

A similar access method, used by AppleTalk networks, is called carrier sense multiple access with collision avoidance (CSMA-CA). This scheme is similar to CSMA-CD except that CSMA-CA attempts to avoid collisions altogether. Network devices accomplish this by sending a short broadcast requesting control of the network segment before sending a packet. This helps prevent collisions of

Figure 3: T-connector.

complete packets, thus reducing network traffic due to rebroadcasting packets (Tittel & Johnson, 2001).

Another type of access method is called token passing, used by token ring protocol. Token passing eliminates network collisions altogether by passing a token from node to node on the network in one direction. A token is similar to a packet. When a network device receives a token, it examines it to determine whether its contents are for that particular node. If not, the network node rebroadcasts the token to the next device on the network. When the token finds its destination, it unloads the data and rebroadcasts an empty token to the next device. The empty token will ask each passing node whether it has any data to send. The empty token is passed on down the line until a device generates information to place in the empty token (Tittel & Johnson, 2001).

Network Topologies

A network topology is the physical cable layout or configuration. There are three basic types: star, bus, and ring. Each network protocol (i.e., Ethernet, token ring) will specify the cable type and topology supported. The star topology, as illustrated in Figure 1, requires a central wiring point for all network devices on a particular network segment. A device called a hub or concentrator is used to serve this purpose. A hub is a multiport repeater that regenerates signals received. In some applications a device called a switch is used. A switch is more intelligent than a hub because it can learn which devices are connected to its ports and send packets directly to the destination port only, thus reducing network traffic.

Figure 2: Bus topology.

Figure 4: Terminator.

The bus topology (see Figure 2) requires no special external device for computers to connect to. It consists of network nodes connected to the communications media via a special T-connector that connects the computer's NIC to the bus (see Figure 3). You will notice in Figure 2 that a small box is shown at both ends of the bus. This represents a terminator that is required for this cable layout (see Figure 4). Its purpose is to prevent signal bounce, which occurs when a cable is not terminated. Signal bounce is the result of a broadcast signal that continues to oscillate. The terminator is used to absorb the signal once it has reached the end of the cable, thus eliminating signal bounce.

The ring topology (see Figure 5) is similar to bus topology in that each computer is connected directly to its neighbor without the need for a hub or other special device. The big difference between the two is that ring topology provides a closed-loop design, which does not require termination.

In some applications more than one topology may be used. For example, the token ring protocol uses a topology called a star-wired ring, as shown in Figure 6. In this example, multistation access units (MAU) or concentrators

Figure 5: Ring topology.

are used to connect the network devices. The MAUs are then connected to each other in a physical ring configuration. The physical connection to the MAU represents the star portion of the topology; however, a logical continuous ring is actually created when using MAUs and the token ring cabling system. Figure 6 shows only the physical connections even though a token is passed into and back out of each MAU port that has a device connected to it in a continuous loop, which forms the logical ring.

Each topology has its advantages and disadvantages. For example, the bus topology has the advantage of low cost because it does not require any special devices to connect computers. A disadvantage, however, is that if there is a break in any of the cables, the entire network segment will go down because of a loss of termination. On the other hand, computers connected to a star topology would most likely remain operating on the network if one of the cables malfunctioned between a device and a hub. Star topology requires more wire than a bus topology, and it also requires hubs or switches, which is more costly. Ring topology has an advantage over bus and star topologies because it typically provides an alternate path for data transmission in case of a cable break. For instance, a star-wired ring topology provides a logical continuous ring that provides a redundant path if a cable was cut.

Figure 6: Star-wired ring.

The purpose of this section on network transmission basics is to help you understand the concepts and characteristics related to conducted transmission cable. Each media type differs in physical and electrical-optical characteristics, as well as in application. The following section discusses the three major types of conducted transmission cable: coaxial, twisted-pair, and fiber optic.

COAXIAL CABLE

Coaxial (coax) cable is used in a wide range of applications, including television, radio, and computer network communications. This section looks at the physical makeup of coaxial cable and the specific characteristics that distinguish the different types of coax.

Components

Coaxial cable consists of an inner and outer conductor that share the same axis, which is how it got its name, coaxial (Carr, 1999). The inner conductor, sometimes called the conducting core, is typically made of a copper alloy. Most applications use a solid core, except where flexibility is required, and then a stranded core may be used. The outer conductor is either braided metal or foil, which acts as a conductor and a shield to reduce interference. An insulator, or, more accurately, a dielectric, is between the two conductors. Depending on the type of coax, this material is made out of Teflon or an inert gas. Finally, for protection, there is an outer sheath that surrounds the inner components. This is made from PVC (polyvinyl chloride), or special fire-retardant material, for installations where wire must be run in the plenum areas above the false ceilings in a building (Carr, 1999; Tittel & Johnson, 2001).

Coaxial cables come in a variety of forms: flexible, helical line, and hard line. Flexible coax is made of flexible material in the outer conductor, typically braid or foil. This cable is mostly found in LANs and home television-to-antenna connections. Helical line coax is a semiflexible cable that consists of a slightly more rigid, spiral-wound outer conductor. Normally, this type of cable is used for network backbones or interconnections between networks that require long cable runs. This type of cable is able to carry a signal over longer distances at higher frequencies than can flexible cable types. Hard-line coaxial cable is used to connect equipment that transmits in the microwave frequency range. This form of coax uses a thin-walled pipe as an outer conductor, which is rigid and difficult to work with. As the frequency of a transmitted signal increases, there is a greater chance of the signal radiating beyond the outer conductor, which also acts as a shield, thus resulting in signal loss, or in the case of external electromagnetic interference, the type of outer conductor will determine which frequencies will be rejected from the transmitted signal (Carr, 1999).

Another characteristic of coaxial cable is its impedance. Impedance is the resistance of a cable to the transmitted signal, which is measured in ohms (Tittel & Johnson, 2001). Carr (1999) stated that the lowest loss of signal occurs at higher impedances; however, more power can be achieved when the impedance is low. Cable

television uses coaxial cable rated at 75-ohm impedance because of its lower signal attenuation with long cable runs. Most network and radio applications use 50-ohm impedance as a middle ground between low signal loss and more power.

Cable manufacturers use a radio government (RG) specification for the coaxial cables they produce. Cable television uses RG-6, RG-11, or RG-59 spec cable. All of these are rated at 75 ohms. RG-6 and RG-11 are larger diameter cables used for major trunk lines. RG-59 is employed between the trunk lines and the customer's television.

RG-58 and RG-8 are 50-ohm cables used for computer network communications. As does cable television, computer networks use trunk lines to connect network segments together. RG-8 is the cable used for trunk lines or network backbones and is often referred to as thick-wire Ethernet, or thicknet for short. RG-58 is used with thin-wire Ethernet, or thinnet, to interconnect smaller segments of the network (Tittel & Johnson, 2001).

Coaxial Cable Network Applications

Thick-Wire Ethernet

Thicknet (RG-8) is typically used as an Ethernet backbone to connect various network segments together. Thicknet can be used to directly interconnect devices on the network, but usually thinnet is used for this purpose. Thicknet uses the bus topology with the CSMA-CD cable access method. Normally it is used as a network backbone, which consists of a length of RG-8 cable with network devices, such as hubs, connected to it. Each device connected to the backbone requires a special device called a transceiver. The transceiver is connected to the coax by use of a vampire tap (seeFigure 7). A special cable then attaches the transceiver to the device through its AUI (attachment unit interface) port (seeFigure 8).

Each conducted transmission cable exhibits certain standardized characteristics that describe its advantages and disadvantages within network applications. Table 1 describes thick-wire Ethernet characteristics. Each cable type reviewed contains similar specifications. The reason there is a maximum length is because of attenuation, which is the reduction in signal strength that occurs as cable lengths increase. At some point, the signal loss becomes excessive and causes the network to stop functioning. As with this and other wire specifications,

Figure 7: Thick-wire coax attached to transceiver via vampire tap.

Figure 8: AUI (attachment unit interface) cable connected to a transceiver.

cable manufacturers rely on IEEE (Institute of Electrical and Electronics Engineers) standards when producing their products. The Ethernet standards for thicknet and thinnet are covered in the IEEE 802.3 specification (Tittel & Johnson, 2001).

Table 1 shows a total network cable length of 2,500 m, which is based on the 5-4-3 rule. This rule states that each network cannot exceed a total of five cable segments connected by four repeaters, with not more than three of the segments populated by nodes (see Figure 9).

Figure 9 shows five complete cable segments. Each segment is connected to a device called a repeater. A repeater is used to compensate for the attenuation caused by cable lengths that exceed 500 m for thicknet. Its function is to amplify and repeat what it receives so that its signal will be strong enough to reach another repeater or the end of the next cable segment. Note that two segments do not have any network devices connected to them. This implies that only three of the five segments may have network devices attached. Tittel and Johnson (2001) stated that in reality what this means is that any two network devices cannot

Table 1 Thick-Wire Ethernet Specifications

Characteristic	Specification
Maximum cable segment length	500 m
Maximum total network length	2,500 m
AUX (drop cable length)	50 m
Maximum number of devices per segment	100
Maximum number of segments	Five connected by four repeaters, with not more than three populated segments
Bandwidth	10 Mbps (megabits per second)
Termination	50 Ohms
Cable Access Method	CSMA-CD

AUI = attachment unit interface.

be separated by more than four repeaters (five segments) with three populated segments. So the 5-4-3 rule does not say a network is limited to only five segments. It states only that network devices cannot communicate with each other if they are separated by more than five segments.

The AUX or drop cable length refers to the cable that attaches to the transceiver unit connected via the vampire tap to the thick-wire Ethernet backbone. This type of connection is used to connect such devices as repeaters or hubs to the Ethernet backbone. The AUX cable must be fewer than 50 m long.

Table 1 shows a maximum of 100 devices per segment for thick-wire Ethernet. Every time a device is attached to an Ethernet backbone, there will be some signal loss. Any device attached beyond the limit is not guaranteed to function properly. When designing a network, these limits should not be pushed. If a segment is fully populated, there is no room for expanding your network without adding another segment, assuming that the network is not already comprised of the maximum allowable five segments.

Some IEEE specifications, such as bandwidth, are preset and cannot be altered. If the network bandwidth will not support the needs of the network, a different protocol or standard will need to be used. The bandwidth specification of 10 Mbps for thick-wire Ethernet describes how much data can be transmitted, which ultimately determines the speed of communications. As with all bus topologies using coax, a terminator is required at both ends of the bus to eliminate signal bounce. Because thicknet coaxial cable is designed for 50-ohm impedance, a 50-ohm terminator is required. A terminator is simply a connector that has been retrofitted with a 50-ohm resistor between the inner and outer conductors.

Thinwire Ethernet

Networks can be quickly set up using little more than RG-58 cable and a few connectors. Thin-wire cable is commonly used to interconnect computers or other network devices on a network segment using the bus topology. In the past, thinnet was one of the most popular transmission cables for Ethernet networks because of its low cost and ease of setup.

Thinnet cable uses a special connector, called a BNC (British naval connector or bayonet nut connector) connector (see Figure 10). Computers and other network devices are connected to the bus topology by way of a BNC T-connector (see Figure 3), which connects to the NIC. The NIC is a transceiver that provides the physical connection between the network device and the transmission media. In addition, the NIC is responsible for packaging the data coming from the network device into a form acceptable to the network cable.

As with thicknet, thinnet follows the IEEE 802.3 standard with regard to the use of RG-58 coaxial cable. Table 2 summarizes these cable specifications. You will notice that thinnet characteristics are similar to thicknet except in cable lengths and number of devices per segment. Also, there is no specification for a drop cable for thin-wire Ethernet because the NIC card serves the same function as the external transceiver used by thicknet (Tittel & Johnson, 2001).

Figure 9: 5-4-3 rule diagram.

The physical characteristics of thin-wire coax attenuate signals over shorter distances than does thick wire. This is typically not an issue because thinnet is normally used to interconnect computers within a relatively small area. In situations where computers need to be separated by more than 185 m, a repeater can be used to accommodate these devices. The low cost of this wire often outweighs the distance limitations.

The number of devices that can be attached to a thinnet bus topology is 30. This is fewer than can be attached to thicknet because of the reasons noted in the previous paragraph for cable length. Be aware that a network can have more than one segment. With repeaters, thin-wire Ethernet can support multiple populated segments. The 802.3 standard specifies a maximum of 1,024 devices per network as long as the 5-4-3 rule is followed (Tittel & Johnson, 2001).

In addition to network protocol standards for Ethernet and token ring, IEEE references cable-type standards such as 10Base5 and 10Base2 for thick wire and thin wire,

Figure 10: British naval or bayonet nut connector (BNC).

Table 2 Thin-Wire Ethernet Specifications

Characteristic	Specification
Maximum cable segment length	185 m
Maximum total network length	925 m
Maximum number of devices per segment	30
Maximum number of segments	Five connected by four repeaters, with three populated segments
Bandwidth	10 Mbps (megabits per second)
Termination	50 ohms
Cable access method	CSMA-CD

CSMA-CD = carrier sense multiple access with collision detection.

respectively. The number 10 represents the bandwidth of the cable specification. Base refers to a baseband (single-channel) signal type and the last number represents the maximum length of a network segment in meters rounded to the nearest hundred. For example, 10Base5 refers to a coaxial cable that carries a baseband signal transmitted at 10 Mbps with a maximum segment length of 500 m (thicknet). Thinnet is referenced by 10Base2, meaning a baseband signal with a 10-Mbps bandwidth at 200 m, approximately. In reality, thin-wire Ethernet can only support 185-m segments. Twisted-pair and fiber optic cables carry 10BaseT and 10BaseF IEEE cable standards. These are discussed in more detail later.

There are several advantages to using coaxial cables for computer networks. For LANs, RG-58 uses the bus topology, which offers lower cost options and ease of installation. Also, the outer shielding of coax provides moderate protection from interference. 10Base2 applications allow for fairly long cable runs compared with other cables, such as twisted pair. The major drawback of coax is its narrow bandwidth compared with contemporary applications using twisted-pair and fiber optic cable. Plus, thicknet installations can be somewhat difficult and expensive because of the rigidity of the cable, the rather difficult task of installing network connections, and the overall cost of the interface devices.

TWISTED-PAIR CABLE

Twisted-pair cable consists of one or more pairs of twisted wire. Twisted pair has a longer history than coaxial cable, but its usage was restricted to voice only until the 1980s. Omnet or 10Net began to use twisted pair in the early 1980s for PC-based LANs. One of the first PC applications using twisted-pair cable was in 1984, when IBM introduced the token ring network protocol. By the end of the 1980s, Ethernet technology began using twisted pair. Some advantages of twisted-pair over coaxial cable include its light weight and flexibility, and in some cases, existing twisted-pair cables within buildings can be used without having to install new wiring (“Cabling,” 1999).

Components

Twisted-pair media come in one of two forms: STP (shielded twisted pair) or UTP (unshielded twisted pair). STP consists of several pairs of twisted wires that are surrounded by a foil shielding and an outer jacket or sheath. The number of wire pairs can vary from either two or four for basic telephone and network applications, to hundreds of pairs for major communication trunk lines. Each wire within the pair consists of a solid or stranded copper center core surrounded by an insulating cover. Stranded wire is typically used where greater flexibility is required.

The reason for the twist in each pair of wire is to reduce crosstalk. When a signal travels down the wire, it produces a magnetic field. If not controlled in some way, this can produce unwanted interference with other pairs of wire within the same cable (crosstalk). The twist in the pairs works to reduce the effects of crosstalk. It also helps to reduce the magnetic field’s effect on other pairs. Cables with more twists per foot offer the best performance

Figure 11: Unshielded twisted pair (UTP) cable.

and are normally more expensive. The foil shielding that surrounds the twisted pairs blocks sources of interference from electronic noise outside of the cable in addition to keeping stray noise from escaping to the outside world. STP is often the choice of transmission media when heavy electrical or electronic equipment exists near cable runs.

The outer sheath exists to protect the inner components of the cable. Like many cables, twisted-pair jackets are made of some form of PVC or special plenum sheaths that are used in applications that require nontoxic and fire-resistant cable.

UTP is basically the same as STP except that it does not have a foil shield (see Figure 11). Without the shield, it is more prone to crosstalk and other forms of interference, although some crosstalk is reduced because of the twists in the pairs of wire.

UTP is probably the most popular cable type for networks today. The Electronic Industries Alliance (EIA) and the Telecommunications Industries Association (TIA), with the endorsement of the American National Standards Institute (ANSI) have defined several categories of UTP cable for different applications (“Cabling,” 1999; Fogle, 1995; Tittel & Johnson, 2001). Category 1 is traditionally used for telephone and voice transmissions. Category 2 is capable of data transmissions of up to 4 Mbps. Category 3 is certified for up to 10 Mbps for 10BaseT Ethernet and suitable for 4-Mbps token ring. New technology applications, including 100BaseT4 and 100Base-VG AnyLAN, can utilize this lower rated cable for 100-Mbps bandwidth. Category 4 can handle up to 16 Mbps, which includes token ring 16 Mbps and 10-Mbps Ethernet applications. Category 5 cable type supports bandwidths of up to 100 Mbps. Category 5E cable has been tested up to 400 MHz and supports 1,000 Mbps under the 1000BaseT (gigabit Ethernet) standard. The Category 5E cable is the cable of choice today because of its enhanced features and has taken the lead in twisted pair applications. Categories 6 and 7 are newly developed or in the development stage. These cables will basically support

Figure 12: RJ-45 connector.

higher bandwidths, further reductions in crosstalk, and increase stability at frequencies above 500 MHz (Global Technologies, 2002).

Twisted-Pair Cable Network Applications

Twisted-pair cable uses a special modular connector. Standard telephone wire uses a four-connection plug called an RJ-11. For network applications, an eight-connection RJ-45 is used (see Figure 12). UTP cables often consist of a solid core with a thin layer of insulation. The installation of RJ-45 connectors, called insulation displacement connectors (IDCs), requires a special tool that pushes the insulated wire into the connector. When each wire is pushed into the connector, the insulation is sliced just enough to make contact with the center core of the wire (Spurgeon, 2000).

Twisted-pair cable is typically used for point-to-point wiring, such as with star topology configurations. UTP is connected to a network device via a NIC card's RJ-45 jack (see Figure 13), with the other end connected to a hub, switch, or router. In some cases, a patch panel or punch-down block may be used to better organize cabling before it is attached to the devices.

There are several IEEE Ethernet standards for twisted-pair media. The most documented are the 10BaseT, 100BaseT, and 1000BaseT standards (see Table 3). All twisted-pair Ethernet standards require a maximum cable length of 100 m and use star topology, which allows only one network connection for each cable segment. You

Figure 13: RJ-45 connection to a network interface card.

Table 3 Ethernet Twisted-Pair Cable Specifications

Characteristic	Specification
Maximum cable segment length	100 m
Maximum number of devices per segment	1
Bandwidth	
10BaseT	10 Mbps
100BaseT4, 100BaseTX	100 Mbps
1000BaseT	1,000 Mbps
Topology	Star
Cable access method	CSMA-CD

CSMA-CD = carrier sense multiple access with collision detection.

may note that this is considerably less than the coaxial cable specifications. It is much more difficult to control high-frequency signals over twisted pair; thus, shorter cable runs are used to cut down on the effects of a harsher electrical environment (Spurgeon, 2000). The major differences between 10BaseT, 100BaseT, and 1000BaseT are their bandwidths: 10, 100, and 1,000 Mbps, respectively.

Each IEEE specification describes which wire type is most suitable for a particular application. Category 3 cable is adequate for 10BaseT applications. In fact, only two of the four pairs of wire are actually used. The 100BaseT standard is a bit more complicated. There are three cable configurations for the 100BaseT standard: 100BaseT4, 100BaseTX, and 100BaseFX. 100BaseT4 can produce 100-Mbps bandwidth using all four pairs of category 3, 4, and 5 cables. With 100BaseTX, only two pairs of category 5 or 5E cable are used to transmit and receive at 100 Mbps. 100BaseFX is the fiber optic extension for 100BaseT. 100BaseT is often referred to as fast Ethernet.

One of the newest technologies, gigabit Ethernet, transmits 250 Mbps over each of the four pairs of category 5E wire simultaneously for a total bandwidth of 1 Gbps. Gigabit Ethernet is ideal for network backbones that connect network switches and hubs together. Many are now talking about 10 Gigabit Ethernet, which is in its early stages development and implementation. Currently the IEEE specification for 10-Gigabit Ethernet is for the use of fiber optic cable, but development for a copper based standard is underway and predicted to be completed within the next few years. Once a twisted pair specification comes for fruition, the cost for this super high speed Ethernet standard will be greatly reduced (10 Gigabit Ethernet Alliance, 1999, 2002; Tittel & Johnson, 2001; Violino, 2003).

Ethernet standards for UTP follow TIA/EIA 568 standards. Wire pairs within a particular category of cable are color coded. The preferred 568 standard dictates that wire pairs will consist of a green wire paired with a white wire with a green stripe, an orange wire paired with a white wire with an orange stripe, a blue wire paired with a white wire with a blue stripe, and a brown wire paired with a white wire with a brown stripe. Each pair will be attached to a specific connection on the RJ-45 connector (see Figure 14). Tip and ring are used to identify the connections made by each pair. These terms come from the old telephone systems, which required a patch cable to connect one telephone line to another. The connector on the patch

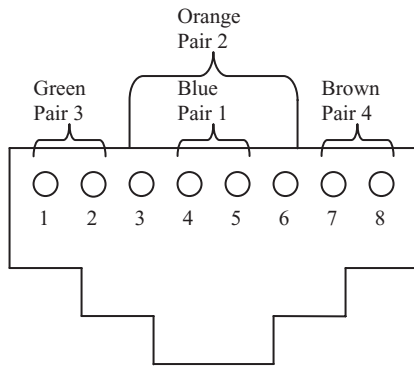

Figure 14: T568A wiring scheme.

cable consisted of a tip at the end and a ring separated by an insulator that separated the two conductors. These two conductors provided the path for transmitting or receiving communications. Traditional analog telephone lines require only one pair for operation. Network transmissions typically require two or four pairs. Note the earlier discussion regarding the required pairs for each of the Ethernet standards 10BaseT, 100BaseT, and 1000BaseT (Spurgeon, 2000).

The majority of network device connections using UTP use straight-through wiring, which means that both ends of the RJ-45 connector are wired exactly the same way. Each pair of cables either transmits or receives data. Likewise, each NIC card transmits data through certain connections and receives through others via its RJ-45 port. If a straight cable was connected to two NIC ports, the result would be that the transmit connections of both ports would be connected to each other, as would the receive links. It should be apparent that when one NIC card transmitted, the other would not receive it because of the direct connections between the ports. Therefore, there must be some kind of crossover that makes a connection between the transmit and the receive pairs. In reality, most network connections between devices are made via hubs or switches. These devices provide the crossover for the transmit and receive pairs.

For some applications, a special cable called a crossover cable is required. A crossover cable is made by crossing pairs two and three on the opposite end of the connecting cable. This allows you to connect two network devices together independently without using a hub or other central wiring point. For example, if you had a small office with two computers that you wanted to network, you could build or buy a crossover cable and connect the NICs from both computers together to form a small network without the expense of a hub. Crossover cables are also used to connect hubs or switches together if they are not supplied with an uplink port. Uplink ports are optional ports that take care of uncrossing the links between these centralized wiring points.

In comparison, there are several advantages and disadvantages to twisted-pair and coaxial cabling. Coax appears to have the distance contest won; however, it is waning with regard to the bandwidth race. During the mid-to-late 1980s, coax was the wire of choice, but now twisted-pair seems to be the predominate cable used for most

LAN interconnections. Twisted-pair cable offers great flexibility within network design and layout. Even though maximum cable runs are shorter than coax, 100 m is still a significant distance for most network connections. With applications being developed to use the newest categories of UTP, Categories 6 and 7, the potential advances for twisted-pair cable are encouraging with regard to increased bandwidth and expanded connection options.

Token Ring Cabling

In the mid-1980s, IBM developed the token ring architecture that used a special type of twisted-pair wiring. IBM engineered a cabling system that included nine cable types, numbered from one to nine. These cable types included STP, UTP, and fiber optic mediums. For token ring networks, types 1 (STP) and 3 (UTP) were the most prevalent. Type 1 cable allowed for lengths of up to 101 m, with a maximum bandwidth of 16 Mbps. Because of its lack of shielding, type 3 cable runs were limited to 45 m and a bandwidth of 4 Mbps (Tittel & Johnson, 2001). Today, most token ring applications use UTP category 3 or 5 cable with RJ-45 connectors. As noted in Table 4, there have been some improvements in cable lengths with the use of this media (Feit, 2000).

The IEEE specification for token ring is 802.5, which describes the bandwidth of 4 or 16 Mbps using the token passing cable access method. In 1999, High-Speed Token Ring (HSTR) introduced an improved bandwidth of 100 Mbps with twisted-pair or fiber optic cable. Token ring uses a star-wired ring topology (see Figure 6). Fault tolerance is probably the biggest advantage the token ring architecture has to offer because of the logical continuous ring that is created when using the IBM cabling system along with the star-wired ring topology that provides a dual path for data transmission. Theoretically, if a cable is cut, the token ring network can continue to operate because of the redundant path. Another plus is the use of the token passing access method, which eliminates collisions (Dean, 2003; Feit, 2000; Tittel & Johnson, 2001).

FIBER OPTIC CABLE

The bandwidth capacities of coax and twisted pair are dwarfed by that of fiber optic cable. Consider that the capacity of a simple telephone line to carry data is equivalent to the flow of liquid through a drinking straw. It would

Table 4 Token Ring Cable Specifications

Characteristic	Specification
Maximum cable segment length	101 m (type 1)
	45 m (type 3)
	100 m (Cat 3)
	225 m (Cat 5)
	400 m (STP)
IEEE specification	802.5
Bandwidth	4, 16, or 100 Mbps
Topology	Star-wired ring
Cable access method	Token passing

IEEE = Institute of Electrical and Electronics Engineers.

Figure 15: Fiber optic cable with connectors.

take a tunnel large enough to drive a bus through to equal the bandwidth of a single fiber optic strand using today's technologies. Furthermore, if technology existed to fully utilize fiber optic capabilities, it would take a tunnel the diameter of the moon to handle the flow of liquid equal to its potential bandwidth (Jamison, 2001).

Fiber optic cable carries optical pulses rather than electrical signals, which eliminates any possible electrical interference. All types of conducted communication media are vulnerable to electronic eavesdropping to some degree, but fiber optic cable is less prone to eavesdropping because its signal does not radiate outside of the media like copper-based wire. Therefore, the only way to intercept data from fiber optic cable would be to tap into it, which would require a great deal of effort and skill.

Fiber optic cable lengths are measured in kilometers rather than meters, which greatly reduces the number of signal repeating devices required for long-distance cable runs. One of the most impressive characteristics is the high volumes of data that can be pumped through optical fibers. All this makes fiber optic cable the medium of choice for many WAN applications, where network traffic can cause major bottlenecks (Tittel & Johnson, 2001). In addition, many people believe that fiber optic cables may become the norm rather than the exception for interconnecting network devices on a LAN (Kostal, 2001; Sinks & Balch, 2001; Vickers, 2001).

Components

Fiber optic cable consists of three components: a fiber core, cladding, and a protective outer sheath. The inner core is either glass or plastic fiber. Plastic is used when a flexible cable is needed; however, plastic cable is more susceptible to attenuation than glass, which limits the length of the cable. Cladding provides a coating that keeps the light waves within the fiber. The outer protective jacket is used to protect the fiber inside (Tittel & Johnson, 2001).

Fiber Modes

Fiber optic cable comes in two forms, single and multiple mode. Single-mode fiber is best for applications that require great distances. This fiber is very narrow and requires an extremely focused source of data transmission that can keep the light waves on a straight, continuous path. The narrow internal core makes room for one-way traffic only. This reduces obstacles (stray light) that might interfere with the delivery of packets, resulting in more

reliable transmissions over longer distances. A laser is normally used as the generating source for single-mode transmissions because it can produce the narrow band of light needed (Jamison, 2001).

Multimode fiber (MMF) is less expensive than single-mode because its transmission devices consist of LEDs (light emitting diodes), which are not as costly as laser sources. MMF fibers also have a larger core than single mode. A wider core helps to compensate for information loss due to light dispersion when using less precise light-emitting sources. A larger core allows the light wave to bounce around, which results in shorter transmission distances. The connections to the fiber are easier to make to the larger core, however. MMF is ideal for shorter cable runs within single buildings for LAN backbones (Jamison, 2001).

Fiber Optic Cable Network Applications

There are four major types of fiber connectors: straight (ST), straight connection (SC), medium interface connector (MIC), and subminiature type A (SMA) (see Figure 15). ST is often used for interconnections between individual fibers and optical devices. When joining optical fibers, an SC connector may be used. This connector consists of connections for two fibers: one for receiving and the other for sending. MIC connectors are one-piece connectors similar to the SC used to connect both the transmit and the receive fibers. It is primarily used with the fiber distributed data interface (FDDI) protocol. As with the ST connector, SMA uses individual connectors for each fiber. The major difference is that SMA uses either a straight or a stepped ferrule to ensure a precise fit, whereas the ST connector uses a bayonet twist-lock connection (Tittel & Johnson, 2001).

The major differences between fiber optic and other cable types are fiber optics' long-distance cable runs and high bandwidth. For example, the maximum fiber length for the 100BaseFX Ethernet standard is 2,000 m and the bandwidth for 1000baseSX tops out at 2,000 Mbps. These specifications easily exceed other cable specifications. The potential of fiber optic cable is limited by the technology that exists today. As the cost of fiber declines and the advances in transmission devices continue to improve, the use and performance of fiber will continue to grow.

In some applications, fiber optic is not needed for its high bandwidth, but to facilitate long cable lengths or to block unwanted electrical interference. For example, the 100BaseFX specification supports the use of fiber optic cable. With the exception of distance, the other

Table 5 Fiber Optic Cable Specifications

Characteristic	Specification
Maximum cable segment length	2,000 m
IEEE specification	802.3
Bandwidth	100 Mbps
Topology	Star
Cable access method	CSMA/CD

CSMA-CD = carrier sense multiple access with collision detection; IEEE = Institute of Electrical and Electronics Engineers.

specifications for 100BaseFX are essentially the same as that described for UTP cabling (see Table 5). Token ring also has a cable specification for the use of fiber optic for connecting its MAUs. Again, this does not fully utilize fiber optic's full bandwidth potential, but it allows for longer cable runs.

Fiber optic applications do not stop at 100 Mbps. Gigabit Ethernet, 1000BaseLX and 1000BaseSX, each sport bandwidths of 1,000 Mbps. The major difference in these two standards is the type of laser used. 1000BaseLX uses a long-wavelength laser that can transmit a signal over 5,000 m of fiber in full-duplex mode. A short-wavelength laser is used in 1000BaseSX applications, which support a maximum cable length of 550 m and 2,000 Mbps bandwidth in full-duplex mode. Still in its early stages, 10-gigabit Ethernet is sure to accelerate the use of fiber optic cable into the future (10 Gigabit Ethernet Alliance, 2002; Tittel & Johnson, 2001).

The only thing holding fiber optic transmission rates at bay is the devices used to drive the signals through the fibers. As noted at the beginning of this section, the potential of fiber optic media is truly enormous. Currently, the primary application for fiber optic cabling is for long connections and network backbones. There are some limited applications of direct connections between individual computers and hubs, but many people feel that this will increase over time as equipment and installation costs continue to decrease.

COMPARISONS AND CONTRASTS

When comparing and contrasting the advantages and disadvantages of the various types of cables, you must look at the particular application. It may be true that fiber-optic cable has the potential to transmit data at much faster rates than UTP; however, if bandwidth is not an issue, the added complexity involved in installing fiber optic where it is not needed would make it a bad choice. One must

look at all the characteristics of the transmission medium before choices are made. In some cases, a network may require a mixture of cables to meet specific needs for data transmission. Table 6 compares and contrasts each cable type discussed in this article, showing more clearly how a particular cable may be applied (Tittel & Johnson, 2001).

MEDIA SECURITY

When designing a network infrastructure, the security of conductive communications media should be a strong consideration in the overall network design. Most common security breaches are the result of someone hacking into an organization's network through security holes in user authentication policies or vulnerabilities in network operating systems from far distances. Security flaws of this order seem to upstage the potential risks associated with the physical security of network devices and cabling, but these risks are not inexistent. For example, a network's infrastructure could be at risk if the physical cable routes are not carefully thought out. The physical path of a cable must be secure to prevent someone from tapping into the network, which would result in an unauthorized connection. Also, connecting devices, such as hubs or switches, placed on the floor or up in a crawl space in a common area of a building may pose a security risk.

As noted earlier, the physical location of the network cabling has the potential of creating a security risk if not protected. Copper cabling, such as coax and twisted-pair, are probably the most vulnerable because of the simplicity of splicing into an exposed cable. Areas of special concern would be the cable routes that run through or above common areas of a building, along with cables that are run outside of the building or underground. In many ways, tapping into a computer network by an unauthorized cable tap may make a network more vulnerable to attacks than from external security threats. If access is gained via a wire tap to the internal network infrastructure, external security measures, such as firewalls, would provide no protection. Also with direct access to the LAN, a person might be able to use eavesdropping or sniffing utilities to access security devices and reconfigure them to allow external access. Once a security device has been reconfigured, sensitive company data, such as loss of product design secrets, customer information, or financial data, might be lost or stolen (Campbell, Calvert, & Boswell, 2003).

Another risk involving communications media security is electronic eavesdropping. Cable that uses a copper-type conductor can be vulnerable because of the electromagnetic emissions that it produces. With the right type of equipment, sensitive network traffic could be intercepted. Twisted-pair cables used in Ethernet applications

Table 6 Comparison of Cable Types

Cable	Bandwidth	Length	Interference	Installation	Cost
Thinwire coax	10 Mbps	185 m	Moderate	Easy	Low
Thickwire coax	10 Mbps	500 m	Low	Hard	High
UTP	100 Mbps	100 m	High	Easy	Low
STP	1,000 Mbps	100 m	Moderate	Moderate	Moderate
Fiber optic	10 Gbps	100 km	None	Hard	Expensive

are most likely targets for electronic eavesdropping because most of these cables are not shielded. This type of threat is often hard to combat if a network is constructed using nonshielded wire.

Once the potential physical security threats have been identified, it is fairly simple to eliminate many of these concerns. With regard to wiretaps, network designs should make sure that all cable runs are not exposed to unsecured areas or in the case where cables have to be routed in public areas or outside of buildings, copper-based media should be replaced with fiber optic cable, which is difficult to tap. Several options of protection are available for electronic eavesdropping. One is to reduce electromagnetic emissions by using a shielded twisted-pair cable. Another, expensive, option would be to replace copper-type transmission media with fiber optic cables, which would eliminate any possible electronic emissions. Of course it would be very expensive to use fiber throughout an entire network. A final alternative, which is orthogonal to transmission media decisions, would be to encrypt any sensitive company information before it is transmitted over the communication lines (Campbell et al., 2003).

Threats to a network's physical transmission media is real and needs to be considered in all infrastructure designs. In most cases, it is not expensive for an organization to protect its network from wiretaps and eavesdropping. Business and industry need to consider the possible holes in physical security and plan cable runs and use cable types that will reduce or eliminate the possible risks to the internal network. In addition, using encryption for sensitive data transmissions should protect against any breach of security with regards to electronic eavesdropping.

CONCLUSION

Conductive transmission cables provide the highway for data communications. This chapter has discussed the most popular types of cable in use today. As times change, the applications and uses for these various cable types will change. Some limiting factors for conductive transmission media are cable attenuation and the devices that drive the information through them such as NICs, hubs, and switches. We saw that bandwidths for twisted-pair cable have increased from around 1 to 1,000 Mbps. Transmission speeds over fiber optic cable are only now being realized. What are the limits? What does the future hold for conductive transmission cables? How do wireless technologies fit into network communications? No one knows the answers to these questions, but at least the questions are being asked, so researchers can continue to experiment and produce new applications for all transmission options.

GLOSSARY

Bandwidth The maximum range of frequencies a communications medium can carry.

Baseband A digital transmission signal that uses a single channel to communicate with devices on a network.

Broadband An analog transmission that carries multiple digital signals over multiple channels.

Crosstalk An electromagnetic field surrounding certain types of cable that may interfere with adjacent wires.

Hub A central wiring point for network devices configured in a star topology. Its purpose is to repeat the broadcast packets to all connected nodes.

Impedance The resistance of conducted communications media to a transmitted signal.

Insertion Loss The loss or attenuation of a signal that occurs each time a device is inserted into a network using conductive communications media.

Local Area Network (LAN) A collection of computers connected to a network within a single floor, or building.

Network Interface Card (NIC) An electronic device that is installed in a network node that provides a link to the network media.

Node Any device connected directly to a network.

Packet An entity that contains data plus other information, such as destination, origination, and error-checking bits and is transmitted over a network.

Protocol A set of rules that specify how communicating entities will format data and process events.

Signal Attenuation The loss of signal strength as data travel the length of the cable that is caused by the cable, connectors, or other devices on the conducted communication media.

Terminator A device attached to a cable configured with a bus topology that eliminates signal bounce.

Topology The physical cabling configuration of a network.

INTRODUCTION

Communication networks are systems in hardware and software to facilitate information exchange in a broader arrangement than a single point-to-point link. The telephone network is the most familiar and ubiquitous communication network, designed primarily for voice transmission. A computer network is a communication infrastructure between computing devices in different locations to enable digital information exchange and sharing of resources such as messages, software, compute time, storage space, or peripherals. Finding efficient ways to share communication links is one of the main problems in designing networks. Network design traditionally seeks to optimize several criteria at the same time: minimizing the cost of deployment; maximizing the aggregate bandwidth between two end-points; avoiding “hot spots” where a small number of network nodes and links handle a large percentage of the total traffic; minimizing the latency between any sender and receiver; and maximizing scalability, that is, performance should scale with the number of nodes in the network.

Routers and switches are the key devices in meeting these demands and are traditionally attributed to Layer 2 and 3 in the 7-layer OSI model and the 5-layer TCP/IP protocol stack, with the latter shown in Figure 1 together with respective processing units. Routers process packets, whereas Layer-2 switches operate with frames. Layers indicate which device uses specific header information pieces to decide how to process and forward a message with the goal to cooperatively move frames and packets from one network segment to another to ultimately reach the designated receiver.

Today’s routing and switching technology is a legacy from the early packet switching networks created for the ARPANET in the 1970s. With increasing Internet population and complexity of service provision, infrastructure security for more dependable communication is a major concern. A plethora of new services creates new loopholes for compromising the security of a computer network and requires steady countermeasure investigation and innovation. This article describes the working principles of routers and switches, their prominent security vulnerabilities, and suggests some best practices for router and switch security.

Principles of Routing and Switching

Although the various types of digital communication networks differ in how they are used and transmit information, they have routers and switches as architectural components in common. Routing is provided in a layer above switching and concerned with establishing an optimal communication path. Routing may also take quality-of-service concerns into account (Shenker, 1995). In the Internet, many protocols work together to accomplish this goal to establish end-to-end connectivity. For interior routing within administratively autonomous domains, protocols such as the routing information protocol (RIP) and open shortest path first (OSPF) are predominant. RIP is used in small to medium-sized networks and is simple to configure but slow in responding to network failures, which in itself can be a threat to network security. OSPF scales well in mid-size to very large networks, but incurs greater messaging and computation overhead. For inter-domain, policy-based routing the exterior path-finding protocol BGP (Border Gateway Protocol) is used as a standard in large routers (Huitema, 2000).

On the other hand, switching is mainly concerned with data relay and the associated policing and output scheduling. Switching is the mechanics of creating a connecting path between input and output in a switching device, with the goal to effectively relay a message from an incoming link to a chosen destination designated by an output port. It has played a vital role in telecommunication networks since first-generation telephone exchanges were installed. Switching technology seeks to maximize capacity for a given cost and reliability, and to minimize blocking and packet loss. With switching, data can be forwarded across dynamically created communication paths, whose sections are multiplexed among various senders and receivers. Switching is performed by telephone circuit switches for voice calls in the public switched telephone network (PSTN), “virtual circuit” switches in asynchronous transfer mode (ATM) networks with fixed-sized cells, or packet switches with variable-sized messages.

Circuit-switching, based on telecommunication services, pre-establishes a path from one end-system to another via a sequence of switches, where device resources are reserved to guarantee a dedicated circuit for the

Figure 1: Routers and switches in the TCP/IP protocol stack and processing units.

duration of the transmission. A circuit switch must reject a call if it cannot reserve a path from input to output, which is referred to as call blocking. Circuit switching is implemented as connection-oriented service in the public switched telephone network (PSTN), where voice samples are switched from a source to a receiver, or with virtual circuit-switching in ATM networks. Recent progress in peer-to-peer telephony has shown that it is also possible to establish connection-oriented communication in a self-organizing peer-based logical network.

In contrast, device resources are not reserved in packet-switched networks, but shared and utilized on demand by using statistical multiplexing among data packets, which are composed of a header with control information and the payload. Packet switching can be implemented connectionless using the Internet protocol (IP), or in connection-oriented mode using for example ATM. Routers performing connectionless packet switching are also called datagram or packet switches. In connectionless switching, packets are self-contained and independently routed towards a destination, whereas connection-oriented switching associates data to a specific, fixed forwarding path. Table 1 shows networking vs. switching modes with their prototypical implementation (Keshav, 1997). Besides ATM there are other connection-oriented packet switching technologies such as frame relay or X.25.

ROUTERS AND SWITCHES IN A NUTSHELL

How Routers Work

Routers are Layer 3+ devices (the + means that these devices may perform higher-layer routing functions.) A router forwards packets based on IP addresses and routing tables. Routers are available for small and large scale networks, for wired and wireless networks, and for non-optical and optical communication networks. Home networks typically are equipped with DSL or cable

modems connected to access network routers. At the network edge we find enterprise wide-area-network (WAN) access switches and edge routers. Backbones use carrier class routers besides ATM switches or frame relay switches. Unlike switches, routers always require some configuration.

Routers pass traffic between two different IP networks which may be either LANs or WANs, forwarding packets on the best-possible path towards a destination, in terms of the number of hops, the cumulative delay, or some other optimization criterion. When a packet arrives at a router, the frame header and trailer are stripped off and the packet contained in the payload field of the frame becomes input for the routing software, which uses the packet header to choose an output line. Packets may be queued in a router until they can be switched through to the appropriate port based on a routing table lookup to find the best-possible path. An IP packet processed by a router will contain a 32-bit (IPv4) or 128-bit (IPv6) address. The routing software is oblivious of the frame address and whether the packet arrived from a LAN or point-to-point link. A router examines the destination IP address of each incoming packet and sends data through an egress port based upon a routing table entry. Routing tables can be manually configured or incrementally learned using discovery procedures in routing protocols. Such routing algorithms are either static or dynamic. Static routing is applicable when network topologies do not change significantly and route calculations can be performed offline. Typically, however, the dynamics of networks (Paxson, 1997) necessitates more sophisticated algorithms to allow routers to adapt to rapidly changing network conditions, where nodes and links can be congested, go down, or come up at any instant. Routers hence store and forward packets with the goal to adaptively optimize path-finding between sources and destinations in dynamic networks. While Internet routers until recently serviced packets in a first-come-first-served “best-effort” manner, differentiated service qualities are now required to cater to application

Figure 2: Traditional and Modern Router Design.

specifics, which necessitates that routers support new mechanisms such as admission control, per-flow queuing, resource reservation, and fair scheduling. These mechanisms require routers to use packet classification algorithms to distinguish and isolate traffic in different flows for suitable processing (Gupta and McKeown, 2001).

Router Architecture and Performance

Routers incorporate a hierarchical packet forwarding logic in hardware plus computational capabilities to maintain routing tables. A router consists of a set of input ports, a backplane, and a set of output ports, including a CPU and memory to maintain a routing table for shortest path calculations. In a black box view, a router is a device that switches data packets arriving at an input port to an output port according to a routing criterion and after some queuing delay. From an inside view, data are shifted in traditional design from input ports ideally collision-free through an internal fabric to an output port, as shown in Figure 2a.

In high-performance systems, datapath functions such as forwarding decision making, backplane switching, and output link scheduling are typically implemented in special purpose hardware, while control functions such as routing table exchanges with neighbors or management are software-based. Instead of shared, congested backplanes, modern router design now incorporates switched backplanes, which results in a compact, parallel design with extremely high throughput for both unicast and multicast traffic. Figure 2b depicts the use of more complex hardware on the main datapath and a crossbar design in the backplane to achieve more parallelism for high-speed routers (McKeown, 1997).

The main performance characteristics of a router are the number of ports or links, the throughput possible at each link, the maximum rate of packets that can be switched through, and the delay across the switch. Crucial for the performance of a router are fast table lookups and calculations of routes based on available network topology information (Keshav and Sharma, 1998). A current bare-bones router operates in software only without routing protocols and is simple to configure with built-in NAT. Low-end routers support around 200 Mbps

full-duplex with Fast Ethernet and offer simple hardware-based operation, built-in NAT and firewall functionality, but lack fault tolerance. With an increasing number of channels transmitted on a single fiber, routers must scale port densities to handle these channels. Midrange routers add support for virtual LANs (VLANs) and virtual private networks (VPNs) with a broader range of WAN connectivity. High-end routers add component redundancy and resilience, scaling from 2.5 Gbps to 40 Gbps per slot with multi-terabit switching capabilities and several OC-192/STM-64 interfaces. A top-end ISP carrier router offers a theoretical capacity up to 92 Tbps with support for up to over 1000 OC-768c interfaces on the data plane and multimillion packet-per-second performance.

The advent of broadband access for end-users has raised expectations in IP reliability and performance. While earlier switches and routers offered single-purpose functionality, more recent products are convergence devices incorporating several functions in one box. Examples are combined firewall and VPN appliances (Cisco, 2004), wireless broadband routers with print server functionality, routers supporting VoIP and multimedia, or Layer 4+ content routers relaying packets based on URL semantics rather than IP-based semantics. As a result, there is great demand for rich-featured convergence devices used in SOHO and small business networks, and for Gigabit and Terabit (Singhal and Jain, 2002) electronic and optical routers used in backbones. These routers not only forward packets at a rate of billions of packets per second, but also must provide quality guarantees for differentiated services with data, voice, or video; work with a wide variety of interface types; offer scalability in terms of port density and capacity; and offer backward compatibility with various packet formats and routing protocols.

How Switches Work

A switch can be compared to a train station or airport dynamically interconnecting different travel pathways. Switches essentially interlink physical segments of a network and allow data to be exchanged between these segments. On a microscopic scale, the intrinsic design of a switch determines how effective this interlinking of communication paths is performed within each switch

stage. On a macroscopic scale, the interlinking of switches in the overall network topology determines the aggregate performance of the network.

Switching functions vary depending on the operational needs of applications and may include higher layer switching functions. A typical switch operates at Layer 2 in the OSI model and TCP/IP stack. It checks address information in link and interface-level headers in hardware, and directs frames to the next hop on the path to some destination host based on data link layer addresses, for example Ethernet MAC addresses. Layer 2 switches are adequate for high-volume traffic generated between local devices, such as workstations and servers. A flat address space in broadcast domains, the possibility of broadcast storms, and the limited number of links supported by a Layer-2 switch led to the development of Layer-3 devices able to optimally route traffic in a hierarchy of nodes. Layer 3 switching is functionally identical to routing and typically added in large switches. Layer 4-7 switches deliver intelligent traffic and bandwidth management based on the application content of a session, not only based on network connections (Srinivasan et al., 1998) and can provide load balancing, denial-of-service attack protection, intelligent application scanning and virtual local area network (VLAN) configuration.

Switches are usually “plug-and-play”, which simplifies installation. Switches operate either in store-and-forward or in cut-through mode. A store-and-forward switch accepts a frame on an input line, buffers it briefly in the input port, the fabric or output port, before forwarding it to the next processing stage ready to handle the entire frame. When frames arrive faster than they can be forwarded, buffers overflow and packet loss occurs. In contrast, cut-through switching is based on the idea to start forwarding a frame as soon as its destination header field

has arrived, which is usually handled entirely in hardware. It boosts throughput at the possibility of forwarding bad frames, since the cyclic redundancy check (CRC) cannot be checked before transmission. The switching process is executed in hardware at wire-speed with effectively zero latency.

Switches originally linked segments with multiple devices but with dropping switch prices it became normal to attach a single device to each port, which is known as “switched” Ethernet. No packet collisions are possible with only one device per port, which improves network performance by allowing devices to run in full-duplex to achieve maximum throughput.

Depending on the layout of the physical space, multiple smaller switches or a few very large switches may be chosen in the design of a network, which is a matter of manageability, cost, traffic characteristics, and reliability, among other reasons. Figure 3 shows an unsecured sandbox network with switches connecting Ethernet cluster, which are again connected via the root switch R together to access a server farm and linked to a router connecting the intranet with the Internet. By using switches A, B, and C, traffic in leaf subnetworks is localized and degradation in one subnet does not affect the other parts of the network.

In the context of Ethernet LANs, switches are often called bridges, if used to connect multiple Ethernets, and run a spanning tree protocol to form a loop-free forwarding topology to relay traffic between LAN segments. Looping occurs when devices are linked in a way that creates a loop in the topology, for example by linking switches B and C directly (dashed link.) This means that packets could circulate between switch B and C, which can be avoided by forming a spanning tree if bridges are being used instead for B and C. The terms switch and bridge are often used

Figure 3: Switching in a LAN environment.

synonymously, because both devices route on frame addresses at Layer 2. While bridges are used to interconnect two or more LANs and perform frame forwarding in software, switches are typically used to connect individual computers, which requires many more line cards with buffer space for frames arriving on switch ports.

Instead of a bridge or switch in a switched Ethernet, devices could also be interlinked via a hub in a “shared Ethernet” architecture. A hub repeats any incoming transmission on all of its other ports, regardless of packet content and addressing information. If two or more packets arrive at the hub at the same time, packets from different network sections (“domains”) collide. Unlike switches, which are capable of transmitting multiple packets full-duplex via different ports by examining source and destination addresses, hubs do not separate collision domains. The more transmissions are placed between disjoint senders and receivers, the larger the throughput advantage using a switch, which makes a hub an inefficient and outdated choice.

State-of-the-art switches come with a small number of ports in desktop form for small office/home office (SOHO) environments, or in modular, stackable form with hundreds of ports for wiring closets and enterprise deployment. They include support for the IEEE 802.3af standard for end devices, and Ethernet support for in-line power devices beyond IP phones and wireless LAN access points to connect more power-hungry devices such as IP-powered video surveillance cameras, security systems, or fire protection and motion detection devices.

Switch Architecture and Performance

Switches are essentially the distributor nodes, across which various communication lines fan in from different sources and fan out to different locations. First generation switching networks were purely electromechanical and blocking, i.e., an existing connection prevents links between other input and output ports. They were invented to automate the interlinking of segments in communication exchange due to the fact that building networks by laying out point-to-point links between each pair of users would be cost prohibitive and an enormous waste of resources. Over decades switch technology has evolved from electromechanical through electronic to optical or photonic switching (Veeraraghavan et al., 2001), and from using space-division switching in first-generation systems, through time-division circuit switching and multi-channel and multi-rate switching, to wavelength-division switching in photonic networks. The predominant relay mechanics in switches are consequently called time-division multiplexing (TDM), frequency-division multiplexing (FDM), and wavelength-division multiplexing (WDM).

The three prevalent implementation paradigms for switches are based on shared memory, time-division, or space-division fabrics. Shared-memory switches can be built simply from off-the-shelf components, and access shared memory space to carry out forwarding of packets from input port to output port. Time-division switches rearrange the order of incoming data on a multiplexed line according to a time schedule, whereas space-division switches, as common building blocks in

high-performance networks, forward packets across a spatial fabric layout in a single stage or in multiple stages.

Crossbar switches are the most prominent example of a single-stage switch, where every input link is directly connected to every output port in a matrix with cross points that can be selectively enabled. With this simple principle of connectivity, such switches have no internal blocking and low latency due to the minimal number of connecting points between arbitrary input and output links, and can be easily implemented in VLSI. However, the number of cross points required grows quadratically with the number of input and output ports, which increases the capacitive loading and signal distribution time, and hence slows transmission. In addition, crossbars have no fault tolerance and are difficult to expand and too costly. Small crossbar switches are often used to as components in more complex switch designs.

Multistage switches are composed of networks of smaller switches, which works well if each stage in the pipeline takes the same time. The interlinking of low-complexity switches in intermediate stages increases reliability, because input and output can still be connected in case of failure of a component switch. An example is the knockout switch, which is a crossbar with concentrators modeled on a knockout tournament to reduce space complexity. Multistage switching can be more effectively implemented by recirculation or with spatially separate switches. This class is represented by Clos networks, Banyan networks, and Batchier sorting networks (Jajszczyk, 2003). In Clos networks, a strictly non-blocking switching network can be constructed with fewer cross points than a crossbar of the same capacity. Each switch of one stage has an output feeding into each switch of the next stage. With a minimum number of cross points, a Clos switch becomes strictly non-blocking, otherwise it is blocking. While Clos networks have been primarily of theoretical interest, they are considered again today as a promising architecture for optical cross-connect systems and for high-capacity and high-performance backbone IP routers. Banyan switches are self-routing using a binary representation of output ports. The direction at each stage is specified by a bit corresponding to that stage. Half of the traffic is blocked in the worst case, and multiple planes of latter stages are used to buffer blocked traffic. Batchier networks are based on the idea that sorting and switching are essentially the same, except that outputs need to be spread after sorting to account for idle ports (Ahmadi and Denzel, 1989). Buffer placement and scheduling turn out to be a greater challenge in switch design than creating the fabric.

Switching throughput is measured either in bits-per-second (bps) or packets-per-second (pps), which is correlated with link speeds, support for half or full-duplex connections, support for jumbo frames, and non-blocking behavior. The goal is to achieve an overall throughput equal to the sum of the full theoretical bandwidth of each switch port. Current low-end switches offer connectivity to a small user base, typically with 5 to 16 ports at 10 to 100 Mbps, and lack spanning tree protocol support, VLAN support, or remote management. A current typical midrange switch offers support for 16 to 250 users with a bandwidth of 10 Gbps (non-blocking), a packet forwarding throughput of 2 Mpps, and a packet buffer memory of

1 GB. Top-end midrange switches may include redundant power supply and forwarding engines to greater availability, a greater number of Ethernet ports, remote access and configuration, and support for VLANs, spanning trees and Layer 3 switching. These switches are either unmanaged Layer-2 devices with auto-sensing, or managed Layer 2 or 3 devices, which can be used to inexpensively off-load routers segmenting a network to lay the groundwork for innovative IP-based services such as IP telephony or video conferencing.

High performance switches (Newman et al., 1997) offer the same features as mid-tier switches, plus Layer 4-7 switching, security features, modular gigabit connectivity for several hundred full-duplex ports, integrated IP address lookup (Waldvogel et al., 1997), multicast support, an address database size of several thousand media access control (MAC) addresses per system, and a bandwidth of at least 10 Gbps. Multicast support inherently impacts blocking properties and the routing strategy to set up multicast connections via a switching network. At a packet size of 240 bytes, a router with a T1 line rate of 1.5 Mbps requires a lookup performance of 0.78 Kpps, or 5.21 Mpps at an OC-192 line rate of 10 Gbps. Current carrier-class switches can be scaled to 100 terabit per second (Tbps) capacity, processing hundreds of millions of packets per second (pps) depending on the switch fabric, the line cards and their performance, and port speeds ranging from OC-48 to OC-192.

ROUTER AND SWITCH SECURITY

Various taxonomies on Internet infrastructure security have been proposed to categorize vulnerabilities and propose remedies. Generally, threats can be aimed at the devices themselves, or attack the services provided. At more detail, four major areas of protection can be considered to secure routers and switches from external intrusions, as well as violations from within a network: physical access, administrative control over a switch or router, intrusions against a switch or router, or intrusions through a switch or router (Microsoft, 2004). Alternatively, Pfleeger and Pfleeger (2003) classify threats to computing systems into four kinds: interceptions, interruptions, modifications, or fabrications. Interception allows an attacker to read traffic and threatens confidentiality, interruption leads to lack of availability through service degradation or denial, modification threatens data integrity, and fabrication may cause traffic or service alteration and enable future attacks.

However, the majority of successful remote attacks on switches and routers can be traced to exploitation of a small number of security flaws. Chakrabarti and Manimaran (2000) identify four main categories of concrete concern for Internet infrastructure security: Domain name system (DNS) hacking, routing table poisoning, packet mistreatment, and denial-of-service attacks.

The implications of these attacks are as diverse as the nature of their approach. IP packets are misrouted, confidential information is disclosed, deceptive or incorrect information is injected into the network through message modification, wrong address-name translations corrupt the routing process, network activities are disrupted through denial of service attacks, and network partitions

or congestion can occur. Countermeasures can be preventive or reactive, and may be implemented at the network edge or core, with the latter generally being more costly due to deployment issues.

Best Practices in Securing Routers and Switches

Router and switch security concerns device treatment aspects such as physical access, administrative access and access control, availability and reliability, and traffic treatment aspects such as authentication among routers, confidential exchange of control and regular messages, as well as the integrity of messages transferred. Device mistreatment can be divided into physical and network intrusions. Entry-level switches, such as plug-and-play devices, are relatively immune to network born violations, while mid-range switches and routers are typically most vulnerable. High-end routers and switches need various measures such as access control to hold off intrusion. Physical intrusions can be trivially prevented by limiting access to device, for example with a locked wiring closet. Network-based intrusions may be curtailed by adding firewalls to the network perimeter or to routers themselves and employing intrusion detection intelligence. Availability and reliability can be boosted through full duplication of equipment, but this solution adds considerable cost and necessitates automatic switchover. Traffic mistreatment is more complex due to the large spectrum of possible attacks. The next sections discuss notorious vulnerabilities (ISS, 2004) of routers and switches and suggest best practices for keeping attacks in reign.

Router Vulnerabilities and Attacks

Routing protocols to date have largely remained unprotected and open to attacks. Routing attacks can be targeted at the intra-domain and inter-domain level to disrupt correct routing in terms of the ability to reach the destination in compliance with a given forwarding policy. Generally, threats to routing protocols can be external or internal. External threats come from outside attackers who are non-participants in the protocol. Internal threats come from compromised protocol participants, which are referred to as Byzantine due their unpredictable nature. These attackers may corrupt, forge, or delay messages, or send conflicting messages (Puig et al., 2004).

These threats can be exerted in various ways. Deliberate exposure occurs when routing information is revealed to unauthorized parties, for example by taking control over a router. By sniffing on control exchanges, an attacker can observe or record routing information. Traffic analysis is a more systematic method to detect patterns and vulnerabilities in router exchanges. Spoofing is an identify change problem. Falsification includes misadvertising network resources, tampering with protocol header fields, and mistating route attributes. Finally, attackers can interfere with exchanges between legitimate routers, or place excess burden on such routers.

Threat actions may result in usurpation, deception, disruption, or disclosure, listed with decreasing impact. Usurpation lets an attacker gain control over legitimate

Table 2 Summary of threats to routers and their implications

Threat Source	Concerns	Threat Actions	Outcomes	Consequences	
• Outside • Byzantine	• Access Control • Authentication • Availability • Confidentiality • Data Integrity • Physical Access • Reliability	• Deliberate Exposure • Sniffing • Traffic Analysis • Spoofing • Falsification • Interference • Overload	• Usurpation • Deception • Disruption • Disclosure	<u>Infrastructure:</u> • Blackholing • Churning • Clog • Congestion • Instability • Looping • Overcontrol • Partition	<u>Hosts:</u> • Cut • Delay • Eavesdrop • Looping • Starvation

router functions. Deception happens when a forged routing message is accepted as authentic by a legitimate router and results in similar damages as usurpation. Disruption, as in a denial-of-service attack, causes temporary service outage and becomes more pressing when its frequency, duration, or range increases. Disclosure allows attackers to monitor a link due to lack of confidentiality in routing exchanges. Table 2 summarizes this taxonomy (cf. Babir et al., 2005).

The consequences are varied, and may damage the infrastructure of the whole network, or damage communication for a particular host or network. Blackholing occurs when one router is overburdened with redirected traffic. Churning happens when network forwarding patterns change rapidly and cause large variation in data delivery. Clogging describes the situation, when a router runs out of resources to handle excessive load, as caused by blackholing or congestion. Congestion is caused by overburdening a network portion with traffic. When routing becomes unstable, a global forwarding state is not reached. Looping may result in data never delivered. Overcontrol happens when protocol control overhead dominates actual message exchanges, and partitioning designates artificial breaks in the network topology such that routers do not communicate with each other when they could. Consequences of attacks on particular routers include cuts, delays, eavesdropping, looping, and starvation. When routers are cut off, they do not communicate when in fact they could. Through eavesdropping, rogue routers receive and see traffic when they should not.

Frequent exchanges of routing updates among neighboring routers in distance vector routing, and flooding of updates in link state protocols make intra-domain routing protocols vulnerable to attacks. Various strategies have been proposed to protect routing updates, including adding sequence and predecessor information to updates, or introducing authentication and cryptographic measures for router exchanges such as digitally signing updates. Implied drawbacks are increased traffic volume and more processing overhead at routers. Although BGP is the de facto standard for inter-domain routing, it does not ensure the integrity, freshness and authentication of messages or the authenticity of path attributes and permits forging of path vectors, with the consequences that packets often get misrouted and BGP operation can be compromised. Butler et al., (2004) present a comprehensive overview on the various approaches to secure BGP,

which include encryption of session information and message attributes, introduction of a public key mechanism into the routing infrastructure, route validation, using certificates for authenticating and authorizing network entities, and using a routing registry and building various forms of cryptography into BGP communication.

From a more concrete and practical perspective, at the administrative level a remote attacker could bypass *access control lists (ACLs)* in a router due to configuration errors. In an otherwise properly configured ACL, this problem could allow a remote attacker to connect through the switch onto the 'protected' side. Edge routers with an integrated DHCP server can be susceptible to a *BOOTP denial of service attack*. When a specially crafted BOOTP packet is sent to the router, a remote attacker could obtain sensitive information using a DHCP reply or cause the device to crash. An ADSL router integrated switch can also be vulnerable to *cross-site scripting*, when a remote attacker creates a malicious URL link containing embedded code, which would be executed in the victim's Web browser within the security context of the hosting site, once the link is clicked. Since any device in a network could send address resolution protocol (ARP) messages, an attacker on a LAN can easily spoof the gateway in a *gratuitous ARP attack*. Using *TCP sequence prediction*, an attacker could hijack another user's session or perform an IP spoofing attack to manipulate connections to the TCP services or modify the configuration of the router.

Router Configuration and Deployment Practices

Router security includes firmware and software patches and updates, administrative access, auditing and logging, intrusion detection, routing protocol configuration, and additional services. The National Security Agency (NSA, 2003) makes various recommendations to secure routers against intrusions.

First and foremost, most devices have back-door access and should therefore be physically locked up. A written router security policy should be maintained to define management and logging practices, in particular, who can access, configure, and update a router. Updates should always be tested before deploying them in a production environment. Administrative access must be restricted to specific locations and interfaces and use encryption to prevent hijacking, which entails strong password policies, using an administration access control system, controlling physical access, shutting down

Web-based configuration, and disabling unused interfaces. Passwords should be encrypted and configured securely for console and virtual terminal lines, and SSH should be adopted for remote administration. Consistent deployment of the same services across large scale networks can be provided by including the ability to rapidly configure routers for specific services with macro configuration templates comprising series of command line configuration commands, however, these templates and master versions of configuration files should be well commented, stored offline, and kept in sync with running configurations to diagnose attacks and enable fast recovery. Router security should be audited regularly, especially after any reconfiguration.

Protocol-level vulnerabilities are often the target of denial-of-service attacks, for example by flooding the network, and can be countered, among other measures (SANS, 2004) by using ingress and egress filtering, screening ICMP traffic, and limiting broadcast traffic or other unnecessary traffic. Unneeded services in the router such as BOOTP, Finger, SNMP, source routing, trace route, or protocols such as the Cisco discovery protocol (CDP) should be disabled. If SNMP is required for a network, it should be configured with ACLs and hard-to-guess community strings.

Loop-back addresses, source addresses from any internal network, and packets having the same source and destination address should be blocked in order to prevent TCP sequence number guessing of packets with obviously fake or reserved addresses from untrusted networks. Blocking illegal addresses not only prevents attackers from hijacking a router but also helps to diagnose poorly configured internal networks and hosts. ICMP echo and redirect may be used by remote attackers to scan a network and manipulate routing behavior, and should also be blocked. Broadcast packets, as generated by DHCP and BOOTP, should not be used on external interfaces or cross border routers and should be blocked. On border routers, only internal addresses should be allowed to enter the router from internal interfaces, and only traffic headed to internal addresses should be permitted from external interfaces. Multicast packets should only be allowed in networks supporting IP multicast.

Access control lists prevent certain traffic to enter or exit a network and should be implemented to allow only those protocols, ports, and IP addresses required by users and services and explicitly disallow any others. Previous access lists should be cleared out when implementing a new list and traffic address restrictions should be enforced at all times. Logging should be enabled for all denied traffic, and unusual traffic patterns should be audited, with logs being centrally stored and secured. Errors and blocked packets should be logged to an internal, trusted SYSLOG host, and SYSLOG traffic from untrusted networks should be blocked. Logs should include event timing and at least two network time protocol (NTP) servers should be configured to ensure availability and accuracy of timing information to enable precise tracking of network attacks.

Standard routers typically perform little filtering of data and therefore inherently may allow forwarding of compromised traffic. Stateful packet inspection (SPI) is

a network layer mechanism to examine packet contents up through the application layer rather than merely looking at packet header information, and compiling connection state information in a table. Filtering decisions are hence established based on a context of prior packets having passed through the router and allow to establish dynamic filtering criteria beyond static administrator-defined rules. SPI also thwarts port scanning by closing off ports until a connection to a specific port is requested. Packet filtering is fairly effective and transparent to users, but difficult to configure and susceptible to IP spoofing.

Routers become application gateways when applying security policies to specific applications. Although a firewall is only a first line of defense against network intrusion, modern routers incorporate firewall features and contain numerous mechanisms in hardware and software to strengthen their lines of defense against attacks, with the idea to provide plug-and-play security. A variety of router security features handle denial-of-service attacks via detection and logging, dropped packet logging, time-based usage control, URL filtering, deep packet filtering, and trusted user identity management.

Router manufacturers have therefore integrated such services increasingly in their hardware as a more efficient layer of defense for the network infrastructure. If a router acts as circuit-level gateway by applying security mechanisms to a transport level connection, packets could flow between hosts without further checking. For greater security, information exchanges should be encrypted. Current routers typically offer 56-bit to 168-bit encryption with DES, Triple DES, RC4, MD5, or SHA-1 encryption algorithms (Stallings, 2000).

As edge devices in local networks, routers can also shield private networks from outside access by mapping external, global addresses to internal addresses. Routers hence often include support for NAT, PPTP and L2TP, DHCP, DMZ, IPsec, and VRRP.

NAT (network address translation) is a popular but also controversial (Phifer, 2000) mechanism to counter IP address depletion, and makes a network appear to the outside world with a single IP address by hiding its internals. NAT serves the three main purposes of providing a type of firewall by hiding internal IP addresses, enabling a company to use more internal IP addresses, and combining multiple broadband connections into a single Internet connection. A translation table is maintained to map application-specific outside requests to internal IP addresses and associated port numbers. In static NAT, a private IP address is mapped to a public IP address, where the public address is always the same. This allows an internal host, such as a Web server, to have an unregistered, private IP address and still be reachable over the Internet. With dynamic NAT, a private IP address is mapped to a public IP address drawing from a pool of registered, public IP addresses. Dynamic NAT helps to secure a network as it masks the internal configuration of a private network and makes it difficult for someone outside the network to monitor individual usage patterns. A router using the point-to-point tunneling protocol (PPTP) or the Layer 2 tunneling protocol (L2TP) is able to establish secure, tunneled connections through an open network as a baseline service to establish VPN connections.

The dynamic host configuration protocol (DHCP, RFC 2131) enables routers to automatically obtain a different IP address when reconnecting mobile hosts with intermittent connectivity. It typically operates in conjunction with NAT and supports hybrid use of static and dynamic IP addresses. Due to the dynamic nature of the address assignment, attackers will regularly have to rescan a network to obtain current addresses.

A DMZ (demilitarized zone) inserts a neutral zone between a private network and public networks. Routers supporting setup of a DMZ allow users from the public network to access only the DMZ host. This “exposed host” provides limited access to company data, and can operate as proxy server for inside hosts to request data from the public network, but is not able to initiate sessions back into the private network.

IPsec operates with two different encryption modes, transport and tunnel, to introduce tighter security at the network layer. Transport mode encrypts only the data portion (payload) of each packet, but leaves the header untouched. In the more secure tunnel mode a router encrypts both the header and the payload. On the receiving side, an IPsec-compliant device is needed to decrypt each packet. For IPsec to work, the sending and receiving devices must share a public key through the Internet Security Association and key management protocol/Oakley (ISAKMP/Oakley) protocol, which allows the receiver to obtain a public key and authenticate the sender using digital certificates.

Finally, the virtual router redundancy protocol (VRRP) runs on a link in a fault-tolerant arrangement between one device operating as master and another device operating in standby mode, so each router knows whether the “alter ego” is alive and is able to react in failover mode if necessary.

Securing ad hoc routing presents difficulties not existent in traditional networks. Neither centrally administered secure routers nor strict policies exist in ad hoc networks, where nodes communicate without regulation through centralized access points. If routers go mobile, a new class of security mechanisms needs to be introduced. So far, security provisions for wireless networks entail support for Wi-Fi protected access (WPA), pre-shared key (PSK), MAC authentication, SSID hiding, and wired equivalent privacy (WEP) (Miller, 2001). However, software-only defense solutions are not sufficient in the face of distributed denial-of-service attacks, spoofing, and other attacks bogging down the network. For example, while the WEP protocol was designed to provide confidentiality, access control, and data integrity, it fails to fulfill these goals due to keystream reuse and message authentication flaws (Borisov et al., 2001).

Greater service complexities in routers, such as differentiated quality or voice telephony support, create new loopholes and necessitate constant updating of security measures. Mechanisms such as IP traceback, while still a topic of research (Savage et al., 2000), could be useful in the future in pinpointing attackers. Newer development in security information management (SIM) tools and intrusion detection systems (IDS) may help to correlate feeds from various audits and logs to recognize and diagnose attacks, using database and visualization tools with “dash-

board” functionality for more effective monitoring and securing of networks.

Switch Vulnerabilities and Attacks

Switch operation can be compromised at various service layers. An attacker, who gains administrative access to a vulnerable switch in a *password attack*, could take complete administrative control of the device. Proper password management, in particular the avoidance of default passwords, and restricted network and console access to these devices is therefore critical. In a *MAC address sniffing attack*, an attacker connected to a vulnerable switch could use a packet sniffing tool to obtain the MAC addresses of connected systems and can cause traffic to be broadcast to all systems connected to the switch. In a *frame injecting attack*, an attacker could inject 802.1q frames into a VLAN and transfer data to unauthorized network segments. In a *spanning tree protocol (STP) attack*, an attacker connected to two different switches could send bridge protocol data unit (BPDU) messages to gain root switch privileges over the tree and intercept transmissions among subtrees. In a *frame forwarding attack*, a switch receiving an 802.1x packet frame on a spanning tree protocol (STP) blocked port does not drop the packet but instead forwards it in the VLAN. This can cause an 802.1x frames network storm, which slows the performance of the network. By sending a malformed Internet control message protocol (ICMP) packet to a switch or to a computer behind it, a remote attacker can cause the switch to crash in a *denial-of-service attack*.

A remote attacker can also cause a denial of service by sending a flood of TCP SYN packets to the vulnerable device. In both cases, the power to the switch must be completely shut off and restored for the switch to regain normal functionality. A content switch can be vulnerable to a *denial of service attack of hypertext transfer protocol (HTTP) requests* to the Web management interface. A remote attacker could send a malformed HTTP POST request or extended markup language (XML) data to the Web management interface to cause the device to reboot, and hence deny services to legitimate users. A content service switch can also be vulnerable to a *UDP denial-of-service attack* when malformed UDP packets are sent to the management port (e.g., UDP port 5002) and a remote attacker can cause the device to reload. Finally, in a *Web-based switch management vulnerability* a remote attacker could access a switch via its administrative Web interface, and gain access to sensitive information without authentication by bookmarking the Web management URL.

Switch Configuration and Deployment Practices

The National Security Agency (NSA, 2004) recommends for threat defense that switches should be covered in an institution’s network security policy, including operating systems, port management, passwords, network services, spanning tree protocol, logging and debugging, access control lists, authentication, authorization, and accounting. First and foremost, physical access to a switch must be restricted, and switches should be securely configured so that sessions automatically time out and only necessary network services are enabled. The switch configuration

Figure 4: Simple secure SOHO Network.

file should be well commented and kept offline with limited access permissions. Software on switches should be regularly patched to run the latest stable release. Password access could be configured at different privilege levels, and SSH should be used instead of TELNET to administer a switch.

Securing a switch configuration entails various aspects, including the proper configuration of services and VLANs; the disabling of unused ports, the use of an access control system, and employing encryption, in particular on wireless links. Traditionally encryption is not implemented in a switch, but it ensures that intercepted packets are useless when an intruder sniffs on the same switched segment or where the switch is compromised. Switch management should be either “out-of-band” or on a separate VLAN for in-band management. Access control lists (ACLs) allow controlling of inter-VLAN traffic between IP subnets by restricting the flow of traffic between different segments of the network, and must be configured correctly. Typically, a simple static packet filter is used, in contrast to functions such as stateful packet inspection or application-layer proxying performed by dedicated firewall devices.

Port security should disable unused ports and limit access based on MAC addresses. The spanning tree protocol and auto-trunking should be disabled in loop-free topologies. A static VLAN configuration should be used when possible, the number of VLANs that can be transported over a trunk should be limited and trunk ports should be assigned to an otherwise unused native VLAN number. In addition, 802.1x and the extensible authentication protocol (EAP) can be used to leverage edge-security by authenticating a machine before it is allowed to access the network. Finally, logging should be enabled and logs should be sent to a dedicated, secure log server. Logs should be reviewed for incidents and archived in accordance with the general security policy. While these NSA recommendations are based on Cisco IOS products, they apply to switches in general.

Current software-based enhancement services of high-end switches include the ability to prevent MAC address flooding attacks by locking down ports, prevent attacks from false DHCP servers, and limit network access through port-level ACLs. Current switches also include authentication capabilities in standard IEEE 802.1x to be able to attribute authenticated traffic to a specific virtual LAN or add quality of service features as well as prevent denial-of-service attacks by dynamically inspecting address resolution protocol traffic and binding MAC and

IP addresses to specific ports. Layer 2 and 3 switches also typically support standards such as IEEE 802.1Q (static VLAN groups), port-based VLAN (any one port can belong to different VLAN groups), IEEE 802.1p class of service (CoS), IEEE 802.1D spanning tree protocol, and manual port trunking as per IEEE802.3ad. In addition, IGMP snooping, port mirroring, RFC 1157 (SNMP), RFC 2819 (RMON), RFC 1213 MIB II, RFC 1643 (Ethernet managed objects), RFC 1493 (bridge managed objects), RFC 951 (BOOTP), RFC 2998 (differentiated services), and RFC 2865 (RADIUS) are often supported.

Case Studies

Deploying a switched network entails choosing which class of routers or switches is needed, what functionality is required, and where those devices should be placed in relation to each other. Decisions on current connectivity and future growth, communication between devices, the required bandwidth and acceptable latency, and what VLAN architecture may be required are all interdependent parameters affecting overall security. Among the many possible organizational structures, SOHO and multilevel switching architectures are most common. A simple, secured SOHO setup, shown in Figure 4, may include a modem, usually a cable or DSL modem, a router, and a switch, which are often combined in a low-cost broadband router acting as an Ethernet switch with a firewall function.

In an example for a basic secure multilevel design in Figure 5, routers separate the public Internet from an intranet through a perimeter network. The first segment uses a border router facing the Internet with initial firewall capability, switched to a perimeter firewall that in turn connects to a Web server cluster in the perimeter network via a switch. Another switch connects the server farm to an internal firewall, which is switched to backend PCs and internal servers. Aside from the border switch, which is located in a more vulnerable zone, all other switches could be separate VLANs on the same switch, which could be one larger unit or consist of multiple smaller devices. Scenarios far more complex than presented are conceivable, but composition and the idea of isolation of critical components are principally the same.

CONCLUSION

The phenomenal growth in digital communication traffic has transformed the Internet from a research testbed into

Figure 5: Secure multi-level switched network.

both a daily convenience and a mission-critical service. As critical network infrastructure components, routers and switches are key devices in controlling network traffic and linking together computer networks at greater scale. Routers, from small to very large scale, perform primarily path finding optimization based on interior routing protocols such as RIP and OSPF, or exterior policy-centric protocols such as BGP. In security terms, routers can be used to segregate intranets from Internetworks through packet filtering and address translation. While attacks on access network routers may only compromise the local network, vulnerabilities in backbone routers could create large-scale damage to a communication infrastructure. Switches can radically improve network throughput by reducing packet collisions in the forwarding process. Switches segment networks according to the operational and security policies of an organization. Physical and administrative loopholes can make switches vulnerable to attacks that may impact the greater network around the switch. Tight physical, administrative, and protocol-centric security measures hence need to be enacted upon routers and switches alike to minimize network downtime and to fend off attacks on the integrity of distributed communication.

At the dawn of the next generation of massively ubiquitous communication tools and interactive applications exchanging high-volume traffic, such as video conferencing, video-on-demand, multiplayer simulations, and distance learning, switching and routing technologies may once again have to change to adapt to the next wave of innovation in communication, and the implied greater needs in security. In this section we discussed the essentials of router and switch mechanics, their vulnerabilities, and some current best practices in securing these devices, with main focus on wired networks. Issues such as content switching and routing, quality-of-service provision in its interplay with security, or wireless security need to be addressed separately. The ultimate vision is to equip routers and switches with the inherent adaptive intelligence to make networks self-organizing, self-defending, and self-healing against any conceivable attack at the hardware or software level, while offering uninterrupted high-performance service.

GLOSSARY

- ACL** Access Control List, a predefined set of rules that configure router packet filtering capabilities for routed network protocols based on an organization's security policy.
- ARP** Address resolution protocol, a distributed protocol to convert an IP address into a physical (data link control) address such as an Ethernet address. A host broadcasts an ARP request with an IP address to a TCP/IP network and the host with this IP address replies with its physical address. With the reverse ARP protocol (RARP) a host broadcasts its physical address to receive an RARP reply with the host's IP address.
- Autotrunking** Multiple ports are configured to be one and the same trunk for data transferring from one network switch to another network switch with the same trunking features and settings, in order to increase bandwidth.
- Crossbar** Simple non-blocking switch with inputs and outputs arranged as rows and columns in a matrix, where data are switched by activating cross points in the matrix.
- DHCP** Dynamic host configuration protocol, a protocol for assigning IP addresses dynamically from a pre-configured pool of IP addresses to devices on a network. With dynamic addressing, a device can have a different IP address every time it connects to the network. Dynamic addressing simplifies network administration because the software keeps track of IP addresses rather than requiring an administrator to manage the task.
- DMZ** Demilitarized zone, a computer or small subnetwork placed between a trusted internal network, such as a corporate private LAN, and an untrusted external network, such as the public Internet.
- DoS** Denial-of-service, a type of attack on a network to bring the network to its knees by transmission of useless traffic. Many DoS attacks, such as the ping of death and teardrop attacks, exploit limitations in the TCP/IP protocols.
- Firewall** A system, implemented in both hardware and/or software, and designed to prevent unauthorized

- access to or from a private network as a first line of defense. A firewall examines each incoming or leaving message and blocks those that do not meet specific pre-configured rules.
- Gateway** Node on a network serving as entrance to another network. This term is often associated with both a router and a switch but modern uses of the term indicate higher-layer functionality. For example, an application-specific type of firewall is also called an application-level gateway.
- Ingress Filtering** Examination of packets going through a router from the outside network to the inside. The opposite is **egress filtering**.
- IPsec** IP security, a set of protocols developed by the IETF to support secure exchange of packets at the IP layer and implement VPNs.
- L2TP** Layer 2 tunneling protocol, an extension to the PPP protocol that enables ISPs to operate VPNs.
- Line Card** Contains physical layer components to interface external data link to the switch fabric.
- NAT** Network address translation, an Internet protocol standard that enables a local-area network (LAN) to use one set of IP addresses for internal traffic and a second set of addresses for external traffic. A NAT box located where the LAN meets the Internet makes all necessary IP address translations.
- Network Processor** Runs the routing protocol, computes the routing tables that are copied into each forwarding engine, handles network management, and processes special handling for unusual packets.
- OC** Optical carrier, a frame format and speed metric in the SONET multiplexing hierarchy used to assess high-performance network throughput. OC-1 offers a data rate 51.84 Mbps.
- OSI Model** The open systems interconnection reference model defines a 7-layer architecture of communication functions for cooperating network devices.
- Pps** Packets per second, a metric to measure switch and router performance.
- PPTP** Point-to-point tunneling protocol, used to ensure that messages transmitted from one VPN node to another are secure. With PPTP, users can dial in to their corporate network via the Internet.
- Router** An Internetworking Layer 3 device connecting two or more networks running the same routing protocol. It uses the Internet protocol to address devices and maintains routing tables to determine the next hop on the optimal path to forward packets based on header information and routing policies.
- Spanning Tree Protocol** Link management protocol in the IEEE 802.1 standard for bridges, which provides path redundancy in a network with several possible paths between hosts while preventing undesirable loops.
- SPI** Stateful packet inspection is a firewall architecture that works at the network layer. Unlike static packet filtering, which examines a packet based on the information in its header, stateful inspection tracks each connection traversing all interfaces of the firewall and makes sure they are valid. Also referred to as dynamic packet filtering.
- Spoofing** A variety of ways in which hardware and

software can be fooled. In IP spoofing a message is altered in its header to appear as if it came from the authorized IP address of a trusted host.

- Switch Fabric** Interconnects the various components of router and offers higher aggregate capacity than the more conventional backplane bus.
- Tunneling** Encapsulation of packets to enable one network to send its data via another network's connections. Packets from one network protocol are embedded within TCP/IP packets carried through public Internet.
- VLAN** Virtual LAN technology is used to create logically separate LANs on the same physical switch and apply access control based on security rules to devices in logical network segments. A VLAN is a software-configured network of computers which behave as if they are connected to the same wire even though they may actually be physically located on different segments of a LAN.
- VPN** Virtual private network, a logical topology of computers across the public Internet.

INTRODUCTION

Radio-frequency (RF) wireless communication systems have been around for many years with applications ranging from garage-door openers to satellite communication. The technologies cover a broad range of capabilities oriented toward different uses and needs. These technologies have been advancing at an unprecedented rate, and their impact is evident in our daily lives. Less wiring means greater flexibility and efficiency and reduced wiring costs. In many parts of the world, wireless communication is the fastest growing area of the communication industry, providing a valuable supplement and alternative to existing wired networks ("Cellular communications services," n.d.). Based on the number of users of wireless communication products and subscribers to services, it is now the preferred method of communication ("Wireless Communications, Market & Opportunities," 2000). Many systems formerly carried over the wire are now carried over wireless media.

The remarkable success of cellular mobile radio and other wireless technology has fundamentally changed the way people communicate and conduct business. The wireless revolution has led to a new multi-billion-dollar wireless communications industry. Linking service areas, wireless communication has altered the way business is conducted. For example, with a laptop computer, a wireless modem, and a cellular phone, a business consultant can contact his or her office and clients and conduct business while traveling. Field service and sales personnel

can access corporate databases to check inventory status, prepare up-to-the-minute price and delivery quotes, modify schedule activities, and fulfill orders directly to the factory while traveling. Company personnel can use two-way paging services to stay in close contact, even when traditional wired communication services are available. Handheld hybrid phone-computer-fax machines feed information to wireless communication networks, allowing an executive to make decisions while on a leisure outing.

For instance, wireless local area network (WLAN) devices allow users to move their laptops from place to place within their office environment without the need for wires and without losing network connectivity. Ad hoc networks, such as those enabled by Bluetooth, allow data synchronization with network systems and applications sharing between devices. Bluetooth can also eliminate cables for printer and other peripheral device connections. Handheld devices, such as personal digital assistants (PDA) and cell phones, allow remote users to synchronize personal databases, and they provide access to network services such as wireless e-mail, Web browsing, and Internet access. Moreover, these technologies offer dramatic cost savings and added capabilities to diverse applications ranging from the retail setting to the manufacturing shop floor to first responders.

Risk is typically associated with wireless communications technology, because the airwaves can be accessed by intruders. Potential risks include loss of confidentiality, loss of integrity, loss of resource availability, and loss of proprietary information, to mention only a few. Malicious

users may gain access to the network and intentionally corrupt the data by spreading viruses, or they may simply launch attacks that prevent authorized users from accessing the network. Even if data confidentiality or integrity is not compromised, unauthorized users may steal bandwidth and cause a decrease in network performance or use a vulnerable wireless network as a platform for launching a network attack on a third party. These risks are not peculiar to wireless systems, but the risks are exacerbated by the nature of wireless connectivity.

This chapter presents a concise summary of the subject of radio frequency (RF) and wireless communications and introduces the concept of security for wireless communications. This includes a discussion of the general concepts and definitions of RF-based wireless communication, various forms and applications of RF wireless communication, synopsis of radio wave propagation, the cellular communication systems, and a general introduction of the security issues in wireless communications in general and WLAN in particular. Also presented is a summary of current and emerging wireless communication technologies. Of particular interest is the cellular mobile radio system, which has become the most widespread RF wireless communication system.

RF WIRELESS COMMUNICATION

RF wireless communication began at the turn of the 20th century, more than 100 years ago, when Marconi established the first successful and practical radio system. His experiment in 1895 demonstrated the transmission of radio signals a distance of 2 kilometers (Proakis & Salehi, 2002). He conducted additional experiments leading to 1901 when his radiotelegraph system transmitted radio signals across the Atlantic Ocean, from England to Newfoundland, about 1,700 miles away ("Mobile Telephone History," n.d.). Only telegraphic codes were transmitted, however. On December 24, 1906, Reginald Fessenden accomplished the first radio communication of human speech over a distance of 11 miles from Brant Rock, Massachusetts, to ships in the Atlantic Ocean ("Mobile Telephone History," n.d.). Radio was no longer limited to telegraph codes; it was no longer just a wireless telegraph. This was a remarkable milestone highlighting the beginning of the voice-transmitted age.

In the early years of RF wireless communication, radio broadcasting was the most deployed wireless communication technology. The invention of the vacuum tube and vacuum triode hastened the advancement in radio transmission of voice signals. Radio broadcast by way of amplitude modulation (AM) and, later by frequency modulation (FM), was made possible. Amplitude modulation of the radio frequency was used to carry information until FM was introduced in the late 1930s (Mark & Zhuang, 2003). After FM was introduced by Edwin H. Armstrong (Lathi, 1998), many other RF wireless systems such as television, one- and two-way radio, and radar, were introduced between the late 1920s and the mid-1950s. Another milestone was witnessed in the late 1970s, which marked the beginning of the growth in cellular mobile radios and personal communication services. The first successful commercial analog cellular mobile telephone was demonstrated in 1979

(Durgin, 2003). Currently, wireless communication of all kinds abounds in our society.

System Architecture

In RF wireless communication systems, radio waves are used to transfer information between a transmitter (Tx) and a receiver (Rx). RF systems can be classified as either terrestrial-based or space-based systems. Terrestrial-based systems include microwave point-to-point, WLANs, and cellular mobile radio, to mention only a few. Terrestrial microwave systems are limited in distance and line-of-sight (LOS) propagation is the limiting factor. Relay towers with carefully aligned directional antennas are often used to provide an unobstructed path over an extended distance. The data signal is processed, up- or down-converted, modulated or demodulated, filtered, and amplified at the transceivers. The transmitted signal propagates through the air and is attenuated by several propagation mechanisms (discussed later in the chapter).

Space-based systems (e.g., satellites) are similar to terrestrial microwave systems except that signals travel from earth-based ground stations to a satellite (uplink), and a signal is sent back from the satellite to another earth-based ground station (downlink). This achieves a far wider coverage area than the earth-based systems. The satellite system could be in geostationary earth orbit, medium earth orbit, or low earth orbit.

A typical wireless communication system is shown in Figure 1. It consists of a source of information, a hardware subsystem called the transmitter, the channel or means by which the signal travels, another hardware subsystem called the receiver, and a destination of the information (the sink).

The source supplies the information to the transmitter in the form of audio, video, data, or combination of the three. The Tx and Rx combination is used to convert the signal into a form suitable for transmission and then to convert the signal back to its original form. This is achieved through the process of modulation (or encoding) at the Tx side and demodulation (or decoding) at the Rx side. The channel is the medium by which the signal propagates, such as free space, unshielded twisted pair, coaxial cable, or fiber-optic cable. In wireless communication the channel is the free space. Noise and interference are added to the signal in the channel, which increases attenuation, distortion, and eventually error in the received signal.

The transmitter and receiver are complex systems consisting of many internal components. A block diagram representation of some of the components is shown in Figure 1. Components are denoted as transmitter processes, receiver processes, amplifiers, mixers, local oscillators (LO), filters, and antennas. The transmitter processes represent functions of the transmitter such as modulation, encoding, analog-to-digital conversion, multiplexing, addressing, and routing information. The receiver processes, on the other hand, denote the inverse functions such as demodulation, decoding, digital-to-analog conversion, and demultiplexing, as well as addressing and routing information. Effective transmission and reception of radio waves involve processes such as amplification and filtering of the signal at various internal stages, mixing of

Figure 1: Simplified model of terrestrial-based RF wireless communication systems.

the desired signal with a local oscillator signal, translating the signal from one frequency to another, and transmission or reception of the RF energy through the antenna. The amplifier is characterized by its gain, noise figure (or output power), and linearity (Weisman, 2003). The gain (in dB) of the amplifier is a measure of how much bigger the output signal is than the input signal. The noise figure (or noise ratio) is a measure of the quality of the receiver system. Mixers are commonly found in the Tx and Rx subsystems and are used to create new frequencies or translate existing frequencies to new ones. They are sometimes called up or down converters. The most common translation of frequency is from intermediate frequency (IF) to RF and vice versa. The mixer performs this function by effectively multiplying two signals at two frequencies. A signal source that provides one of the inputs to the mixer is the LO. A common type of LO is a voltage-controlled oscillator. A function of the filter is frequency selectivity. Filters select signals based on their frequency components. Regardless of the construction, all filters can be classified as low pass, high pass, band pass, or band stop). These names are descriptive of the function of the filter. For example, a low pass filter will select signals with low frequency and reject signals with high frequency. A special type of filter commonly used in RF systems is the duplexer, a frequency-dependent device that may be used as a separator or a combiner of signals. The duplexer facilitates the use of one antenna for both transmission and reception. The sink or destination (receiver) can vary as much as the source (transmitter) insofar as the type of information processed.

In the RF propagation channel, external noise in the form of manmade noise (generated by electrical man-made objects), atmospheric noise, and extraterrestrial

noise is introduced. Atmospheric noise is produced by electrical activities of the atmosphere. This type of noise is predominant in the range 0–30 MHz and is inversely proportional to its frequency. Extraterrestrial noise is produced by activities of the cosmos, including the sun. The RF propagation channel is time variant, hence the effectiveness of any system may vary because of the effects of atmospheric electrical activities (mostly solar ionization), weather, and random human-made noise sources. This time-variant channel requires careful consideration in the design of any wireless communications system.

In wireless communication, radio waves are used to transfer information, and because radio waves propagate in space, they are susceptible to some security risks. An intruder can intercept the signal or gain access to network services, without being an authorized user. The specific risk associated with wireless communication is presented later.

Radio Spectrum Classification

Radio frequencies or radio waves constitute the portion of the electromagnetic spectrum extending from 3 kHz to 300 GHz. The entire RF spectrum is classified into different bands and ranges, based on propagation properties. Baseband signals or source signals (e.g., audio signals) are in the low-frequency range below 30 kHz. This range of frequencies is classified as very low frequency (VLF), which must be translated into RF before transmission.

Radio waves are also described by their wavelength, as belonging to a particular wavelength range such as shortwave, medium-wave, or millimeter-wave. The higher the frequency, the lower the wavelength, because $\lambda = c/f_c$, where $c = 3.0 \times 10^8$ m/s is the speed of light, and f_c is

the carrier frequency. The wavelength is related to the realizable antenna length, L , system bandwidth, B , and other practical system parameters. In general, higher frequency radio waves produce smaller λ , require shorter L , have lower bandwidth efficiency, ρ (assuming high bandwidth; Haykin, 2000, p. 347), are more susceptible to fading, are less susceptible to atmospheric electrical activity, and suffer from atmospheric thermal and weather distortion. Bandwidth efficiency is the number of information bits transmitted per second per unit of bandwidth (Hz) or the ratio of the bit rate to channel bandwidth expressed in bit per second per hertz (b/s/Hz). Considering that

$$\rho = \frac{R_b}{B} = \frac{\log_2 M}{BT_s} = \frac{1}{BT_b} \text{bits/s/Hz}, \quad (1)$$

it can be seen that as ρ increases, the required bandwidth decreases, if the bit rate R_b is constant. M is the symbol level and T is the period. Any digital system will become less bandwidth efficient if its BT_b value is increased. The capacity (C) of a digital communication system is directly related to bandwidth efficiency because $\rho_{\max} = C/B = \log_{10}(1 + S/N)$ bits/s/Hz, where S is the signal power and N is the noise power. Bandwidth efficient systems transmit more information bits per bandwidth.

The characteristics and applications of radio frequencies are summarized in Table 1. Within each frequency range, several bands of frequencies can be designated for communication. These bands are commonly identified by either f_c or a letter symbol, as illustrated in Figure 2 (Acosta, 1999; Federal Communications Commission [FCC], 1997). For example, in practical applications, one could describe an RF system as operating in the C, X, K, or K_A band instead of using the actual frequency numbers. A complete list of the radio-frequency allocation can be found at <http://www.rfm.com/corp/new868dat/fccchart.pdf>.

Because of the congestion or unavailability of usable spectrum at the lower frequency bands (below 20 GHz) and the recent demand for multimedia communication at high data-rate capabilities, system designers have directed their attention toward the use of SHF and EHF for communication (Acosta, 1999). Currently, there is a great deal of research on developing RF systems operating at frequencies above 20 GHz (K_A band and above; National Aeronautics and Space Administration, 1998).

This interest in the EHF band is justified because of its potential benefits, such as the availability of usable spectrum, high data-rate capability, reduced interference, and high achievable gain with narrow beam widths of small antennas (Ippolito, 1989). The drawback, however, is that at these frequencies atmospheric distortion, especially rain attenuation (absorption of the RF signal), is severe (Acosta & Horton, 1998; Xu, Rappaport, Boyle, & Schaffner, 2000). The severity of the meteorological effects increases with increasing frequency. At some frequency bands, the meteorological effects can cause a reduction in received signal amplitude, depolarization of the radio wave, and increase in thermal noise (Ippolito, 1989).

Radio Wave Characteristics

When electrical energy in the form of high-frequency voltage or current is applied to an antenna, it is converted to electromagnetic (EM) waves or radio-frequency energy. At the Tx, the antenna converts a time-varying voltage or current into a time-varying propagating EM wave. The resulting EM wave propagates in space away from the source (the antenna) at the speed of light with the succeeding wave front changing in amplitude as the voltage or current changes in amplitude. Radio waves propagate through space as traveling EM fields proportional to the time-varying voltage or current. The propagating RF energy is composed of an electric field and a magnetic field component. The two fields exist together because a change in the electric field generates a corresponding change in the magnetic field, and vice versa. At the Rx, the antenna performs an inverse operation of converting a time-varying propagating EM wave to a time-varying voltage or current.

Polarization of the radio wave is important and is given by the direction of the electric field component. Usually the construction and orientation of the antenna determine the electric field component. Many antennas are linearly polarized, either horizontally or vertically. The magnitude of the power radiated in the direction of propagation can be calculated as the effective isotropic (independent of direction) radiated power (EIRP) or effective radiated power (ERP). This is the maximum radiated power available from a Tx in the direction of maximum gain for isotropic or directional antennas, respectively. It is a measure of the effectiveness of an antenna in directing the transmitter power in a particular direction (Rappaport, 2002).

Forms of Radio Waves

Radio waves propagate in space in various forms. The characteristics of the propagating waves are of interest in many wireless communication systems designs. Propagating radio waves can be classified as direct (or free space), ground (or surface), tropospheric, and ionospheric. These types of waves are illustrated in Figure 3.

Direct waves, in which propagation is in free space without any obstruction, are the simplest kind of radio waves. They are projected in a straight LOS between the Tx and Rx. The two-way radio, cellular mobile telephone, and personal communication system seldom have this type of radio wave.

Ground waves are confined to the lower atmosphere or the surface of the earth. A ground wave includes that portion of the radio wave directly affected by terrain and objects on the terrain. It is guided along the surface of the earth, reflecting and scattering off buildings, vegetation, hills, mountains, and other irregularities on the earth's surface. These waves propagate outward from the antenna but undergo refraction due to variation in the density of the atmosphere (Garg & Wilkes, 1996). The signal strength decreases as the distance between the Tx and the Rx increases. This wave affects all frequencies in the MF, HF, and VHF ranges, and it is the dominant wave in cellular mobile radio systems. Vertical polarization, the direction of the electric-field component, is best for this type of

Table 1 Radio-Frequency Band Classifications and Characteristics

Frequency Band	Frequency Range	Propagation Characteristics	λ	ρ	L	Typical Use
Very low frequency (VLF)	<30 kHz	Low attenuation day and night; high atmospheric noise level	Long	High	Long	Baseband signals; powerlines; home control systems; navigation and submarine communication
Low frequency (LF)	30–300 kHz	Slightly less reliable than VLF; absorption in daytime	↑	↓	↑	Long-range navigation; marine communication; radio beacons
Medium frequency (MF)	0.3–3 MHz	Attenuation low at night, high in day; atmospheric noise				Maritime radio; direction finding; AM broadcasting
High frequency (HF)	3.0–30 MHz	Omni-directional energy radiation; quality varies with time of day, season, frequency, and solar activity				International broadcasting, military communication; long-distance aircraft and ship communication
Very high frequency (VHF)	30–300 MHz	Direct and ground waves; cosmic noise; antenna design is critical	Short	Low	Short	VHF TV; FM broadcast; two-way radio, AM aircraft communication and navigational aids
Ultra high frequency (UHF)	0.3–3 GHz	Line-of-sight (LOS); repeaters are used to cover greater distances; cosmic noise				UHF TV; cellular phone; radar; microwave links; personal communications services
Super high frequency (SHF)	3.0–30 GHz	LOS; atmospheric attenuation due to rain (>10 GHz), oxygen and water vapor				Satellite and radar communication; terrestrial microwave; wireless local loop
Extremely high frequency (EHF)	30–300 GHz	LOS; millimeter wave; atmospheric attenuation due to rain, oxygen and water vapor				Experimental; wireless local loop

wave. The polarization is determined by the construction and orientation of the antenna.

Tropospheric and ionospheric waves are commonly referred to as sky waves. They propagate in outer space but can return to earth by reflection or scattering either in the troposphere or in the ionosphere. The tropospheric wave is that portion of the radio wave close to the earth's surface as a result of gradual bending in the lower atmosphere (Garg & Wilkes, 1996). The bending action is due to the changing effective dielectric constant of the atmosphere through which the wave is passing. Its reflective index gradually decreases with height, resulting in a bending path taken by the wave. The troposphere extends about 10 miles above the surface of the earth and applies to waves with wavelength shorter than 10 m (i.e., $\lambda < 10$ m). The ionospheric wave is similar to the tropospheric wave except that it travels farther and the reflection occurs in the ionosphere, 40–400 miles above the earth. Ionospheric propagation in the 3–30 MHz range is highly dependent on the state of solar activity and the subsequent levels of atmospheric ionization. This wave can be highly reliable for telemetry, tracking, weather forecasting, and tactical military applications. It is also used for global maritime, military, and aeronautical communications and shortwave broadcasting. Note that different wavelengths are reflected to dissimilar extents in the troposphere and ionosphere.

Radio-Frequency-Based Systems

Figure 4 shows the various forms of RF-based wireless communication systems, which is classified into six groups: microwave RF systems, fixed and mobile satellite systems, wireless networks and protocols, personal communication systems, remote sensing systems, and emerging wireless technologies. No distinction is made between the communication layers and protocols in this classification. These systems transmit and receive radio waves tuned to specific bands of frequencies. Microwave is loosely used to describe all radio frequencies between 1 and 40 GHz. This includes the UHF, SHF, and EHF systems. The lower microwave frequencies (i.e., UHF) are most often used for terrestrial-based RF systems, whereas the higher microwave frequencies (i.e., SHF and EHF) are used for satellite communications. A terrestrial microwave system transmits carefully focused beams of radio waves from a transmitting antenna to a receiving antenna. A terrestrial microwave system uses LOS propagation to communicate between the Tx and the Rx with a typical distance of 30 miles between relay towers.

Personal communications services (PCS) are a new generation of wireless-telephone technologies that introduce a wide range of features and services greater than those available in analog and digital cellular phone systems (International Engineering Consortium [IEC],

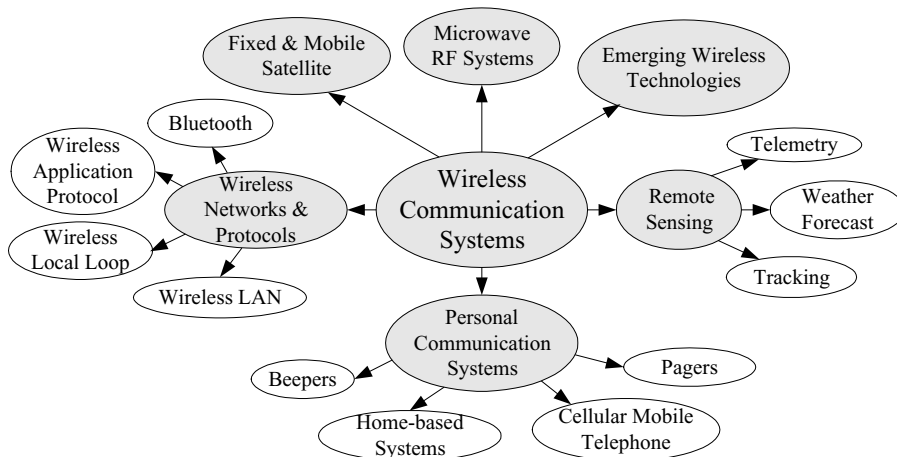

Figure 4: Different forms of radio-frequency (RF)-based wireless communication systems. LAN = local area network.

n.d., a). It includes any system that provides people with access to information services, such as cellular telephones, home-based systems (cordless telephones, remote control, short-range two-way radio), beepers, pagers, and much more (Goodman, 1997; Rappaport, 2002). PCS provides the user with an all-in-one wireless phone, paging, messaging, and data services. The most significant segment of this technology is the cellular mobile radio. It is the fastest growing segment of the telecommunications industry. Based on the number of new subscribers worldwide and the number of services, the cellular mobile radio system has evolved as the dominant wireless communication system. Its history dates back many decades, but the modern-day mobile radio became widespread in the 1980s (Rappaport, 2002). The cellular mobile radio system is discussed in more detail later. Wireless networks and protocols include systems such as WLAN, wireless local loops (WLL), wireless application protocol (WAP), and Bluetooth. These systems are used mainly to provide data communication. WLAN is an extension to or an alternative for a wired local area network (LAN). WLAN provides the functionality of wired LAN, without the physical constraints of the wire, combining data connectivity with user mobility (Bing, 2000; Geier, 1999; Wenig, 1996). WLANs have the potential to support user mobility and constant and unlimited access to information by linking several wireless devices to the wired infrastructure network. With WLAN, packets of data are converted into radio waves that are sent to other wireless devices or to a wireless access point (AP)–client connection from the wired LAN to the mobile user. The AP can reside at any node on the wired network and acts as a gateway for wireless users' data routed to the wired network. WLANs require special medium access control (MAC) layer protocols because of the broadcast nature of radio communication (Chen, 1994). A detailed discussion of WLAN is beyond the scope of this chapter. WLANs have gained strong popularity lately and are used widely in health care, industry, commerce, warehousing, and academia. An important feature of the WLAN is that it can be used independent of a wired network. That is, it can be used as a stand-alone network anywhere to link multiple computers together without extending a wired network. WLAN uses one of the three basic transmission protocols, namely, direct sequence spread spectrum (DSSS), frequency hopping spread spectrum (FHSS), or low-power narrowband. The majority of RF-based WLANs operate in the industrial, scientific, and medical (ISM) frequency bands, which are located at 902 to 928 MHz, 2.4 to 2.483 GHz, and 5.725 to 5.85 GHz, respectively. The different architectures of WLAN based on Agrawal and Zeng (2003) are summarized in Table 2, with symbols defined in the Glossary.

WLL is a system that connects telephone subscribers to the public switched telephone network using radio waves (IEC, n.d., b). With WLL, the traditional copper wire providing a link between the subscriber and the local exchange is replaced by a wireless RF network. WLL is advantageous for remote areas where the cost of wire would be prohibitive (i.e., adverse terrain or widely dispersed subscriber areas). With WLL, new service providers can quickly deploy wireless networks to meet customers'

telephony needs rapidly. Existing landline operators can extend their networks using WLL. Cellular telephone companies can deliver residential service using WLL without going through the local telephone company.

WAP is an application environment and set of communication protocols (application, session, transaction, security, and transport layers) that allow wireless devices easy access to the Internet and advanced telephony services (WAP Forum, 2000; Stallings, 2002). WAP offers the ability to deliver unlimited range of mobile services to subscribers, independent of their network, manufacturer, vendor, or terminal. With WAP, mobile subscribers can access information and services from wireless handheld devices. WAP is based on existing Internet standards such as the Internet protocol (IP), extensible markup language (XML), hypertext markup language (HTML), and the hypertext transfer protocol (HTTP) and is designed to work with all wireless network technology. More information can be obtained from the WAP Forum (2000) and in the chapter on WAP in this encyclopedia.

Bluetooth is a wireless technology that makes possible connectivity to the Internet from mobile computers, mobile phones, and portable handheld devices without the need for cable connection. It facilitates fast and secure transmission of both voice and data, without LOS propagation. Some characteristics of Bluetooth technology are summarized in Table 2. Detailed information on Bluetooth can be found in another chapter in this encyclopedia.

Satellite communication is one of the traditional RF wireless communication systems. Signals can be transmitted directly from a ground station (GS) or gateway on earth to a satellite, and back to another GS. Sometimes the signal can be routed through another satellite (intersatellite) before it is transmitted back to the GS. We can identify a satellite system by how far the satellite is from the earth. The closer the satellite is to the earth, the shorter the time it takes to send signals to the satellite. There are three satellite orbits: low earth orbit (LEO), medium earth orbit (MEO), and geosynchronous earth orbit (GEO). A geosynchronous satellite completes one orbit around the earth in the same time it takes the earth to make one complete rotation. A geostationary satellite is in an orbit located directly above the equator.

LEO satellites are closest to the earth, beginning about 100 miles above the surface, and only take a couple of hours to circle the earth. Because LEO systems are orbiting so quickly, multiple satellites are required to provide constant coverage in one location. LEO systems have the capability to receive calls from the earth and pass them to an earth-based switching system in much shorter time than other satellites. However, because of the speed of the satellite, it is frequently necessary to hand off a particular call to a second satellite just rising over the horizon. This is similar to a cellular mobile radio system (discussed later), except that in this case it is the cell site (the satellite) that is moving rather than the user. The lower orbit has the advantage of allowing access to very low-power devices (Printchard et al., 1993). LEO satellites are used mainly for wireless transfer of electronic mail, pager systems, worldwide mobile telephony, spying, remote sensing, and video conferencing.

Table 2 Examples of Wireless Local Area Networks

Properties	IEEE 802.11	HiperLAN	Ricochet	HomeRF	Bluetooth
Spectrum (GHz)	2.400–2.48; 5.15–5.35, 5.525–5.825	5.15, 17.1	0.902–0.928	2.404–2.478	2.402–2.480
Range	150 feet	150 feet	1,000 feet	<150 feet	10 cm to 100 m
Power consumption	Not specified	Not specified	Not specified	100 mW	1 mW, 10 mW, and 100 mW
Energy conservation	Directory based	Yes	Unknown	Directory based	Yes
Physical layer	DSSS/FHSS/IR	DFS with BPSK/ QPSK/QAM	FHSS 162 hops/s	FHSS 50 hops/s	FHSS 1600 hops/s
Channel access	CSMA/CA	TDMA/TDD	TDMA	Hybrid TDMA and CSMA/CA	FHSS, Master slave TDMA
Mobility support	Not specified	Yes	Yes	No	No
Raw data rate	2, 11, 6–54 Mbps	23.5, 54 Mbps	288 kbps	1 and 2 Mbps	1 Mbps
Traffic	Data (DCF)	Data	Data	Voice + Data	Voice or Data
Speech coding	Unknown	OFDM	Not available	ADPCM, 32 bps	64 kbps with CSVD/log PCM
Security	40 bit RC-4	DES, Triple DES	RSA/RC-4	Blowfish	Minimal (in PHY)
Communication technology	Peer-to-peer, MS-BS	Peer-to-peer, MS-BS	Peer-to-peer	Peer-to-peer, MS-BS	Master/slave

Note. ADPCM = adaptive pulse code modulation; BPSK = binary phase shift keying; CDMA = code division multiple access; CSMA/CA = carrier sense multiple access with collision avoidance; CSVD = continuous variable slope delta; DES = data encryption standard; DFS = dynamic frequency selection; DSSS = direct sequence spread spectrum; FHSS = frequency hopping spread spectrum; IEEE = Institute of Electrical and Electronics Engineers; IR = infrared; MS-BS = mobile station–base station; OFDM = orthogonal frequency division multiplexing; PHY = physical layer; QAM = quadrature amplitude modulation; QPSK = quadrature phase shift keying; RC4 = Rivest cipher 4; RSA = Ron Rivest, Adi Shamir, and Len Adleman, inventors of the RSA code; TDD = time division duplexing; TDMA = time division multiple access.

GEO satellites circle the earth at a height of 22,300 miles, orbiting at the same rate as the earth rotates so that they appear stationary from the earth's perspective. Most GEO satellites rely on passive bent-pipe architecture so that they receive signals from transceivers on earth, amplify them, and send them back to specific regions on earth. GEO systems are used for a wide array of services including television broadcasts, long-distance telecommunications, and various scientific and military applications. GEO satellites are well suited to transmitting data but may be undesirable for voice communications because of the long propagation delay. It takes about one fourth of a second for a signal to travel from a terrestrial GS to the satellite and back. If the receiver GS replies, it takes another one fourth of a second, resulting in a total of half a second (Printchard, 1993). This is an unacceptably long delay for voice communication. Hence, voice communications are seldom carried via GEO satellites.

MEO satellites can be found between 1,000 and 22,300 miles and are mainly used for global positioning and navigation systems. MEO satellites are not as popular as the LEO or GEO for reasons beyond the scope of this chapter.

RADIO WAVE PROPAGATION

Propagation is the process of wave motion, which is important in the design and operation of RF systems. Because the received signal is always different from the transmitted signal, due to various propagation impairments, and because of the nature of the propagation itself, it is necessary to understand the properties of radio wave propagation. This is most important in telecommunication applications in predicting the transmission characteristics of the channel. When radio waves are radiated from an antenna, propagation is governed by the following mechanisms.

Free Space Propagation

This is the ideal propagation mechanism when the Tx and the Rx have direct LOS and are separated by a distance d between the Tx and the Rx. If P_t is the transmitted power, the received power P_r , a function of distance d , is given by (Rappaport, 2002)

$$P_r(d) = G_t G_r P_t \frac{\lambda^2}{(4\pi d)^2 L} = P_t \frac{A_{et} A_{er}}{(\pi d)^2 L}, \quad (2)$$

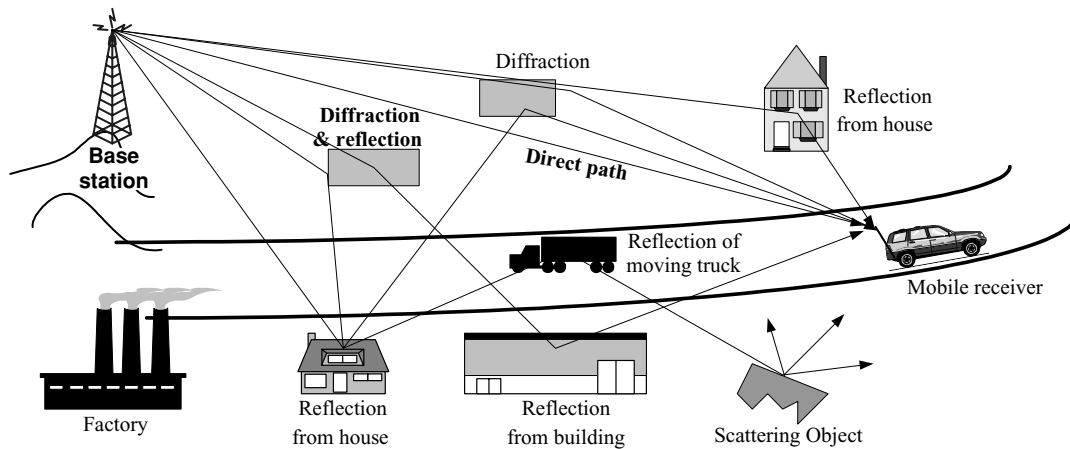

Figure 5: Illustration of reflection, diffraction, scattering, and absorption.

where A_e , G , and L are the effective area, antenna gain, and system loss factor, respectively. The subscripts t and r refer to the transmitter and receiver, respectively. From this relationship, we observe that the received power diminishes at the rate of 20 dB/decade as the distance increases. The product $P_t G_t$ is defined as EIRP, introduced earlier (i.e., $EIRP = P_t G_t$).

Reflection and Refraction

When a radio wave strikes an object with dimensions very large compared with its wavelength, reflection occurs. All radio waves will undergo reflection if the propagation medium undergoes abrupt changes in its physical properties. This is illustrated in Figure 5. The more abrupt the discontinuity, the more pronounced the reflection. Depending on the type of object, the RF energy can be partially reflected, fully reflected, or absorbed. It is possible to compute the amount of reflection from the properties of the two media. If the incident object is a good conductor, the wave is totally reflected and the angle of incidence is the same as the angle of reflection.

Refraction (see Figure 5) occurs at the boundary between two dielectrics, when the incident wave propagates into another medium at an angle. When radio waves propagate from a medium of one density to a medium of another density, the speed of the wave changes. This change in speed will cause the wave to bend at the boundary between the two media. The wave will always bend toward the denser medium.

Diffraction

Diffraction of radio waves occurs when the waves encounter some obstruction along their path and tend to propagate around the edges and corners and behind the obstruction. This is illustrated in Figure 5. The height or dimension of the obstruction has to be comparable to the wavelength of the transmission. The same obstruction height may produce lower diffraction loss at higher λ than at lower λ . The result of this effect is that the object shadows the radio wave. The field strength of the wave decreases as the receiver moves deeper into a shadowed region.

Scattering

Scattering is also illustrated in Figure 5. It is due to small objects and irregularities in the channel, rough incident surfaces, or particles in the atmosphere. When the radio wave encounters objects or particles with dimensions smaller than the wavelength of the wave, scattering occurs, which causes the signal to spread in all directions.

Interference

Interference can occur when the transmitted radio wave arrives at the same location via two or more paths (multipath). One of the ways this can happen is illustrated in Figure 6. This figure shows three waves arriving at a mobile receiver (the car) after traveling slightly different paths. Because of their phase differences, the radio waves can add either constructively or destructively at the receiver. If the phase shift experienced by the propagating waves is time-varying, then it can cause a rapid variation in the received signal, resulting in fading.

Absorption

Absorption describes the process where radio energy penetrates a material or substance and gets converted to heat. Two cases of absorption of radio waves are prevalent. One occurs when radio waves are incident upon a lossy medium and the other is due to atmospheric effects. When the radio wave strikes an object, the incident wave (perpendicular wave) propagates into the lossy medium and the radio energy experiences exponential decay with distance as it travels into the material. The wave either is totally dissipated or will reemerge from the material with smaller amplitude and continue the propagation. The skin depth is the distance for the field strength to be reduced to 37% of its original value—the energy of the wave is reduced by 0.37. Particles in the atmosphere absorb RF energy. Absorption through the atmosphere also depends on the weather conditions—fair and dry, drizzle, heavy rain, fog, snow, hail, and so on. Usually, the absorption of RF energy is ignored below 10 GHz.

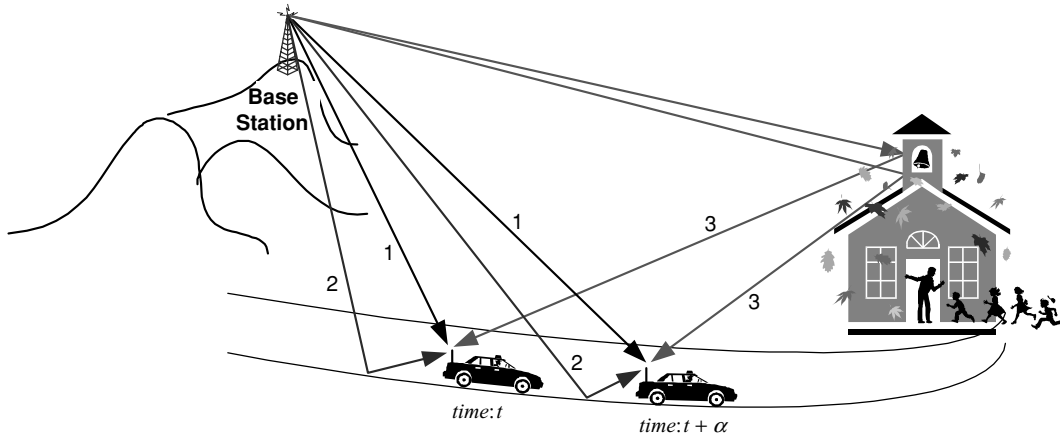

Figure 6: Interference of radio wave.

Doppler Effect

Doppler shift is the change in frequency due to the difference in speed between two points in space. It is observed whenever there is relative motion between the Tx and the Rx. For a mobile moving with a constant velocity v , the received carrier frequency f_c will be shifted by the amount

$$f_d = f_m \cos \theta = \frac{v \cos \theta}{\lambda} = \frac{v_{eff}}{\lambda} = \frac{v_{eff} f_c}{c}, \quad (3)$$

where θ is the path angle, $f_m = v/\lambda$ is the maximum Doppler frequency f_d , at $\theta = 0^\circ$; and v_{eff} is the effective velocity of the mobile (Garg & Wilkes, 1996). The Doppler shift, bounded by $\pm f_m$, is related to the phase change $\Delta\theta$ caused by the change in path length. Because each component of the received multipath signal arrives from a different direction, each contributes a different value to the Doppler spreading. This effectively increases the bandwidth of the received signal. Depending on the direction of motion and the source, the frequency can be shifted up or down (i.e., $\pm f_m$). The result of this shift is a random phase and frequency modulation of the received RF carrier, which may necessitate the use of differential phase and frequency detection techniques.

The propagation mechanisms just described strongly influence system design parameters such as the choice of transmitting and receiving antennas, Tx powers, modulation techniques, and much more. Each of these propagation mechanisms contributes to losses in the RF energy and hence limits system performance. In wireless mobile communications, propagation losses are commonly classified into path loss, shadowing, and multipath fading. These losses are described next.

Path Loss

Path loss (PL) refers to the large-scale envelope fluctuation in the radio propagation environment, which varies with the distance between the Tx and Rx. Because the Rx is located at some distance d from the Tx, a loss factor is used to relate the transmitted power to the received power. For amplitude fading, an increase in d normally results in an increase in PL. Different models have been used to model path loss, but each model obeys the distance

propagation law. In free space, PL is expressed as the ratio of the radiated power P_t to the received power P_r and is given by

$$PL(dB) = 10 \log_{10} \frac{P_t}{P_r} = -10 \log_{10} \left[\frac{G_t G_r \lambda^2}{(4\pi)^2 d^2} \right] \quad (4)$$

Shadowing

Because of topographical variations along the transmission path, the signal is diffracted and the average power of the received signal is not constant. Shadowing or large-scale fading refers to slow variations in the local mean of the received signal strength. This variation causes shadowing. The signal is shadowed by obstructions such as buildings and natural terrain, which leads to gradual variations in the mean power of the received signal. The effect is a very slow change in the local mean signal, say P_s . Shadowing is generally modeled by a lognormal distribution, meaning that $s_d = 10 \log_{10} P_s$ is normally distributed, with s_d given in dB (Yacoub, 1993). Shadowing is the dominant factor determining signal fading.

Multipath Fading

The collective effect of reflection, refraction, diffraction, and scattering leads to multipath propagation. Because of reflection, refraction, and scattering of radio waves along the channel by manmade structures and natural objects along the path of propagation, the transmitted signal often reaches the receiver by more than one path. This results in the phenomenon known as multipath fading. The signal components arriving from indirect paths and a direct path (if it exists) combine at the receiver to give a distorted version of the transmitted signal. These radio waves are attenuated differently, and they arrive with different path gains, time delays, and phases. The resultant signal may vary widely in amplitude and phase depending on the distribution of intensity and relative propagation in time of wave and bandwidth of the transmitted signal. The number of paths may change drastically when the mobile unit changes its position depending on the increase or decrease in the number of intervening obstacles. Unlike shadowing, multipath fading is usually used

to describe small-scale fading or rapid fluctuation in the amplitude of a radio signal over a short period of time or over short distances. It is affected by rapid changes in the signal strength over short distances or time intervals and random frequency variations due to varying Doppler shifts on different multipath signals (Rappaport, 2002).

The loss factor associated with multipath fading is usually modeled in the channel impulse response. A transmitted impulse will arrive at the Rx as the sum of several impulses with different magnitudes, delays, and phases. For M multipath, the composite impulse response $h(t, \tau)$ for any given locations of the Tx and Rx is given by

$$h(t, \tau) = \sum_{k=1}^M \alpha_k(t) \delta(t - \tau_k(t)) e^{-j\phi_k(t)}, \quad (5)$$

where $\alpha_k(t)$, $\tau_k(t)$, and $\phi_k(t)$ represent the time-varying amplitude, delay, and phase of the k th path signal, and $\delta(\cdot)$ is the Dirac delta function. This shows that, in general, the received signal is a series of time-delayed, phase-shifted, attenuated versions of the transmitted signal. The variables $h(t, \tau)$, $\alpha_k(t)$, $\phi_k(t)$, and $\tau_k(t)$ are random.

WIRELESS COMMUNICATION TECHNIQUES

Because the wireless channel is not a reliable propagation medium, techniques to achieve reliable and efficient communication are necessary. In mobile channels, for example, the Rx has to constantly track changes in the propagation environment to ensure optimal extraction of the signal of interest. As the receiver moves, the surrounding environment changes affecting the received signal's amplitude, phase, and delay. The multipath received signals are combined at the antenna either constructively or destructively. During destructive combining, the received signal may not be strong enough to produce reliable communication because of the degradation in the signal-to-noise ratio (SNR). It is not uncommon in shadowed signals for the amplitude of the received signal to drop by 30 dB or more within a distance of a fraction of a wavelength (Eng et al., 1996). Hence, achieving reliable communication over a wireless channel is a daunting task.

To counter this problem, techniques have been developed for efficient wireless communication. These include spread spectrum, multiple access, diversity, equalization, coding, and related techniques such as multicarrier modulation, orthogonal frequency division multiplexing, multicode and multirate techniques, and multiple input multiple output system, to mention only a few. All these techniques are aimed at increasing the reliability of the channel and the performance of the system. Discussion of some of these techniques is beyond the scope of this chapter. However, a summary of the major wireless communication techniques follows.

Spread Spectrum

Spread spectrum (SS) is a modulation technique in which the transmitted bandwidth B_{ss} is much greater than the data bandwidth B_s . The idea is to transform a signal with bandwidth B_s into a noise-like signal of much larger

bandwidth B_{ss} . Spreading is usually achieved by modulating the data with a pseudo-random noise (PN) sequence called the "chip" at a rate that is much higher than the data rate. The significance of SS is evident from the capacity equation, given by

$$C = B \log_2(1 + SNR), \quad (6)$$

where C is the channel capacity in bits and B is the bandwidth in hertz. Observe that by increasing the bandwidth B , we may decrease the SNR without decreasing the capacity and, hence, the performance.

The main parameter in SS systems is the processing gain, G_p , defined as

$$G_p = \frac{\text{Spread Bandwidth}}{\text{Information Bandwidth}} = \frac{B_{ss}}{B_s} = \frac{T_b}{T_c}, \quad (7)$$

where T_b and T_c are the bit period and the chip period, respectively. G_p is sometimes known as the "spreading factor" (Rappaport, 2002). From a system viewpoint, G_p is the performance increase achieved by spreading. It determines the number of users that can be allowed in a system, and hence the amount of multipath reduction effect. It is used to describe the signal fidelity gained at the cost of bandwidth. It is through G_p that increased system performance is achieved without requiring a higher SNR. For SS systems, it is advantageous to have G_p as high as possible, because the greater the G_p , the greater the system's ability to suppress interference. SS techniques are used in cellular mobile telephones, global positioning satellites (GPS), and very small aperture satellite terminals. The strength of this system is that when G_p is large, the system offers great immunity to interference.

There are two major methods of SS modulation: direct sequence spread spectrum and frequency hopping spread spectrum. In DSSS, the frequency of the given signal is spread across a band of frequencies, as described earlier. The spreading algorithm changes in a random fashion that appears to make the spread signal a random noise source. FHSS is the repeated switching of f_c from one band to another during transmission. Radio signals hop from one f_c to another at a specific hopping rate and the sequence appears to be random. In this case, the instantaneous frequency output of the Tx jumps from one value to another based on the pseudo-random input from the code generator. The overall bandwidth required for FHSS is much wider than that required to transmit the same information using only one carrier. However, each f_c and its associated sidebands must stay within a defined bandwidth.

Diversity

Diversity is one of the techniques widely used to increase system performance in wireless communication systems. Diversity combining refers to the system in which two or more closely similar copies of some desired signal are available and experience independent fading. In diversity systems, the received signals from several transmission paths, all carrying the same information with individual statistics, are combined with the hope of improving

the SNR of the decision variables used in the detection process. Diversity-combining techniques could be based on space (antenna), frequency, angle of arrival, polarization, and time of reception (Eng, 1996; Yacoub, 1993). For example, in space diversity, the transmitted signal is received via N different antennas with each multipath received through a particular antenna. This can be regarded as communication over N parallel fading channels. Diversity reception is known to improve the reliability of the systems without increasing either the transmitter power or the channel bandwidth. Regardless of the type of diversity used, the signals must be combined and detected at the receiver. A proper combination of the signal from various branches results in improved performance. The method of diversity combining chosen will affect the receiver performance and complexity. The common combining techniques in wireless communication are maximal ratio combining (MRC), equal gain combining (EGC), and selection diversity (SD). In MRC, the received signals from individual paths are weighted and added so as to emphasize more credible signals and suppress less credible ones (Yacoub, 1993). In EGC, the received signals are equally weighted and then combined without regard to the individual signal strength. In SD, the branch with the best or most desirable signal is selected and the weaker ones are ignored.

Multiple Access

Because the RF spectrum is finite and a limited resource, it is necessary to share the available resources between users. Multiple access techniques are the primary means of sharing the resources in wireless systems. These techniques are multiplexing protocols that allow more than a pair of transceivers to share a common medium, which can be achieved through frequency, time, or code, giving

rise to three popular techniques known as frequency division multiple access (FDMA), time division multiple access (TDMA), and code division multiple access (CDMA). In FDMA, the whole spectrum is divided into subbands, and the subbands are assigned to individual users on demand. The users use the entire channel for the duration of their transmissions. If the transmission path deteriorates, the user is switched to another channel. This access technique is widely used in wireless multiuser systems. Instead of dividing the available frequency as in FDMA, the available time is divided into frames of equal duration in the case of TDMA. Only one user is allowed to either transmit or receive in each time frame. The transmissions from various users are interlaced into cyclic time structure. Instead of using frequencies or time slots, CDMA techniques distinguish between multiple users using digital codes. Each user is assigned a unique PN code sequence, which is uncorrelated with the data. Because the signals are distinguished by codes, many users can share the same bandwidth simultaneously (i.e., signals are transmitted in the same frequency at the same time).
