Currently, cellular mobile communication is undoubtedly the most popular RF wireless communication system. In cellular systems, instead of using a single large coverage area with one high-power transceiver (used in traditional mobile systems), the coverage area is divided into small, localized coverage areas called cells. Figure 7 compares the traditional mobile telephone with the cellular telephone structures. Each cell has a base station (BS) or cell site, which in comparison uses much less power. The BS can communicate with mobiles as long as they are within range. To prevent interference, adjacent cells are assigned different portions of the available frequencies.

Figure 7: Traditional and cellular mobile radio structure showing frequency reuse, cell splitting, and cell sectoring (R = cell radius, D = frequency reuse distance).

With a certain distance between two cells, the assigned spectrum of a given cell can be reused. To explain the concept of cellular mobile communication, a summary of the major concepts and techniques is now presented.

Cells and Clusters

A cell is the basic geographic unit of a cellular system, commonly represented as a hexagon. The term *cellular* comes from this hexagonal or honeycomb shape of the coverage area. Each cell has a BS transmitting over a cell. Because of constraints imposed by natural terrain and manmade structures, the true shapes of cells are not hexagons. The coverage area of cells is called the footprint. The BS simultaneously communicates with many mobiles using one channel (pair of frequencies) per mobile. One frequency is for the forward link (BS to the mobile), and the other frequency is for the reverse link (mobile to the BS). Each cell size varies depending on the landscape, subscriber density, and demand within a particular region. Cells can be added to accommodate growth, for example, creating new cells by overlaying, splitting, or sectoring existing cells. These techniques increase the capacity of the system. Sectoring existing cells and then using directional antennas can also increase capacity.

A cluster is a group of cells. No frequencies are reused within a cluster. Figure 7 illustrates a 7-cell cluster, indicated by the dotted circle. Frequency can be reused for all cells numbered 7. Frequencies used in one cell cluster can be reused in another cluster of cells. A larger number of cells per cluster arrangement reduce interference to the system.

Frequency Reuse

Frequency reuse is a technique of allocating channels to cellular systems. Because of the unavailability of spectrum at the cellular band, channel frequencies must be reused. Cells are assigned groups of channels that are completely different from those of neighboring cells. Cells with the same number have the same set of frequencies. If the number of available frequencies is 7, the frequency reuse factor is $1/7$, which implies that each cell is using one seventh of available frequencies (Rappaport, 2002). Frequency reuse introduces interference into the system.

Interference

In cellular mobile communications, there are two types of intrinsic interference: co-channel interference (CCI) and adjacent channel interference (ACI). These interferences are a result of frequency reuse. CCI is the interference between signals having the same frequency (i.e., the reuse frequencies), whereas ACI is the interference between signals having frequencies close together. For example suppose channel 1 has frequencies 825.030 MHz (mobile) and 870.030 MHz (BS), and channel 2 has frequencies 825.060 MHz and 870.060 MHz. Channels 1 and 2 have frequencies close to one another, which will result in ACI. Any other signals having the frequencies of channel 1, 825.030 (mobile) and 870.030 MHz (BS), are co-channel signals and will suffer from co-channel interference. Note that the interference effect is related to the ratio of the reuse

distance D and the cell radius R . This is known as the Q-factor ($Q = D/R$) and is used to measure the level of CCI. A higher Q value improves transmission quality due to smaller CCI. That is, increasing D improves isolation of RF energy between cells and hence minimizes interference. The ACI is mainly due to imperfect filtering allowing nearby frequencies to leak into the passband of the desired signal (out-of-band interference).

Cell Splitting and Sectoring

Cell splitting is the process of subdividing a congested cell into smaller cells, each with its base station. As the traffic load carried by a large cell reaches capacity, cell splitting is used to increase system capacity. In this way, heavy-traffic regions can be split into as many smaller areas as necessary to provide acceptable service levels. Cell splitting decreases R , while leaving Q relatively unchanged. Notice that more cells imply that more cell boundaries will be crossed more often, increasing trunking and handoff. Only those cells that have traffic overloads are candidates for splitting. However, if cells are split in only a part of a system, serious channel assignment problems may result. The difficulty encountered when all the cell sites are not split can be resolved by implementing cell overlay.

Cell sectoring is the process of dividing cells into sectors and replacing a single omni-directional antenna with a directional antenna. Common sectors sizes are 120° , 90° , 60° , and 30° . Cell sectors of 60° and 120° are illustrated in Figure 7. When cells are sectorized, R is unchanged, D is reduced, the amount of frequency reuse is increased, and hence capacity is increased. It is observed that the spectral efficiency of the system is enhanced because the frequency can be reused more often.

Handoff

Handoff is the process used to maintain a call in progress when the mobile user moves between cells. Handoff is generally needed when a mobile is at a cell boundary or reaches a gap in signal strength. Because adjacent cells do not use the same frequency, a call must either be dropped or transferred from one radio channel to another when a mobile user crosses the line between adjacent cells. Because dropping the call is unacceptable, the process of handoff is necessary. As the user moves between cells, the transmission is “handed off” between cells to maintain seamless service.

ELEMENTS OF WIRELESS COMMUNICATION SECURITY

In all communication systems, whether wireless or not, it is extremely important to ensure the authenticity of all messages. Also, because a wireless system consists of both wireless and wired components, system security involves the security of both components. In a wireless system, communication through an open-air medium makes the information more vulnerable to additional security risk. Given that RF signals propagate beyond walls and buildings, the task of securing wireless RF transmissions has become more complex. This situation is compounded by

additional difficulties of a wireless system such as limited bandwidth, high latency, and unstable connections. In all cases, however, the objective is to authenticate the user, secure the data, and ensure that the traffic is not altered during communication.

Security Methods and Practices

One of the important ingredients in the security or integrity of information transmission is secrecy. The need for secure communications particularly over the airways is more profound than ever, given that the conduct of much of our commerce, business, and personal matters is being carried out by computer and communication systems. The main components of the security processes for communication systems cryptographic techniques, security protocols, access control methods.

Cryptography. Cryptography is the transformation of a message into coded form by encryption and the recovery of the original message by decryption. Encryption and decryption are the primary tools used to ensure secure communication, which makes the message indecipherable to anyone other than the intended user. Encryption of a message could be as simple as permuting the message bits in a prespecified manner before transmission or as complex as source and channel coding and decoding (Agrawal & Zeng, 2003). Cryptographic systems offer three important services: (a) *secrecy*—the denial of access to information by unauthorized users; (b) *authenticity*—the validation of the source and use of a message; and (c) *integrity*—the assurance that a message in transit is not modified by accidental or deliberate means.

Conventional cryptography, commonly referred to as *single-key cryptography* or *secret-key* or *shared-key cryptography*, uses a single piece of private and secret information known as *key*. This form of cryptography operates on the assumption that the key is known to the transmitter and the receiver only, and that once the message is encrypted, it is not possible to be deciphered without knowledge of the key. Another type of cryptography is the *public-key cryptography* or *two-key cryptography*, in which each user is provided with the key consisting of a public portion generating the public transformation, and a private portion (secret), generating the private transformation (Computer Security Resource Center [CSRC], 2001). Finally, because of the limited bandwidth and processing power of wireless systems (e.g., mobile device), robust encryption schemes may be difficult to attend.

Security Protocol. *Protocol* is a set of rules that govern the communication between the transmitter and the receiver. In wireless systems, wired equivalent privacy (WEP) and the wireless transport layer security (WTLS) are the two main *security protocols*. WEP is the standard for encryption in the IEEE 802.11 wireless LAN standard. One weakness of WEP is that a single key is shared between all the users (mobile stations) and access points (APs). This is not very reliable and also cumbersome to manage as security problems have been reported with the WEP (CSRC 2002a, 2002b). However, the Wi-Fi protected access (WPA) provided better security features compared with the WEP. Yet no matter how messy the birthing process, WPA seems to be an improvement over the present state of WLAN security by providing improved encryption and simple but robust user authentication that can be used in home wireless networks.

The WTLS is the security layer in the WAP that adds security to mobile devices with little computing power by making the encryption process efficient. At the WAP gateway, the wireless data must be unencrypted from WTLS and reencrypted into a wired encryption protocol like the secure socket layer (SSL).

Access Control. Illegal intrusions into a network are controlled by *access-control* methods or devices such as firewalls, RADIUS (remote authentication dial-in user service), and authentication servers. A firewall provides preliminary filtering of unauthorized traffic to specific resources or network segments, and a typical firewall classifies traffic on the basis of predefined addresses (IP addresses).

Authentication and authorization mechanisms restrict access to the network and its resources, enabling usage only when provided with a legal identification and password. With authentication the genuineness of the user, or lack of it, is determined. Unfortunately, this is not very reliable, because user identifications and passwords can be obtained or guessed, and therefore a user connecting to a network or service may not necessarily be the authorized user.

A secure wireless system must be capable of protecting the confidentiality, integrity, and nonrepudiation of the message (Bhargarva & Agrawal, 2001; Venkataraman & Agrawal, 2000). Threats on security can be viewed as potential violations of security. Hence, a wireless communication system requires secure medium access control (MAC) protocols. MAC protocols must be able to have various mechanisms to handle the diverse traffic demands of different services as securely as possible. Figure 8

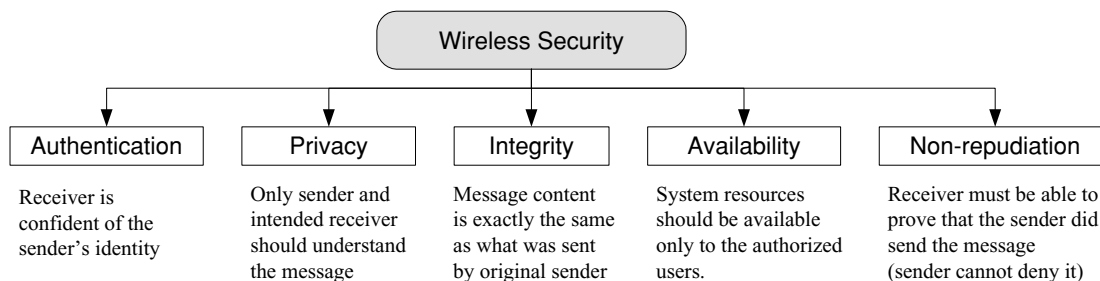

Figure 8: Wireless security services.

Table 3 List of Security Mechanisms

Security Mechanism	Remark
Security prevention	Enforces security during the operation of a system by preventing security violations. It is implemented to counter security attacks.
Security detection	Detects both attempts to violate security and to address successful security violations. An intrusion detection system (IDS) comes under this category
Recovery	Used to restore the system to a presecurity violation start after a security violation has been detected

summarizes the various categories of attacks that could be brought on wireless.

Security maintenance services enhance the security of all information transfers in the wireless system, by implementing countermeasures to the various possible attacks. Security requirements of wireless systems depend on the amount of investment and the characteristics of applications running on the system. For example, electronic funds transfer, reservation systems, and typical control systems have different levels of security demands and expectations. For most systems, the cost for security increases exponentially with increased level of security needed. Hence, there is a tradeoff between the level of increasing system security and the potential cost incurred. The wireless security services are summarized in Figure 8. To provide efficient security, the system must address the five cardinal security services depicted in Figure 8. Some of the mechanisms used for preventing or mitigating the effect of attacks in wireless systems are summarized in Table 3.

Wireless Security Risk and Threats

According to the National Institute for Standards and Technology (NIST), security threats in general can be classified into one of the following categories (NIST, 2003): (a) fraud and theft, (b) malicious hackers, (c) malicious code, (d) threats to personal privacy, (e) employee sabotage, (f) loss of physical and infrastructure support, (g) industrial espionage, (h) errors and omissions, and (i) foreign government espionage. All of these represent potential threats in wireless systems as well. These threats, if successful, place information at risk. Security services (e.g., confidentiality, integrity, and availability) of wireless systems are the prime objectives of all security methods and practices.

Risks in wireless networks include the risks of wired networks in addition to the new risks introduced by the wireless nature of the system. Threats can be accidental or intentional. Accidental threats result due to operational mistakes of system and hardware or software failure. Intentional threats (attacks) are actions performed by an entity with an intention to violate security. Specific threats and vulnerabilities to wireless systems in general are summarized in Table 4.

Security attacks can be broadly divided into two groups: active and passive attacks. These two broad classes are then subdivided into other types of attacks as illustrated in Figure 9. An attack is said to be *passive* when an unauthorized user simply gains access to a network without modifying its content such as in eavesdropping and traffic flow analysis. In *eavesdropping*, the attacker simply monitors transmissions for message content. An example of this attack is a person listening in on transmissions on a local area network between two workstations, or tuning into transmissions between a wireless handset and a base station.

In *traffic analysis*, the attacker, in a more subtle way, gains intelligence by monitoring the transmissions patterns for messages between communicating units, which can yield significant amounts of information through the flow of information.

An attack is said to be *active* when an unauthorized user makes modifications to a message, data stream, or file. It is possible to detect this type of attack, but it may not be preventable. Active attacks may be in the form of one or more of the following: *masquerading*, *replay*, *message modification*, and *denial-of-service (DoS)*. In *masquerading*, the attacker impersonates an authorized user and thereby gains certain unauthorized privileges. In *replay*, the attacker monitors transmissions (passive attack) and, using the obtained information, retransmits messages as the legitimate user. *Message modification* involves an attacker who alters a legitimate message by deleting, adding to, changing, or reordering the message. In DoS, the attacker prevents or prohibits the normal use or management of communications facilities. DoS involves hijacking of the resources, thereby preventing authorized user from utilizing network resources.

In general, it is harder to detect passive attacks because they do not disturb the system. Encrypting messages can partly solve the problem. The consequences of passive or active attacks include loss of privacy, loss of proprietary information, legal and recovery costs, tarnished image, and loss of network service (Agrawal & Zeng, 2003).

SECURITY OF WLAN

The technology of a wireless network, which enables one or more devices to communicate without physical connection, ranges from complex systems such as cellular phones and WLAN to simple devices such as wireless headphones, microphones, and other devices that do not process or store information. All these technologies use radio waves for transmitting and receiving information. Based on the coverage area, wireless networks can be classified into wireless wide area network (WWAN), WLAN, and wireless personal area network (WPAN). WWAN technologies include mobile cellular network, cellular digital packet data (CDPD), global system for mobile communications (GSM), and Mobitex. WLAN includes systems such as IEEE 802.11a (54 Mbps @ 5 GHz), IEEE 802.11b (11 Mbps @ 2.4 GHz), IEEE 802.11g (54 Mbps @ 2.4 GHz), and HiperLAN (54 Mbps @ 5 GHz, used in Europe). WPAN are network technologies such as Bluetooth and HomeRF. Although their coverage areas are different, their communication techniques are similar because they transmit and

Table 4 Threats and Vulnerabilities to Wireless Systems in General

Security Risk and Threats	Remark
Wired system risks	These include all the vulnerabilities that exist in a conventional wired network.
Unauthorized access	This includes unauthorized access to a network through wireless connections, bypassing any firewall protections.
Fraud and theft	<ol style="list-style-type: none"> 1. Due to the portability of wireless devices, theft is more likely to be committed by authorized and unauthorized users of the system. Hence, the information contained in the device can be compromised. 2. Stolen wireless devices can reveal sensitive or private information.
Malicious hackers	<ol style="list-style-type: none"> 1. Malicious hackers or crackers can break into a system without authorization, usually for personal gain or to do harm. Such hackers may gain access to the wireless network access point by eavesdropping. 2. Sensitive information may be intercepted and disclosed and perhaps maliciously used. 3. Malicious entities may steal the identity of legitimate users and masquerade on the networks. 4. Malicious entities may be able to violate the privacy of legitimate users and be able to track their actual movements. 5. Data may be extracted without detection from improperly configured devices.
Malicious code	<ol style="list-style-type: none"> 1. Denial of service attacks may be directed at wireless connections or devices. 2. Malicious code such as viruses, worms, Trojan horses, logic bombs, or other unwanted software, designed to damage files or bring down a system, can easily be introduced into a wireless system. 3. Sensitive data may be corrupted during improper synchronization. 4. Through wireless connections, malicious entities may connect to the wired network for the purposes of launching attacks and concealing their activity. 5. Interlopers may be able to gain connectivity to network controls and thereby disable or disrupt operations.
Industrial and foreign espionage	<ol style="list-style-type: none"> 1. Industrial and foreign espionage involves gathering proprietary data from corporations or intelligence information from governments through eavesdropping. In wireless networks, the espionage threat stems from the relative ease with which eavesdropping can occur on radio transmissions. 2. Spying for military applications also falls under this category.

receive information using radio waves. Because wireless network and technology are so diverse, I limit our discussion on the security issues related to the IEEE 802.11 WLAN technology as an example.

Security Methods in Wireless LAN

WLAN is a flexible data communication system implemented as an extension to or as an alternative for, a wired LAN (CSRC, 2002). Using RF technology, WLAN transmits and receives data over the air, minimizing the need for wired connections. It combines data connectivity

with user mobility. A WLAN has wireless client stations that use radio waves to communicate to an access point (AP). The client stations are generally equipped with a wireless network interface card (NIC) consisting of the radio modem and the necessary logic and software to interact with the access point. An AP, a stationary device that is part of the wired infrastructure, comprises essentially a radio modem on one side and a bridge to the wired network on the other. The AP is analogous to a cell-site (base station) in cellular communications. All communications between the client stations and the wired network go through the AP. Having gained strong

**Figure 9:** Different types of security attacks.

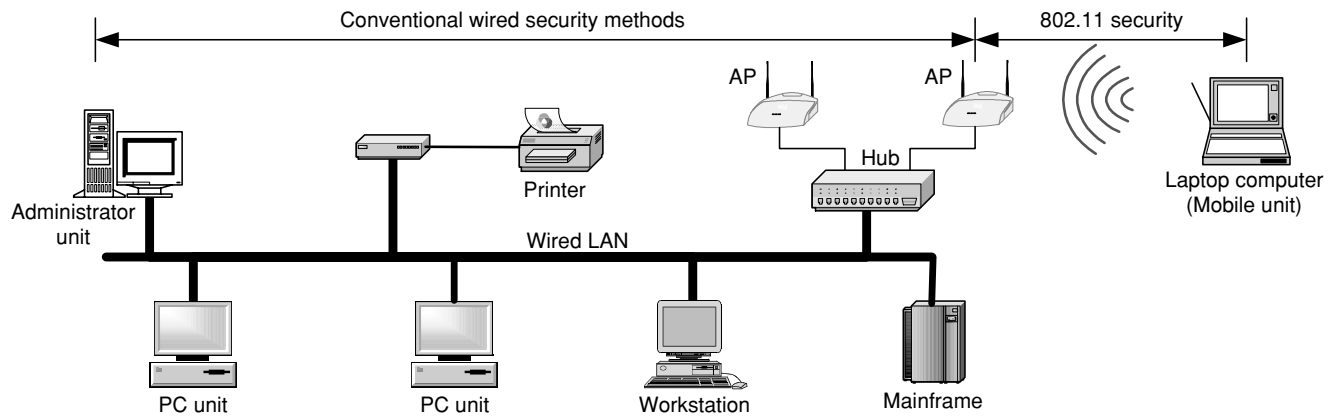

Figure 10: Security infrastructure in IEEE 802.11 wireless networks.

popularity lately, WLAN is used in health care, retail, manufacturing, warehousing, and academia.

The preferred protocol for WLAN is the IEEE 802.11 standard (The IEEE Working Group for WLAN Standards, n.d.). Without authentication and encryption, WLANs are extremely vulnerable. The security services are provided largely by the WEP security protocol. WEP has two main design goals: to protect against eavesdropping and to prevent unauthorized access. WEP uses RC4 encryption on a 40- or 128-bit shared key. Encryptions of payload is undertaken while frame is “in the air.”

IEEE 802.11 defines mechanism for encrypting frames using WEP as follows:

1. A key is shared between all members of network.
2. The encryption algorithm for WEP is RC4. It is used to generate the key stream, which is added to the plaintext code using modulo-2 addition (exclusive-ORed) against plaintext to produce ciphertext.
3. The decryption algorithm for WEP is also RC4 which is exclusive-ORed with the ciphertext to reproduce plaintext.
4. WEP appends 24-bit initialization vector (IV) to the shared key and using this combined key + IV, it generates RC4 key schedule. WEP selects new IV for every packet.

5. Encapsulation transports the IV and ciphertext from sender (encryptor) to receiver (decryptor).
6. WEP uses a cyclic redundancy check (CRC) code of length 32 for integrity check of the frame. The CRC is computed over data payload and appended to the frame before encryption. WEP encrypts CRC with rest of data payload.
7. Authentication process is only a one-way client medium; access control protocol address only.

WEP does not provide end-to-end security, but only for the wireless portion of the connection, as shown in Figure 10.

Security Services for IEEE 802.11 Standards

The 802.11 standard addresses three basic security services—authentication, confidentiality, and integrity. These three basic security services are summarized as follows:

Authentication—WEP authentication process is used to provide access control to the network through denying access to client stations that cannot be authenticated properly. Authentication can be achieved through cryptography or noncryptographic means. The authentication process is illustrated in Figure 11. Please note that

Figure 11: Authentication processes in 802.11 WLAN standards. AP = access point; SSID = service set identifier; WEP = wired equivalent privacy.

Table 5 Security Problems With Current 802.11 WLAN

Security Issues and Vulnerability	Remarks
Cryptography	<ol style="list-style-type: none"> 1. Cryptographic keys are short. Standard 40-bit keys are inadequate and vulnerable to attacks. The longer the key, the less likely the key can be recomputed from a brute-force attack. It has been shown that 80-bit or more key size is more secure. 2. Keys are shared. If keys are shared, confidentiality could be compromised. 3. Keys not updated automatically and frequently. Cryptographic keys should be changed often to prevent brute-force attacks.
Authentication	<ol style="list-style-type: none"> 1. No user authentication. In 802.11, only the device is authenticated. A stolen device can be used to access the network. 2. Device authentication is based on challenge-response. One-way challenge-response authentication is subject to attacks. Mutual authentication is required to provide verification that users and the network are legitimate. 3. Authentication not automatically enabled. Identity-based systems are highly vulnerable particularly in a wireless system because only simple service set identifier; identification occurs. 4. Authentications by MAC address lookup.
Wired equivalent privacy (WEP)	<ol style="list-style-type: none"> 1. RC4 used in WEP has a weak key schedule. The IV in WEP uses a 24-bit key sent in the clear text portion. It has been shown that using this key combined with a weakness in the initial few bytes of the RC4 keystream, it is possible to attack the system successfully
Packet integrity	<ol style="list-style-type: none"> 1. Packet integrity is poor. Cyclic redundancy check (CRC)-32 and other linear block codes are inadequate for cryptographic integrity. Message modification is possible. 2. Cryptographic protection is required to prevent deliberate attacks. 3. Use of noncryptographic protocols often facilitates attacks against the network.
Security hardware	<ol style="list-style-type: none"> 1. Security features in hardware, although poor in some cases, are often not enabled when shipped, and users do not enable them when installed. Hence, many systems operate without security. 2. Bad security is generally better than no security.

the noncryptographic techniques are highly vulnerable to attacks

Confidentiality—In the 802.11 protocol, confidentiality or privacy is implemented through the use of cryptographic techniques with the RC4 symmetric-key encoding. Before transmission, the data stream is added to the “key stream” using modulo 2 additions. Key sizes ranging from 40 bits to 104 bits can be used. In practice, however, most WLANs use 40-bit keys, which is not reliable. In general, increasing the key size increases the security of a cryptographic technique. It has been shown that the WEP confidentiality approach is vulnerable to attacks (CSRC, 2002).

Integrity—Data integrity is achieved by using a simple encrypted CRC encoding and decoding technique. A CRC-32 code or a frame check sequence is computed on each packet prior to transmission. The integrity-sealed packet is then encrypted using the RC4 key stream to provide the encrypted message. On the receiving end, decryption is performed, and the CRC is recomputed on the message received. The CRC computed at the receiving end is compared with the one computed with the original message. Any discrepancy signifies a violation of integrity.

These three techniques are the only security services provided by the IEEE 802.11 WLAN protocol. Security services provided by the IEEE 802.11 WLAN protocol did not address other security services such as audit, authorization, and nonrepudiation.

Security Vulnerability in IEEE 802.11 Standards

The WEP protocol used in 802.11-based WLANs is perceived to have some security problems. The use of 40-bit key in the WEP cryptography has been found to be vulnerable to both passive and active attacks (CSRC, 2002; Ewalt, 2001). Because significant attention is now being focused on the security of 802.11, more vulnerability is likely to be discovered. To present a concise discussion on the issue of security for WLAN, some of the problems associated with WEP security techniques in the IEEE 802.11 WLAN standard are summarized in Table 5.

EMERGING TECHNOLOGIES AND SECURITY STANDARDS

The first-generation (1G) and second-generation (2G) of cellular mobile telephony were intended primarily for voice transmission. This will not be adequate for the new generation of users. The need for multimedia communications over wireless channels, the rapid growth of wireless voice subscribers, the continued popularity of the Internet, and the increasing use of portable computing devices suggest that high-speed, high-capacity, and high-quality wireless communication systems will become a major focus in the telecommunication industry. In today’s technology era, emerging personal communication systems

Figure 12: IMT-2000 terrestrial radio interfaces.

are expected to provide a wide range of services that require high data rates—not only for voice, but also in data, images, video, and multimedia information transmission over wireless channels. With the continued growth of the Internet and World Wide Web, mobile users are continually looking for high-performance wireless Internet technology to enhance their communication capabilities. The third-generation (3G) systems were intended to provide high data rates (between 384 kbps for low mobility users to 2 Mbps for stationary users; The Shoesteck Group, 2001), significantly expands the range of options available to users and allows multimedia communication via wireless terminals. Unfortunately, these objectives have not been fully realized.

One of the challenges of realizing these objectives is the effects of the wireless channel, which includes fading, delay spread, and co-channel interference. To achieve high-speed, high-quality, and high-capacity communications over wireless channels, countermeasures should be employed to combat these impairments.

New wireless or cellular mobile radio technologies, services, and applications are constantly under investigation. Some of the technologies are currently under research and development, and some are experiencing limited field tests. These technologies include the 3G technologies and the fourth-generation (4G) technologies. The goal of these technologies is to integrate seamlessly a wide variety of communication services such as high-speed data, video, and multimedia traffic as well as voice signals. Some of these technologies can be realized by combining existing technologies. For example, one of the most promising approaches to 3G is to combine a wideband code division multiple access air interface with the fixed network of a global system for mobile communications (GSM). It is expected that these new technologies will increase the performance of the existing wireless systems. These technologies will provide multimedia capability at much higher rates with Internet connectivity.

Although 3G technologies have been deployed, they have not experienced market success compared with the 2G systems. The 3G standard was created by the International Telecommunication Union (ITU) and is more widely known as International Mobile Telecommunications—2000 (IMT-2000). The aim of IMT-2000 is to harmonize worldwide 3G systems to provide global roaming. Harmonizing so many standards proved extremely difficult. Furthermore, the definition of what is and what is not “3G” is murky. Figure 12 shows the various terrestrial radio interfaces referred to as 3G standards and is based

on the IMT-2000 standardization. Of many variants, only three dominant standards (wideband code division multiple access (**W-CDMA**), CDMA2000, and TD-SCDMA) allow full network coverage over macro cells, micro cells, and pico cells and can thus be considered as full 3G solutions. As shown in Figure 12, other non-CDMA technologies such as UWC-136 and DECT+ are also considered 3G technologies. In W-CDMA technology, data are transferred over wireless networks in digital format over a range of frequencies, which makes the data move faster but also uses more bandwidth than digital voice services. The competing 3G CDMA technologies differ technically but provide comparable services. Although there are five terrestrial standards, most of the attention in the industry has been focused on the CDMA standards. As technology improves, the functionality of handheld devices is becoming more feature-rich and portable. For example, mobile phones have increased functionality that now allows them to serve as PDAs and digital cameras in addition to phones. Smart phones can now provide voice services, e-mail, text messaging, paging, Web access, voice recognition, and digital camera capability. Next-generation mobile phones, already on the market, are quickly incorporating PDA, infrared (IR), wireless Internet, e-mail, and global positioning system capabilities. More significantly, manufacturers are combining standards as well, with the goal to provide a device capable of delivering multiple services. Table 6 summarizes the services and applications of the various generations of wireless services.

Another emerging application in wireless communication is the use of ultra wideband (UWB) systems for local area network. UWB is defined as any radio technology with a spectrum that occupies a bandwidth greater than 20% of the center frequency, or a bandwidth of at least 500 MHz (FCC, 2000; Intel, n.d.). UWB systems transmit signals across a much wider frequency than conventional systems. The amount of spectrum occupied by a UWB signal, that is, the bandwidth of the UWB signal, is at least 25% of the center frequency. In the United States, the FCC has mandated that UWB radio transmissions can legally operate in the range from 3.1 to 10.6 GHz, at a limited transmit power of -41 dBm/MHz. Consequently, UWB provides dramatic channel capacity at short range that limits interference. UWB communication systems offer several potential advantages. Because of the potentially large processing gain, many of the characteristics and advantages of spread spectrum communication carry over to UWB systems. For instance, a UWB system is capable of supporting multiple users; is robust against jamming,

interference, and multipath fading; and is suitable for applications requiring low probabilities of interception and low probability of detection by unintended user. It follows that their wide bandwidth makes them more robust to multipath interference with multiuser access capability. UWB provides the highest bandwidths with the lowest vulnerability to multipath interference. It also offers potentially high bit rate transmission with capacity increasing almost linearly with power. The fine time resolution makes it a good candidate in applications such as ranging, remote sensing, search and rescue missions, and measurement applications under extremely harsh weather conditions.

Unfortunately, before UWB systems can become fully implemented and commercially viable, many challenging problems need to be resolved. Some of these include wideband antenna design, timing acquisition and synchronization, channel modeling, and interference from or to other systems. For example, the performance of UWB systems under a realistic channel model is being

investigated. In addition, with low transmission power and a highly spread bandwidth, acquisition of a UWB signal is difficult (Fleming, Kushner, Roberts, & Nandiwada, 2002). For instance, if packets are transmitted, a long preamble is needed to ensure acquisition of each packet at the receiver, reducing throughput and increasing overhead. This problem is amplified when multiple hops are traversed in a network from the source to the destination. Also, because UWB systems are overlaid on existing wireless systems, issues of interference become critical (Fontana, 2002; Siwiak, 2001). Interference suppression algorithms are needed to minimize interference from or to other users. Other research interests include the implementation of UWB systems in a dense network environment.

Another wireless communication application is local multipoint distribution services (LMDS), a fixed wireless technology that operates in the Ka band and offers LOS coverage over distances up to 3–5 kilometers (Wireless Communications Association International, n.d.). It can

be used to provide digital two-way voice, data, Internet, and video services to numerous customers from a single node. LMDS is a broadband wireless point-to-multipoint communication system operating in the Ka band and above. LMDS is one solution for bringing high-bandwidth services to homes and offices within the “last mile” of connectivity, an area where cable or optical fiber may not be convenient or economical. The technology is similar to the cellular systems in that network architecture of microwave radios placed at the client’s location and at the company’s base station to deliver fixed services—mainly telephony, video, and Internet access. With LDMS, customers can receive data rates between 64 kbps and 155 Mbps. Advantages of LMDS include low deployment costs, fast deployment capability, scalable system architecture, and variable component cost because no large capital investment is required. The system requires LOS between the base station hub and the customer premises, however, and LDMS signals are affected by weather conditions.

There are emerging security standards and technologies that should be mentioned. The security industry, standards organizations, and IEEE are all working to improve the security of wireless systems. For example, the Internet Engineering Task Force (IETF; Cox, 2003) and the IEEE 802.11 Task Working Group I (TGI; IEEE Working Group, 2003) are currently working on initiatives for improving WLAN security. The TGI is defining a second version of WEP, based on the newly released advanced encryption standard (AES). The AES-based solution will provide a highly robust solution for the future but will require new hardware and protocol changes.

In the meantime, a short-term solution to address the problems of WEP, using the temporal key integrity protocol (TKIP) has been proposed. The primary goal of TKIP is to remove all known vulnerabilities of WEP and allow operation on existing wireless-fidelity (Wi-Fi)-certified hardware. This will address the problems without requiring hardware changes (only changes to firmware and software drivers required).

CONCLUDING REMARKS

In this chapter, RF and wireless communication and the related security issues have been discussed. The concept and general definitions are presented. Within these topics, we have discussed the concept of radio waves as propagating electromagnetic waves, including their characteristics and behavior. For wireless and mobile radio systems, it is important to understand distinguishing features of the channel, the properties of the radio wave, and several techniques to enhance the reliability of the channel and increase the performance of the system. RF and wireless communication systems are being used in diverse arenas such as in the home; by the military; and for travel, education, stock trading, package delivery, disaster recovery, and medical emergencies. For example, with wireless technology, field employees can connect a portable computer via a wireless network to the area office. Sales professionals can stay in touch with customers about products and services and orders and contact the home office for status updates to home offices and inventory.

Airline staff can gather information about ticketing, flight scheduling, and luggage using wireless devices. Public welfare agencies such as police, fire safety, and ambulance services can use wireless devices to relay information. Package delivery companies such as Federal Express, UPS, and DHL have adopted wireless and mobile computing technology for parcel tracking, as well as emergency shipment drops or pickups. Also, a summary of the various forms of wireless communication systems was presented, emphasizing cellular mobile radio, currently the most prevalent wireless communication system. Finally, emerging wireless technologies were briefly introduced.

Although wireless systems are commonplace in our society, the future of the industry is filled with both promise and challenge. Future wireless technologies under consideration include the full realization of 3G technologies and the development of 4G technologies. 4G wireless technology based on ultra-wideband communications could enable the use of low-power, high-bandwidth (100–500 Mbps) networks, supporting devices with sense and radar capabilities. Multimedia messaging will allow pictures and sound to be transmitted along with text message over the mobile phone in a seamless manner. Mobile handsets will support full-color display screens, some with embedded Java capabilities, others with built-in digital cameras. It is expected that Bluetooth technology will move from theory and hype to practicality, and issues regarding the security of mobile commerce and information security in general will dissipate.

GLOSSARY

1G, 2G, 3G, 4G First-, second-, third-, and fourth-generation wireless systems.

Access Point A specially configured node that acts as a central transmitter and receiver for on a wireless local area network radio signals.

Ad Hoc Network A “spontaneous” network is a wireless LAN, in which some of the network devices are part of the network only for the duration of a communications session or while in some close proximity to the rest of the network.

Amplifier An electronic device used to boost the strength of a signal along a communications channel.

Antenna A device used for receiving or transmitting signals.

Authentication The process of determining the true identity of a user. Basic authentication is simply using a password to verify that you are who you say you are.

Bandwidth The capacity of a transmission channel.

Base station Central radio transmitter or receiver (or both) that maintains communications with a mobile radio user.

Bluetooth Short-range wireless protocol allowing mobile devices to share information and applications.

Broadband A classification of the information capacity or bandwidth of a communication channel.

Cellular Wireless communication technique used in mobile phones.

Channel A radio-frequency assignment made according to the frequency band used.

- Cipher** Transformations that convert plaintext to ciphertext using the Cipher key.
- Ciphertext** Data output from the cipher or input to the inverse cipher.
- Cryptography** The science of information security usually involving scrambling of plain text into encrypted text at the transmitter, and decrypting the encrypted text back into plain text at the receiver. The encrypted information cannot be understood by anyone for whom it is not intended or altered in storage or transmission without the alteration being detected.
- Cyclic Redundancy Check (CRC)** A method of encryption used by WEP to provide integrity protection for WLAN.
- Data encryption standard (DES)** Widely used method for data encryption using a private key that is difficult to break. It uses a 56-bit key for each 64-bit block of data. There are 72 quadrillion or more possible combinations of keys.
- Decipher** Inverse transformations that converts ciphertext to plaintext using the Cipher Key.
- Decryption** Decryption is the process of converting encrypted data back into its original form so that it can be understood.
- DoS** Denial-of-service. An attack that floods a network with an overwhelming amount of traffic, slowing its response time for legitimate traffic or grinding it to a halt completely.
- Downlink** Data transmission from a network to a subscriber.
- Duplexer** Device for isolating transmitter and receiver signals while permitting a shared channel.
- Effective Isotropic Radiated Power (EIRP)** Product of power supplied to an antenna and its gain.
- Encryption** The conversion of data into a form called a ciphertext that cannot be easily understood by unauthorized users.
- Enhanced Data GSM Environment (EDGE)** A faster version of the GSM wireless service designed to deliver data at rates up to 384 Kbps and enable the delivery of multimedia and other broadband applications to mobile phone and computer users.
- Firewall** A set of related programs located at a network gateway server that protects the resources of a private network from users from other networks.
- Frequency** Rate of signal oscillation in hertz (1 hertz is one cycle per second); the number of times a waveform repeats itself in a second.
- Global Positioning System (GPS)** A worldwide radio-navigation system.
- Ground Station** The ground equipment needed to receive or transmit satellite telecommunications signals, including a dish and other electronics components.
- GSM** Global system for mobile communications; the mobile phone platform used in Europe and many parts of the world.
- Handoff** Transfer of wireless call in progress from one site to another without disconnection.
- HiperLAN** HiperLAN is a set of WLAN communication standards primarily used in Europe, adopted by the European Telecommunications Standards Institute (ETSI).
- HomeRF** Home radio frequency (HomeRF) is a home networking standard that combines the 802.11b and digital enhanced cordless telecommunication portable phone standards into a single system. HomeRF uses a frequency-hopping technique to deliver speeds of up to 1.6 Mbps over distances of up to 150 feet.
- IEEE 802.11** The IEEE's proposed standard for wireless LANs that places specifications on the parameters of both the physical and medium access control layers of the network.
- Infrared (IR)** An invisible band of radiation at the lower end of the electromagnetic spectrum.
- Initialization vector (IV)** A random data used encryption to make a message unique.
- Institute of Electrical and Electronics Engineers (IEEE)** A worldwide professional association for electrical and electronics engineers that sets standards for telecommunications and computing applications.
- Isotropic** Refers to a theoretical reference antenna that radiates equally well in all directions.
- Local Area Network (LAN)** A network that connects computers in close proximity via cable, usually in the same building.
- Malicious Code** A term used to refer to various types of software that can cause problems or damage to the network. The more common types of malicious code are viruses, worms, Trojan horses, macro viruses, and backdoors.
- Modulation** Process of varying a characteristic of a carrier with an information-bearing signal.
- Personal Communications Services (PCS)** Any of several types of wireless voice or data communications systems, typically incorporating digital technology.
- Personal Digital Assistant (PDA)** A handheld computer that serves as an organizer for personal information.
- Propagation** Radiation of electromagnetic waves.
- Protocol** A protocol is a set of rules or agreed-on guidelines for communication.
- Public Switched Telephone Network (PSTN)** A formal name for the landline telephone network.
- Pulse Code Modulation (PCM)** A basic form of digital modulation in which an analog signal is sampled, the sample is quantized independently of other samples, and is then converted to a digital signal.
- Quadrature Phase Shift Keying (QPSK)** A modulation method for digital satellite transmission.
- Radio Frequency (RF)** A radio signal.
- Receiver** A device on a transmission line that converts a signal to whatever type of signal is needed to complete the transmission.
- Remote Authentication Dial-In User Service (RADIUS)** Originally developed to manage dial-in access to Internet; now being used to manage access control for other systems including WLANs.
- Rivest Cipher 4 (RC4)** A common encryption algorithm used by the WEP protocol and TKIP.
- Secure Sockets Layer (SSL)** A protocol for managing the security of message transmission over the Internet.
- Service Set Identifier (SSID)** A sequence of characters that uniquely names a wireless local area network. This name allows stations to connect to the desired network

when multiple independent networks operate in the same physical area.

Spectrum Range of electromagnetic radio frequencies used in signal transmission.

Spread Spectrum (SS) A communications technology in which a signal is transmitted over a broad range of frequencies and then reassembled when received.

Subscriber A cellular telephone user.

Temporal Key Integrity Protocol (TKIP) A wireless encryption protocol that fixes the known problems in the WEP protocol for existing 802.11b products.

Time Division Multiple Access (TDMA) A digital communication technology used by some carriers to provide service.

Transmitter The source or generator of any signal on a transmission medium.

Transport Layer Security (TLS) An authentication and encryption protocol for private transmission over the Internet. It provides mutual authentication with non-repudiation, encryption, algorithm negotiation, secure key derivation, and message integrity checking.

Uplink Data transmission in the direction from the subscriber to the network (back to the provider or Internet provider).

Wavelength Distance between points of corresponding phase in two consecutive cycles of a wave.

Wideband Code Division Multiple Access (W-CDMA). A 3G mobile standard under the IMT-2000 banner, first deployed in Japan.

Wired Equivalent Privacy (WEP) A security protocol, specified in the IEEE 802.11 standard, that attempts to provide a WLAN with a minimal level of security and privacy comparable to a typical wired LAN.

Wireless Application Protocol (WAP) A technology designed to provide users of mobile terminals with limited access to the Internet. A standard for providing cellular telephones, pagers, and other handheld devices with secure access to e-mail and text-based Web pages.

Wireless Fidelity (Wi-Fi) The industry name for WLAN communication technology related to the IEEE 802.11 family of wireless networking standards.

Wireless Local Area Network (WLAN) Wireless network communication over short distances using radio signals instead of traditional network cabling.

Wireless Local Loop (WLL) A wireless system meant to bypass a local landline telephone system.

Wireless Transport Layer Security (WTLS) The security level for WAP applications that was developed to address the problematic issues surrounding mobile network devices—such as limited processing power and memory capacity and low bandwidth—and to provide adequate authentication, data integrity, and privacy protection mechanisms.

INTRODUCTION

Wireless systems have become part of everyday life. In addition to their use in cell phones, they are used inside the homes for networking computers and peripherals, cordless phones, baby monitors, and so on. They are used in factories to ferry information between locations without the use of wires. Medical informatics commonly use wireless systems to exchange vital information between practitioners. These systems have unique operating frequency bands. The choice of the frequencies is often determined by the range of operation (a few meters for a cordless phone to thousands of kilometers for satellite communication systems), the medium through which the signal traverses (from urban areas with tall structures, vast empty spaces in rural areas, and multilevel-multistructure environments in factories and malls), the amount of data to be transmitted (low volume of data in maritime mobile systems to Gbits/s in satellite systems). Other factors that are equally important are the sizes of the transmitting and receiving antennas and the cost and maintenance of installations. Table 1 shows a classification of various frequencies used in wireless communications along with information on antenna sizes and achievable information rates.

Two important considerations of communication systems must be kept in mind:

1. The physical dimensions of an antenna are inversely proportional to its operating frequency. Thus, at low frequencies, the size of the antenna may be too large for these frequencies to be used in practical systems unless under specified conditions. For example, at 30 kHz, the wavelength is 10,000 m,

$$\left[\text{wavelength} = \frac{\text{velocity}}{\text{frequency}} = \frac{3 \times 10^8}{30 \times 10^3} = 10^4 \text{ m} \right].$$

Note that under the assumption of a dipole antenna, the required size of the antennas will be on the order of a half wavelength. This means that for transmission at 30 kHz, we would require an antenna of length 5,000 m.

2. The amount of data that can be transmitted is directly proportional to the operating frequency. The data rates at 30 kHz will be less than 30 kbps, whereas the data rates at 1 GHz can be on the order of 1 Gbps. The

actual data rates will be determined by a number of factors, such as the transmission distance, the characteristics of the intervening medium, the modulation-demodulation schemes and the performance bounds (error rates) set, and so on.

Once we take these considerations into account, it is clear that the very low frequencies can be eliminated from the range of operation of the practical wireless systems that demand transmission at very high data rates, portability (i.e., mobile systems), and compactness. The large size of antennas and low data rates associated with low frequencies eliminate them from considerations in modern wireless systems. Even though the frequencies on the higher end of the spectrum (Table 1) appear to offer smaller size antennae and higher data rates, their use in wireless systems is limited due to other factors. The primary reason for their unsuitability is the fact that these frequencies are severely attenuated by obstructions in their path. A case of a direct path (line of sight [LOS]) between the transmitter and a receiver is shown in Figure 1.

In a typical urban environment with several tall structures, the signals may not reach the receiver via an LOS path. Signals may have to reach the receiver through other physical mechanisms such as reflection, scattering, transmission, and diffraction. The presence of the various objects in the path of the signal as it travels from the transmitter to the receiver not only leads to loss of signal power, but also results in random fluctuations in signal power. The attenuation and fluctuations in signal power are two major detriments to the ability to provide the necessary capacity for the wireless operators. The third major detriment is the interference in wireless systems, a direct consequence of the reuse of the frequency bands in a given geographic location. These three major aspects of wireless systems—power loss, fading, and interference—are reviewed in the following sections, starting with the propagation related effects.

PROPAGATION OF SIGNALS

Power Loss

The mode of signal propagation depicted in Figure 1 is an ideal one. A typical example of the signal propagation in practical wireless systems is shown in Figure 2.

Table 1 Various Frequency Bands Used in Wireless Systems, Their Identification and Characteristics

Frequency Band	Frequency Range	Antenna Size	Data Rate
VLF (Very Low Frequency)	3–30 Kilohertz (kHz)	Large	Low
Low Frequency (LF)	30–300 kHz	↑	↓
Medium Frequency (MF)	300 kHz–30 MHz		
High Frequency (HF)	3–30 MHz	↑	↓
Very High Frequency (VHF)	30–300 MHz		
Ultra High Frequency (UHF)	300-MHz–3 GHz	↑	↓
Super High Frequency (SHF)	3–30 GHz		
Extra High Frequency (EHF)	30–300 GHz	Small	High

As the electromagnetic wave travels from the transmitter to the receiver, it encounters various objects in its path. In typical urban environments, it may not be possible to have a LOS path between the transmitter and the receiver. The signal leaving the transmitter reaches the receiver through a number of different mechanisms such as reflection, diffraction, and scattering (Institute of Electrical and Electronics Engineers [IEEE], 1988a; Rappaport, 2002; Shankar, 2001). Reflection occurs when the signal encounters objects that are much larger than the wavelength. Along with reflection, refraction of the wave may also take place, in which case the signal will penetrate the object, which may be a wall or a partition. The signal may also undergo diffraction (i.e., bending over obstacles) when the signal encounters sharp boundaries such as the ridges of buildings or rooftops. Scattering occurs when the surface of the object is rough and is on the order of the wavelength. The signal may scatter from buildings, trees, or other human-made or natural structures. Indoors, in places such as malls, factories, and office buildings, the signal will reach the receiver after penetrating floors, walls, ceilings, and so forth while undergoing effects of reflection, scattering, and diffraction. These multiple mechanisms may result in additional power loss suffered by the signal as it reaches the receiver relative

to the signal power that would be observed in free space transmission. Signals may also penetrate structures undergoing further loss of signal strength. Environmental factors such as foliage, smog, raindrops (approaching the size of wavelength corresponding to the carrier frequency), and so forth may also influence the attenuation of the signal.

A typical signal received in urban wireless systems is shown in Figure 3a. It is seen that the received power decreases as the distance increases. The power is plotted in dBm (the relationship between power in watts and dBm is given in the Appendix). If we look at a short segment of this curve as shown in Figure 3b, we can see that the power is not monotonic. Fluctuations in power can be seen. They are referred to as long-term fading or shadowing (Parsons, 1996). If we zoom in further into the power-versus-distance curve, we see that the power fluctuates around a mean value. These fluctuations are of very short duration compared with those seen in Figure 3b. These short-term fluctuations, shown in Figure 3c, are referred to as short-term fading. They are also known as Rayleigh fading, based on the statistical fluctuations in the received envelope of the signal (Rappaport, 2002; Shankar, 2001; Steele and Hanzo, 1999; Stein, 1987). Nakagami fading and Rician fading are also used to describe short-term fading.

Thus, the signal propagation from the transmitter to the receiver is subject to several physical phenomena producing attenuation and fading of the signal. We now look at ways to model power loss and fading.

**Figure 1:** A line-of-sight propagation path is shown.

Modeling of Power loss

Several models are available to predict the median or mean value of the received power (Har, Xia, & Bertoni, 1999; Hata, 1980; Lee, 1986; Oda, Tsunkewa, & Hata, 2000; Okumura, Ohmori, & Fukuda, 1968; Vogel and Hong, 1988). These are available for both indoor and outdoor propagation (Bultitude et al., 1989; Harley, 1989; Rappaport & Sandhu 1994; Durgin et al., 1998; Lott & Forkel, 2001). They are also available for different frequency bands of interest in wireless communications. Instead of concentrating on these various models, we initially look at one of the simple ways of predicting loss based on the concept of *path loss exponent*. To understand the concept of the path loss exponent, consider the case of a LOS propagation in free space as shown in Figure 1. If P_t is the transmitted power in W (Watts), the received power P_d (W) at a distance d from the transmitter is given

Figure 2: The signal reaches the receiver via reflection and scattering from buildings, diffraction from rooftops, reflection from the ground, and line-of-sight (LOS) transmission.

Figure 3: The plot of the received signal is shown. (a) Attenuation. (b) Long-term fading. (c) Short-term fading.

by the Friis formula (IEEE, 1988a, 1988b),

$$P_d = P_t G_t G_r \left(\frac{\lambda}{4\pi d} \right)^2 W, \quad (1)$$

where

$$\begin{aligned} G_t &= \text{gain of the transmitting antenna} \\ G_r &= \text{gain of the receiving antenna} \\ \lambda &= \text{free space wavelength} = \frac{c}{f_0} \end{aligned}$$

c being the velocity of light and f_0 the signal frequency. Note that G_t and G_r are dimensionless (i.e., scale factors) and d and λ must have the same units (centimeters, meters, or kilometers). Assuming equal gain antennas ($G_t = G_r$), the received power can be expressed as inversely proportional to the square of the distance,

$$P_d \propto \frac{1}{d^2}. \quad (2)$$

Conversely, we can say that the loss experienced by the signal is directly proportional to the square of the distance. The path loss exponent or the path loss coefficient determines the decay of the power as distance increases and is denoted by n . In free space under LOS conditions, the path loss exponent n is 2. Because we have no obstacles in the path of the signal in LOS propagation in free space, no reflection, diffraction, or scattering takes place, and thus, $n = 2$ will be the best case scenario we can expect in signal transmission. In a general case, where propagation takes place in a region containing obstacles, we expect higher losses than those observed in free space, and n must be greater than 2. The loss experienced by the signal increases as n increases. The excess loss over $n = 2$ is plotted in Figure 4 as a function of the distance. Note that the path loss exponent n is also sometimes referred to as power decay index, distance power gradient, or slope factor.

Figure 4: The losses at $n = 3, 3.5,$ and 4 are compared with the free space loss ($n = 2$).

It must be noted that the low values of n also increase co-channel interference (see the section on interference later in this chapter), such as the interference coming from other cells using the same channel in a frequency reuse situation. As the value of n increases, the interference goes down, leading to an improvement in the capacity of the cellular communication systems.

Calculation of the Received Power

We have seen that the power received at any distance d is inversely proportional to the n th power of the distance,

$$P_d \propto \frac{1}{d^n}. \quad (3)$$

Equation 3 cannot be applied directly because we need to evaluate the proportionality factor. This is done by applying the Friis equation (Rappaport, 2002; Shankar, 2001) at a very short distance d_0 from the transmitter where it can be assumed that the conditions of free space or LOS exist. If P_{d_0} is the power at a distance of d_0 from the transmitter,

$$P_{d_0} = P_t \left(\frac{\lambda}{4\pi d_0} \right)^2. \quad (4)$$

Using Equation 3, we can now write Equation 4 as,

$$\frac{P_d}{P_{d_0}} = \frac{d_0^n}{d^n}. \quad (5)$$

Taking the logarithm, we get the expression for the received power at a distance d ($d > d_0$) from the transmitter to be

$$P_d(\text{dBm}) = P_{d_0}(\text{dBm}) - 10n \log_{10} \left(\frac{d}{d_0} \right), \quad (6)$$

where

$$P_{d_0}(\text{dBm}) = P_t(\text{dBm}) + 20 \log_{10} \left(\frac{\lambda}{4\pi d_0} \right). \quad (7)$$

Note that in Equations 5 and 7, the power is expressed in decibel units, dBm. The question is now what value of d_0 is appropriate. Typically, this value, known as the *reference distance* ($\lambda < d_0$), is chosen to be 100 m in outdoor environments and 1 m in indoor environments (Rappaport, 2002; Shankar, 2001).

The models described so far can be applied for calculating the received power at various operating frequencies indoors and outdoors. A few points are in order. The received power according to the Friis equation as seen in Equation 1 decreases as the wavelength decreases. This means that as we move from the 900-MHz band to the personal communication systems (PCS) band operating at 1800–2000 MHz, the received power decreases. The loss is higher when one goes to the unlicensed frequency band used in homes, cordless phones, Bluetooth systems (Har, 2000), in the 2.4-GHz and 5.8-GHz systems (Durgin et al., 1998). Another factor that becomes critical as the

frequencies go up is the inability of the signal to penetrate buildings. For example, in contrast with 900-MHz signals, 2-GHz signals will not travel far from the transmitter. Signals may even be blocked by a single building between the transmitter and receiver. Thus, the line-of-sight propagation becomes the predominant means by which the signal reaches the receiver. In the case of a microwave signal, a truck obstructing the path can bring down the received signal to extremely small levels (IEEE 1988a, 1988b). This issue is discussed later when we look at interference factors in wireless systems.

The approaches based on the path loss exponent are not the only ones available to estimate the attenuation suffered by the signal as it reaches the receiver. The disadvantage of the path-loss-based approach is that it does not directly take into account a number of system dependent factors such as the heights of the transmitting and receiving antennas and their locations. Models such as the Lee model, the Hata model, the Walfish and Bertoni model (Har et al., 1999; Hata, 1980; Ikegami, Tekeuchi, & Yoshida, 1991; Lee, 1986; Oda et al., 2000; Okumura et al., 1968; Vogel & Hong, 1988) are also available to calculate the received power. These models take the antenna heights and other factors into account. Yet another approach is to use a two exponent model, where two values n_1 and n_2 are used. The loss increases slowly (i.e., the loss occurs as if we have propagation in free space with $n = n_1 = 2$) until a break point is reached. Beyond that point, the attenuation increases with distance at a higher rate, with n taking value of n_2 in the range 3 to 9 (Bertoni, Honcharenko, Maciel, & Xia, 1994; Rappaport & Sandhu, 1994).

The power loss L_p in decibels (dB) suffered by the signal is

$$L_p = P_t(\text{dBm}) - P_d(\text{dBm}), \quad (8)$$

where the transmitted power P_t and the received power P_d are once again expressed in decibel units.

The loss calculation in indoor wireless systems is less straightforward than for outdoor systems. It is possible to use Equations 6 and 7 to calculate the received power or predict the loss. Based on empirical measurements conducted indoors and outdoors, the range of values of n has been proposed by several researchers. Note that these values depend on the environments in which the wireless signal is propagating. The values of n are strongly influenced by the type of building materials used, floor arrangement, location of the transmitting antenna (inside the building or outside the building), height of the transmitting antenna, frequency used, and so on. The values of n range from 2 to 4 as one moves from an open space where free space LOS propagation is possible to urban areas with tall buildings and other structures. In indoor environments, the value of n less than 2 has been observed in grocery stores and open-plan factories (Dersch & Zollinger, 1994; Durgin et al., 1998; Rappaport & Sandhu, 1994). This low value (lower than $n = 2$ in free space) has been attributed to the strong reflections contributed to the received signal by the metallic structures in those places, resulting in higher power levels compared to a

completely open space ($n = 2$). Thus, inside the buildings, n can take values in the range of 1.5 to 4 depending on the following:

1. The number of floors
2. Location of the transmitter
3. Type of partition (hard vs. soft) used

In indoor wireless systems, the base station (BS) can be outside the building. It is also possible to have the base station inside the building, depending on the building complex. The signal may have to travel through multiple floors and multiple walls, each of which may be of a different type, to reach the receiver. The loss calculations are therefore complex, and the wireless systems would have to be designed specifically for a given building complex. It is still possible to write a general equation for the calculation of the loss. The loss at a distance d , L_p can be expressed as

$$L_p(d) \text{ dB} = L_p(d_0) \text{ dB} + 10n_{\text{eff}} \log_{10} \left(\frac{d}{d_0} \right) + \sum_{k=1}^K P_k, \quad (9)$$

where n_{eff} is the effective loss exponent taking into account the multiple floors and walls in the building through which the signal traverses (Durgin et al., 1998; Rappaport & Sandhu, 1994). The loss at a distance of $d_0 = 1$ m is given by $L_p(d_0)$. The other factor in Equation 9 is the specific material attenuation in dB suffered by the signal as it traverses through K floors/walls.

Signal Variability and Fading

We will now briefly review the origins of signal variability seen in wireless propagation (Figure 3). The signal variability may be caused by short-term fading, long-term fading, or both. The short-term fading may result from multipath fading and Doppler fading. This section explores these fading mechanisms and diversity techniques used to mitigate the problems caused by fading.

Multipath Fading

The signal variability is the lack of predictability of the loss or received power (Hashemi, 1993; Kennedy, 1969; Rappaport, 2002). Recall that Figure 3 shows that power loss varies as the distance increases, with the mean or median fluctuations obeying the n th power of the distance. This random nature of the wireless signals is termed fading. This can lead to occasional loss of signal and network breakdown. This is because the systems require a minimum amount of power (threshold) to perform satisfactorily and power fluctuations may bring the power below this threshold. This can be taken into consideration by providing a power margin.

Even though the obvious effect of fading is the random fluctuations of the received power, fading is also responsible for limiting the bandwidth capability of the wireless systems. This section first discusses reasons for the fluctuation in power and the effects of fluctuations on

Figure 5: The existence of multiple paths between the transmitter and receiver.

data transmission and then explains why fading limits the bandwidth.

In a typical wireless environment, the signal reaches the receiver after being reflected, scattered, diffracted, or refracted from a number of objects in its path (Jakes, 1974; Shankar, 2001). Thus, the signal does not follow only a single path to reach the receiver. Instead, the signal reaches the receiver over multiple paths, as shown in Figure 5.

These signals with different amplitudes and phases combine at the receiver. This multipath phenomenon is responsible for the fluctuations in the signal power observed in Figure 3c. This fluctuation in power or fading is termed as *short-term fading*, for which there are two major consequences. First, the random nature of these fluctuations (sometimes termed *Rayleigh fading*) increases the uncertainty in the received signal power, making it necessary to develop methods to mitigate fading through diversity. Second, the paths shown in Figure 5 take different times, leading to a broadening of the received pulse as shown in Figure 6. Figure 6a shows a transmitted pulse $h_p(t)$. This pulse takes multiple paths and the received pulse $r(t)$ can be expressed as

$$r(t) = \sum_{m=1}^M a_m h_p(t - \tau_m), \quad (10)$$

where a_m is the strength of the pulse and τ_m the time taken by the m th pulse. The number of paths is M . These delayed

Figure 7: The impulse response of the wireless channel.

pulses of different strengths overlap, broadening the pulse at the receiver as seen in Figure 6b. Note that the data rate is inversely proportional to the pulse duration, and any broadening of the pulse will lead to overlapping of adjoining pulses resulting in intersymbol interference (ISI). ISI increases the bit error rate (BER). To prevent distortion, it is necessary to operate at a lower data rate when fading is present. If pulse broadening leads to a reduction in data rate or makes it necessary to put in place additional signal processing methods (typically adaptive equalization) to mitigate the effects of pulse broadening, the medium or channel in which this takes place is referred to as a *frequency selective fading channel*. On the other hand, if the pulse broadening is negligible, the medium is referred to as a *flat fading channel*. The relationship between the input and output pulses seen in Figure 6 can be expressed in terms of the impulse response $h(t)$ of the wireless channel as

$$h(t) = \sum_{m=1}^M p_m \delta(t - \tau_m), \quad (11)$$

where τ_m is the time taken by the m th path and p_m is the power in that component, as shown in Figure 7.

The multipath components arise from scattering, reflection, diffraction, or other phenomena described

Figure 6: Transmitted pulse (a) and the received pulse (b) are shown.

earlier. The mean delay τ_{av} can be obtained as

$$\tau_{av} = \frac{\sum_{m=1}^M p_m \tau_m}{\sum_{m=1}^M p_m}, \quad (12)$$

where p_m is the power in Watts and τ_m is in seconds. The root mean square (rms) delay σ_τ can be obtained as

$$\sigma_\tau = \sqrt{\frac{\sum_{m=1}^M p_m \tau_m^2}{\sum_{m=1}^M p_m} - \tau_{av}^2}. \quad (13)$$

The coherence bandwidth B_c of the wireless channel is expressed as

$$B_c = \frac{1}{5\sigma_\tau}. \quad (14)$$

If the information being transmitted through the channel has a bandwidth B , the channel is considered to be *flat* if

$$B < B_c \quad (15)$$

and *frequency selective* if

$$B > B_c. \quad (16)$$

Regardless of whether the channel is flat or frequency selective, the power fluctuations are associated with fading. They cause an increase in the bit error rates making it necessary to operate at higher powers. This case is illustrated in Figure 8, which shows the BER (also known as the probability of error) when no fading is present and also when Rayleigh fading (flat) is present. To maintain a bit error rate of 10^{-3} , we would require an increase in signal-to-noise (SNR) ratio of approximately 17 dB when

fading is present, demonstrating the problems associated with fading.

Now consider a SNR of 10 dB. The results shown in Figure 8 indicate that in the presence of fading a SNR of 10 dB is not sufficient (Shankar, 2001) to have an acceptable level of performance (say, 10^{-3}). This leads to *outage*.

It is possible to have a direct path (LOS) between the transmitter and the receiver in addition to the multiple paths. This condition is more ideal than a pure multipath scenario because the LOS path provides a specular or steady component to the signal. As the strength of the specular component increases (over the multipath components) the deleterious effects of fading decrease. The presence of the specular component leads to a Rician distribution for the envelope of the backscattered signal (Stuber, 1996; Shankar, 2001). The fading channel having a specular component is known as the Rician channel. It can be shown that as the strength of the LOS component increases, the Rician channel starts approaching the ideal Gaussian channel, thus reducing the severity of fading.

The discussion of multipath fading would be incomplete without a few words about the effects of frequency selective fading. The ISI caused by the frequency selective fading not only increases the BER, it also starts to level off the BER to a "floor level." When ISI is present, the adjacent bits leak into the bit under consideration. If now the signal power continues to increase, so does the leakage and interference, effectively negating any improvement that will be expected from increasing signal levels leading to an error floor (Feher, 1995; Vaughn & Andersen, 2003). The effect leads to an "irreducible BER" in communication systems, shown in Figure 9. For a generic digital modulation, the BER is plotted against SNR for the cases of no fading, flat fading, and frequency-selective fading (three levels). As the value of σ_c increases from σ_{c1} to σ_{c3} , the error floor continues to increase.

Use of advanced signal processing techniques, such as adaptive equalization, can overcome the problems of fast fading (Feher, 1995; Vaughn & Andersen 2003).

Figure 8: The probability of error or bit error rate (BER) in an ideal channel and a flat fading channel are shown. The increased signal-to-noise ratio required to maintain a BER of 10^{-3} when fading is present is indicated (17 dB). The improvement in performance obtained through diversity (MRC of order 2) is also shown. The increased signal-to-noise ratio required to maintain the same BER now is only 4 dB. The diversity techniques are discussed later in this chapter.

Figure 9: The concept of irreducible bit error rate (BER). BER does not come down as the signal-to-noise ratio (SNR) increases after a certain SNR is reached. This is a consequence of intersymbol interference.

Doppler Fading

The multipath fading mentioned earlier does not take into account any relative motion of the transmitter and receiver. If the wireless receiver (or transmitter) is mounted on a moving vehicle, the motion introduces Doppler broadening. Motion induced fading is referred to as *Doppler fading* and is responsible for further degradation in the performance of the wireless systems. If a pure tone of frequency f_0 is transmitted, the received signal spectrum will broaden (Doppler broadening) and contain spectral components ranging from $f_0 - f_d$ and $f_0 + f_d$, where f_d is the Doppler shift. If the bandwidth occupied by the information is much greater than the spectral broadening, Doppler spread ($B_D \sim f_d$) does not lead to any significant problems in transmission and reception. The channel in this case is referred to as a *slow-fading channel*. If the bandwidth is smaller than the Doppler spread, motion leads to the channel varying rapidly within the duration of the pulse. In this case, the channel is referred to as a *fast-fading channel*.

Thus, multipath fading decides whether the channel is flat or frequency selective, Doppler fading decides whether the channel is slow or fast (Jakes, 1974; Parsons, 1996). Whereas multipath fading leads to pulse spreading (time), Doppler fading leads to frequency spreading.

$$\begin{aligned}
 & \left. \begin{array}{l} B > B_c \text{ Frequency selective} \\ B < B_c \text{ Flat} \end{array} \right\} \text{multipath fading} \\
 & \left. \begin{array}{l} B > B_D \text{ Slow} \\ B < B_D \text{ Fast} \end{array} \right\} \text{Doppler fading}
 \end{aligned} \tag{17}$$

The various types of fading described in the preceding paragraphs are summarized in Figure 10.

Long-Term Fading

Figure 3 showed that the power fluctuations have a longer period in Figure 3b than those in Figure 3c. These fluctuations with larger periods are statistically described in terms of lognormal fading. Whereas short-term fading is caused by the existence of multipath, long-term fading is

Figure 10: Overview of short-term fading. Pulse broadening (time dispersive) taking place in a frequency-selective channel can be described in terms of the relationship between the message bandwidth and coherence bandwidth. Doppler fading (frequency dispersive) can be described in terms of the variations in the channel relative to the signal.

Figure 11: The signal from the transmitter reaches the receiver after multiple reflections, scatterings, and diffractions from human-made objects and foliage or transmission through them in its path. Two such paths are shown. Many such paths are encountered, each path a result of multiple reflections, scatterings, transmissions, and diffractions. This is different from the case shown in Figure 5 in which each path from the transmitter to the receiver undergoes only a single reflection, scattering, or diffraction.

caused by the existence of several objects in each of the paths. This scenario is depicted in Figure 11. Whereas in the case of a multipath fading, each path to the receiver is the result of a single scattering, reflection, diffraction from each of the objects, in the case of long-term fading each path arriving at the receiver is the result of multiple interactions with the objects. Thus, both multipath and multiple reflections coexist, leading to fluctuations in the average power. Thus, each path will be a result of a multiplicative process, the received signal in each path having a power determined by the number of objects in that path and the relative strengths of the components from each of these objects in that particular path. Because of this, the average power at any given location will be random.

The power expressed in decibels in this case can be shown to be normally distributed and the power in watts will therefore be lognormally distributed (Jakes, 1974; Rappaport, 2002; Steele & Hanzo, 1999). This statistical fluctuation in power caused by multiple structures is also sometimes referred to as *shadowing*. Such situations arise even in indoor channels. The reason for use of the term shadowing is that signal power fluctuation may be caused by the signal being blocked from the receiver by the buildings in outdoor areas or by walls inside the buildings (indoor). To account for the lognormal fading or shadowing, the loss terms in Equation 8 are modified by introducing a term X to the equation for the loss. X is a zero mean normal random variable with a standard deviation of σ_{dB} to take lognormal fading into consideration.

$$Loss = L_p(d) + X \quad (18)$$

The loss calculated now becomes the average of a normally distributed random variable with a standard deviation determined by the severity of the lognormal fading. The long-term fading will also cause outage if the variation in loss is not taken into account during the design of the wireless links. This situation is handled by including a *power margin* in the *link budget* calculations.

Diversity Techniques

Effects of short-term fading can be mitigated through diversity techniques that exploit the randomness existing in the channel. Consider a scenario where it is possible to create N ($N > 1$) multiple (diverse) independent (at least uncorrelated) versions of the signal. If the probability that the signal goes below a threshold is p , the probability that all these multiple versions of the signals will go below that threshold *simultaneously* is p^N . In other words, if we were to choose the strongest signal from this set, the probability that this chosen signal is above the threshold is $(1 - p^N)$, leading to fading mitigation, lessening the chances of outage. The signal processing technique of choosing the strongest signal is known as selection diversity. Other forms of diversity processing, such as maximal ratio combining (MRC), equal gain combining (EGC), and so on are also available to combine the signals from diverse branches (Stein, 1987). In MRC, the signals are combined with appropriate weights using an optimal algorithm resulting in the best performance. In EGC, the weights are equal. The selection diversity is the simplest of these. The improvement in performance through diversity is shown in Figure 8. The BER for the MRC diversity ($N = 2$) plotted along with Rayleigh faded and ideal channel cases show that the additional SNR required to maintain BER of 10^{-3} is brought down to 4 dB (from 17 dB in the absence of any diversity).

Diversity can be implemented either in the spatial domain (spatial diversity) or in the frequency domain (frequency diversity). In spatial diversity, multiple receivers operating at the same frequency band are used. In frequency diversity, the same information is transmitted over multiple carrier frequencies. Other forms of diversity, such as angle diversity, polarization diversity, time diversity, and rake receiver, are also available (Shankar, 2001; Stein, 1987).

Whereas the techniques just described constitute examples of microscopic diversity to mitigate effects of short-term fading, long-term fading or shadowing can be mitigated through macroscopic diversity techniques. Choosing the best base station with the strongest signal to serve a subscriber is a form of macroscopic diversity. It is also possible to combine the signals from different base stations to reduce the effects of long-term fading further.

INTERFERENCE IN CELLULAR ARCHITECTURE

The spectrum available for wireless systems is limited. One of the ways in which the available spectrum can be used to provide coverage to several users is through the repeated use of the same spectrum or frequency channels using the concept known as *frequency reuse*. This concept is shown in Figure 12. A small geographic region, otherwise known as a cell, uses a certain band of frequencies. As noted in the discussion on transmission loss, the power transmitted from the base station drops off as the distance increases. Thus, it is possible to use the same frequency band (A) in Cell 1 in another cell (Cell N) a certain distance away from it as long as the power from the transmitter in Cell 1 at the location of Cell N is less than a certain value

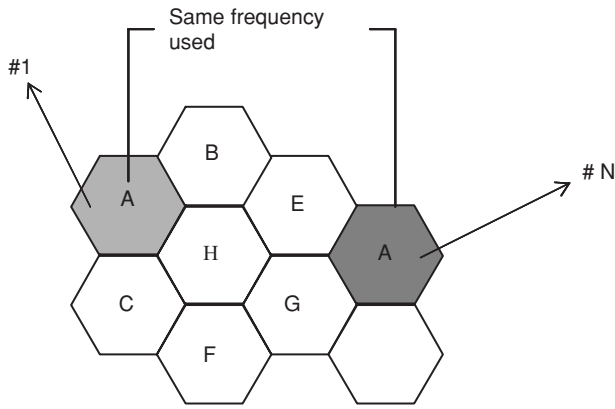

Figure 12: The cellular concept. Cells 1 and N use the same frequency band.

and vice versa. This process can be repeated by reusing the same frequency bands in other cells separated by a minimum distance, allowing the ability to provide service to more users. Several cells are grouped into what is known as a *cluster*. The cells in the cluster use the entire frequency spectrum available to the provider, with each cell using a portion of the spectrum. In the seven-cell cluster shown in Figure 12, frequency bands A through H are used in the seven cells as shown. For example, in Figure 12 frequency band A in Cell 1 is used in Cell N of the adjoining seven-cell cluster.

Interference

Cellular architectures present interference problems that affect the performance of the wireless systems. One is the co-channel interference (CCI), the result of signals from the distant cells in other clusters operating at the same frequency band (called co-channels) as the desired cell in the desired cluster. The second interference arises from within a cluster itself from channels at the adjoining frequency bands. The reason for this interference is the inadequate amount of filtering leading to some overlap between signals from adjoining frequency bands. Nonlinear effects (such as nonlinear amplifiers leading to harmonics) also lead to adjacent channel interference (ACI). Of these two interference factors, CCI is the most serious of the interference phenomena in cellular networks. The performance of the wireless can be measured in terms of signal-to-CCI ratio $\frac{S}{I}$ defined as

$$\frac{S}{I} = \frac{P_{desired}}{\sum_{k=1} P_{Ik}}, \tag{19}$$

where $P_{desired}$ is the signal strength (power) in the desired cell in the desired cluster and P_{Ik} is the power from the k th interfering cell. The summation is carried over all the cells operating at the same frequency band as the desired one. Given a specific geographic region (indoors or outdoors), the power at the receiver decreases as determined by the path loss exponent. If the path loss exponent is n , the received signal power (desired) will be proportional to $P_t d_s^{-n}$, where P_t is the transmitted power and d_s is the distance from its base station. If we assume that all the base station transmitters operate at the same power, the interference signal power from the k th co-channel will be proportional to $P_t d_k^{-n}$, where d_k is the distance of the receiver from the transmitter of the k th interfering channel (Base Station). The signal-to-CCI ratio in Equation 19 now becomes

$$\frac{S}{I} = \frac{P_t d_s^{-n}}{P_t \sum_{k=1} d_k^{-n}} = \frac{d_s^{-n}}{\sum_{k=1} d_k^{-n}}. \tag{20}$$

Consider a simple case of a single interferer ($k = 1$). The S/I ratio now becomes

$$\frac{S}{I} = \left[\frac{d_k}{d_s} \right]^n. \tag{21}$$

Thus, the signal-to-CCI ratio improves if d_k is large as seen in Figure 13. The signal-to CCI ratio also improves with n . Such an improvement comes at the cost of higher losses in the channel. This was stated earlier in the section on ‘Modeling of Power Loss’.

If R is the radius of the hexagonal cell and D is the distance to the cell where the same frequency band is used, it is possible to define the frequency reuse factor q is defined as

$$q = \frac{D}{R}. \tag{22}$$

The number of cells, N_c , in a cluster can be shown to be related to q as

$$q = \sqrt{3N_c}. \tag{23}$$

This would mean that we must have more and more cells in a cluster, putting the interfering cells farther and farther from the desired cell. Such a step reduces interference and consequently increases the signal-to-CCI ratio. This increase in signal-to-CCI ratio comes at a price. If the frequency bands are reused farther and farther, it reduces the capacity of the overall network to provide coverage to more and more users.

Figure 13: The desired cell and the co-channel. R is the radius of the cell.

Note that the frequency reuse depicted in Figure 12 applies to wireless systems employing frequency division multiple access (FDMA) and time division multiple access (TDMA). The frequency reuse factor in code division multiple access (CDMA) systems is unity because the same frequency is used in every cell. In TDMA and FDMA, the reuse factor is larger than unity.

Cell Splitting

While the need to maintain an acceptable value of signal-to-CCI ratio is paramount, the inherent limitation of reduced capacity arising out of larger separation (high values d_k) can be overcome by reducing the size of the cell. The reduction in the cell size is undertaken, maintaining the number of cells in the cluster to be the same. In this technique, known as *cell splitting*, the sizes of the cells are reduced keeping the signal-to-CCI ratio the same as in the case of the larger cells through a reduction in the transmit power. The power received at the boundary of an unsplit cell P_{ur} can be expressed as

$$P_{ur} \propto P_{ut} R^{-n}, \quad (24)$$

where P_{ut} is the transmitted power and R is the radius of the cell (maximum value of d_s). The received power P_{sr} at the boundary of a cell half the size will be

$$P_{sr} \propto P_{st} \left(\frac{R}{2}\right)^{-n}, \quad (25)$$

where P_{st} is the transmitted power. To keep the signal-to-CCI ratio the same in the original cell and the reduced size cell,

$$P_{ur} = P_{sr}. \quad (26)$$

This would mean that the transmitted power in the reduced cell must be reduced as well. If we use $n = 4$, we can obtain

$$P_{st} = \frac{P_{ut}}{16}. \quad (27)$$

Thus, if the size of the cell is reduced to half of the original cell size, the transmit power must be reduced to one sixteenth of the transmitted power in the original cell size to maintain an identical signal-to-CCI ratio. This leads to a larger number of cells in a given area providing increased capacity to accommodate more users without compromising the performance in terms of an acceptable level of signal-to-CCI ratio.

The sizes of the cells vary significantly depending on the traffic fluctuations and the number of users. They will be smaller in size in urban areas and larger in rural areas. A common way to separate these various cell sizes is to classify them as follows:

Mega Cells The cell sizes may be several hundred kilometers in radii. These are mainly used in satellite communication systems.

Macro cells These cells are typically used in traditional wireless systems, both large metropolitan and rural

areas. The radii of these cells may be several kilometers—smaller in metropolitan areas and larger in urban areas.

Micro cells These cells are of several hundred meters in size and are used in urban areas. They are also necessary at higher frequencies of operation (1800 MHz and above) because of the higher levels of attenuation experienced.

Pico cells These are a few tens of meters in range and may be used to increase the capacity in heavy traffic areas. They are also used in wireless systems operating indoors.

Femto cells These cells have a range of a few meters and are typically used in a room to link several computers, printers, fax machines, personal digital assistants (PDAs), and cell phones. Such cells are also used in Bluetooth systems.

CONCLUDING REMARKS

This chapter presented an overview of the propagation characteristics of the wireless channel. Power loss, fading, and interference issues were discussed.

GLOSSARY

Base station (BS) A fixed station in a cellular system that communicates with mobile units within a cell and may be located at the center (or the edge of the cell). It has transmitting and receiving antennas mounted on a tower and is the link between a mobile unit and a mobile switching center.

Bit Error Rate (BER) The ratio of the number of bits received in error to the total number of bits received. It is also referred to as the *probability of error*.

Cell A geographic region served by a base station.

Doppler Shift The upshift or downshift in frequency resulting from the motion of the transmitter with respect to the receiver or vice versa. If the relative speed is v , the Doppler shift is $f_d = \frac{v \cos(\theta)}{c} f_0$, where c is the speed of the electromagnetic wave (3×10^8 m/s), f_0 is the carrier frequency, and θ is the angle between the directions of the transmitter and receiver.

Intersymbol Interference (ISI) The interference caused by the overlapping of adjoining symbols or pulses resulting in signal distortion. Viewed in the frequency domain, existence of ISI implies that the channel cannot carry all frequencies with equal gain, with gain decreasing as the frequencies go up.

Link Budget The process of computing the maximum transmission distance taking into account the transmitted power, loss or attenuation, and power margin.

Mobile Unit (MU), Mobile Station (MS), or Handset A mobile unit is carried by the subscriber. It may be handheld or vehicle mounted.

Outage Whenever the performance of the wireless system does not reach the minimum acceptable levels, the system goes into outage. For example, if a minimum power of P_{th} is required to have an acceptable performance, any time the received power goes below P_{th} , the system goes into outage. The rate at which this happens is the outage probability.

Power Margin The excess power budgeted to account for any effects other than the attenuation or the loss of the signal. For example, if a threshold power of P_{th} (dBm) is required to maintain acceptable performance and M dB is the power margin to account for fading, the minimum acceptable power P_{min} (dBm) at the receiver is required to be set to $P_{min} = P_{th} + M$. This has the effect of reducing the separation between the transmitter and receiver.

APPENDIX (POWER UNITS)

Power is normally expressed in decibel units. Power (P_0) in milliWatts (mW) can be expressed in terms of decibel units, dBm as

$$P_0 \text{ (dBm)} = 10 \log_{10} \left[\frac{P_0 \text{ (mW)}}{1 \text{ mW}} \right]. \quad (17)$$

Thus, the power in dBm is an absolute measure of power in mW. 10 mW of power is 10 dBm, 1 W is 30 dBm, and 1 μ W is -30 dBm. The unit, dB, on the other hand, is the ratio of two powers in identical units. For example, if the average signal power is P_0 (mW) and the average noise power is P_n (mW), the signal-to-noise ratio (SNR) can be expressed as

$$(S/N) \text{ dB} = 10 \log_{10} \left[\frac{P_0 \text{ (mW)}}{P_n \text{ (mW)}} \right]. \quad (\text{A.1})$$

Thus, SNR expressed in dB carries information on the strength of the signal relative to the noise. If the SNR is 0 dB, the signal power and noise power are equal. If the SNR is 20 dB, the signal is 100 times stronger than the noise. If the SNR is -3 dB, the signal is only 50% of the noise. Loss or attenuation can be expressed in dB units as

$$\text{Loss (dB)} = \text{Transmit power (dBm)} - \text{Receive power (dBm)}. \quad (19)$$

If the transmitted power is 10 mW and the received power is 1 μ W, we can calculate the transmission loss as $10 \log_{10}(10 \text{ mW}) - 10 \log_{10}(1 \mu\text{W}) = 10 - (-30) = 40 \text{ dB}$.

INTRODUCTION

Circuit, message, and packet switching are techniques for transferring information. These concepts are not unique to electronic networking. They have common, everyday models and historical prototypes. A ubiquitous example of circuit switching is a voice telephone conversation between two people. Message switching is seen every day in the paper-based postal system.

Visualizing packet switching takes more imagination. Let's move a complete business including staff, furniture, files, business machines, and so forth from an old location to a new one. We assume that the business is sufficiently large that it needs several automobiles and buses to move the people and a number of trucks to move the nonhuman assets. All these vehicles, each containing a portion of the company, move over a system of roads. Each vehicle travels independently, yet as an aggregate, the company is the sum of the payloads of all the vehicles.

We look at security aspects of circuit, message, and packet switching for digital communications networks and their more historical paper and electronic prototypes. Some of the security concerns are common no matter which technique is used, for example, we can communicate using a secret language. In the convoy example, we can keep the route secret until the last moment. Perhaps we can use a private, secret road, or even an underground tunnel, instead of the public highways.

We can take this "company moving" example a little further to illustrate datagrams and virtual circuits. If we allow all the cars, trucks, and buses to select their own routes from the source to the destination, we have a datagram example. Each vehicle arrives on its own schedule. However, if we dictate a specific route and mandate a convoy, or a parade, by assigning a placard—A, B, C, and so on—to all the vehicles and require them to stay in sequence, behind their predecessor, we illustrate a virtual circuit. Note that pedestrians in crosswalks, red lights, and cross traffic can interrupt and delay portions of the convoy. Nonetheless, all vehicles arrive at the destination in their scheduled sequence, albeit with varying delays.

Notice that the convoy model and the free-choice model, in which each vehicle is independently routed,

have different security risks and needs. In the datagram mode, it is more difficult for an observer to watch all the vehicles.

We use the terms "switching" or "routing" because the circuits, messages, or packets traverse a mesh of links and nodes. Links connect nodes. Nodes are also called switches. We "route" or "switch" the entities from one node to another, using the links, from the source ultimate destination. The entire mass of links and nodes is a point-to-point network. Typically, wide area networks are point-to-point networks. Another kind of network is a broadcast network. Local area networks (LANs) are typically broadcast packet networks.

What do we own and control—the links, the nodes, everything, nothing? Can we encase our electronic systems so that no electromagnetic signals whatsoever escape into free space where they may possibly be monitored? If our communications employ optical fibers, then there is no electromagnetic leakage. If we employ broadcast radio techniques, with omnidirectional antennae, then everyone can monitor our signals. If we employ directional antennae, our signals are still "public," but more difficult to monitor. If we employ wired electronic communications, our signals are more protected than radio, but far less protected than optical signals in fibers.

In Figure 1, several nodes are shown with links connecting them. Not all nodes are directly connected to every other node. There may or may not be any loops in the network. Some nodes may be connected to only one other node. There are, however, a sufficient number of links so that, directly or indirectly, all nodes are connected to each other and form one complete network. At the same time, some nodes have more access to communications that do not belong to them. In particular, node D is advantageously situated to intercept communications from A, B, or C destined to E or F. The control and security of node D must either be well trusted or communications flowing through D should be encrypted so that information transmission is secure. The same holds true for other nodes: B can monitor traffic to and from A, and, depending on the routing protocols in use, C, E, and F can all intercept traffic destined for other nodes.

Figure 1: A point-to-point network.

The Internet is largely constructed using links and nodes. Consider a connection between station X in Canada and station Y the United States, just to select two nations. All nodes used to connect X and Y are likely located in the United States and in Canada, not in a third nation. Several designated “gateways” connect U.S. nodes to Canadian nodes. These gateways, like border-crossing stations, are excellent places to monitor communications between the nations. It is highly unlikely that nodes and links in a third nation—say, Mexico—are employed. Why? National security. The Internet has a traceroute diagnostic tool. Use it to examine routing between your location and a computer in another country. For both security and economic reasons, the route probably does not take you through a third nation.

Several nodes are shown in Figure 2. All nodes are contained within a cloud and share a common medium or ether. A pretty, puffy cloud artistically depicts the network’s edges. What is important is that each node is inside the cloud. Each node can, via the common medium, communicate directly with every other node. There is no privacy. Everyone can listen to everything. Information security in such a network usually relies on a trust relationship among all nodes and barriers or firewalls to control gateways to external networks (cf. chapter 30, Local Area Networks), or on some form of asymmetric encryption (cf. chapter 65, Public Key Infrastructure).

LAYERING MODELS

We build and discuss networks using layers, just like houses are built on foundations, usually resting on earth.

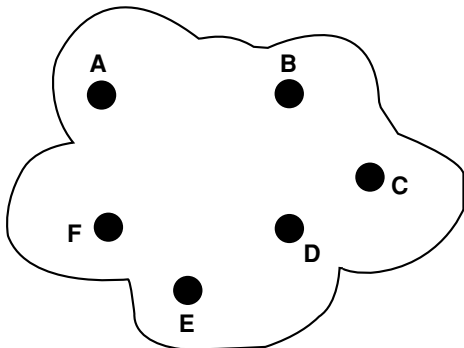

Figure 2: A broadcast network.

A house’s frame rests on the foundation, the interior and exterior walls hang on the frame, and the roof sits on top.

Layering allows us to look at only a portion of the communications process at any one time. This simplifies our examination of something complex. For example, on the data link or network layers, we may use an assortment of protocols, one on each layer or sublayer, as appropriate to the specific network. On the Internet layer, we use IP (Internet protocol), a datagram protocol. On the transport layer, we use TCP (transmission control protocol), a virtual circuit protocol. On the application layer, we might employ SMTP (simple mail transport protocol), a message switching technique, ultimately to transport our electronic mail messages.

If we use a wired (or optical fiber) Ethernet on our own private property, complete with armed patrols and big dogs, we may be satisfied with the security of our communications. On the other hand, when we replace or augment the wired network with IEEE (Institute of Electrical and Electronics Engineers) 802.11 radio communications, we likely want, at a minimum, to employ WEP (wired equivalent privacy), a data link layer encryption scheme. Likely we want to do even more with higher layer encryption—to compensate for WEP, a weak technique that also provides no protection for a LAN user from other LAN users.

Just as a real network is constructed using several layers, each layer has its own set of addresses—for example, hardware addresses, IP addresses, and port numbers—to specify the location of devices and services. In the case of the Internet, addresses don’t always neatly map into layers.

OSI Reference Model

One of the initial models for these layers or “stacks” is the seven-level open system interconnection (OSI) protocol developed by the International Standards Organization (ISO). The OSI standard is a protocol that has never been fully implemented in a production environment. Today it is used primarily for pedagogical purposes. TCP/IP, another, much more informal model, is the backbone of the modern-day Internet. TCP/IP includes many protocols including the two that give it its overall name (transmission control protocol–Internet protocol).

Table 1 outlines the OSI reference model and several variations of the TCP/IP model. Diverse TCP/IP model versions exist because TCP/IP is an informal, loosely defined protocol suite—that is, different authors prefer different models. For our purposes, we employ the three-layer version and discuss the supporting networks, Ethernet, IEEE 802.11, and so forth separately. The two models, OSI and TCP/IP, evolved independently. Exact equivalences cannot be made, and only loosely defined comparisons should be inferred.

TCP/IP Model

The layers of the TCP/IP model include application, transport, and internet layers, and sometimes a data link layer and a physical layer (see Table 1). An internet has no network layer because it is a network built on top of other (likely heterogeneous) networks. (Whatever we say about

Table 1 The OSI Reference Model and Versions of the TCP/IP Model

OSI layer	TCP/IP 5-layer	TCP/IP 4-layer A	TCP/IP 4-layer B	TCP/IP 3-layer
Application		Application		
Presentation	Application			Application
Session			Application	
Transport	Transport	Transport	Transport	Transport
	Internet	Internet		Internet
Network			Internet	
Data link	Network access			
Physical	Physical	Supporting networks	Supporting networks	

OSI = open system interconnection; TCP/IP = transmission control protocol–Internet protocol.

an internet in this section, also applies to the Internet and to intranets.) The strength of an internet is that it allows heterogeneous network layers to seamlessly interconnect. This is done using routers. For example a WAN component of a TCP/IP internet might use frame relay or ATM connections, whereas LAN components of the same internet might use Ethernet, switched Ethernet, or token ring as their physical network layers. Wireless portions might use the IEEE 802.11 protocols. For the nodes, however, the specific physical, data link, and network layers used by any other node is of no consequence. The routing tables and requisite repeaters, bridges, and routers are able to translate the TCP/IP traffic from all the nodes to the appropriate physical networks.

The data link, network, internet, transport, and application layers and security concerns and tools for each layer are discussed here. The physical layer is of interest to us, although it is not a part of the TCP/IP model, because the physical, data link, and network layers of the supporting networks raise security questions. In today's world, the OSI presentation layer as its own entity is pretty much ignored. The session layer is almost always considered a part of the transport layer. This leaves us the physical, data link, network, internet, transport, and application layers from the original OSI and TCP/IP models to examine for circuit, message, and packet switching techniques and their security issues.

Broadcast Model

The OSI reference model was constructed with point-to-point (wide area networks) in mind. It ignores broadcast networks which are not constructed with links joining nodes (Figure 1) but by a set of nodes all sharing the same medium (Figure 2). The OSI model can be adapted for broadcast networks by splitting the data link layer into two sublayers, the MAC (medium access control) and the LLC (logical link control).

MAC sublayer protocols determine how a node or station gains access to the broadcast medium needed to transmit packets into the network. LLC sublayer protocols define a language that stations can use to decode the packets. It also provides a common layer, or glue, for interfacing to upper layers. The LLC protocol defined by IEEE 802.2 defines a common protocol used by several MAC schemes such as Ethernet (802.3), token ring (802.5), and

wireless (802.11). There are many IEEE 802 standards. Some, for example, 802.11, are rapidly evolving today. A fuller discussion is beyond our scope.

The older LLC (802.2), Ethernet (802.3), and token ring (802.5) protocols do not significantly address any security concerns. The newer wireless (802.11) protocol has a weak data link layer encryption scheme: wired equivalent privacy (WEP). There is currently much interest in developing wireless security standards because manufacturers are addressing security concerns with their own ad hoc proprietary extensions.

Broadcast networks can do some things more easily than point-to-point networks. One of these is to “broadcast” to all stations in the network. A special address designated as addressing all stations can exist. Packets with this address are copied by all stations in the network because all share the same medium, the same environment. In a point-to-point network, pains are taken that such broadcast packets are routed and repeated to all stations. This involves many copies of the packet in the point-to-point network compared with only one in the broadcast network.

Multicasting extends the idea of broadcasting. Groups of stations are defined to share a designated multicast address. Many such groups and many such addresses can be created. Packets destined to a multicast address are received by all stations. Those stations recognizing the address as significant should copy the information. Other stations should ignore the message.

Packets directed to a designated destination are read by all stations. The addressed station acts on the information, whereas other stations are expected to ignore it. Note the words “expected to ignore it.” It is easy to spy and to copy everything. This is one of the motivations for using encryption on the higher layer protocols—to keep private information private.

CIRCUIT, MESSAGE, AND PACKET SWITCHING

If two people are in the same room and want to talk, the process of communication is relatively simple and straight forward: “Hey Jane, I’ve been meaning to ask you about. . . .” In the same way, data transmission between two nodes is relatively straightforward when both nodes are on the same network.

A more difficult problem emerges when the two people do not share physical proximity. They could use megaphones, but this becomes problematic if the other six thousand million people in the world want to talk at the same time and have equally powerful megaphones. Clearly, they need some way to transmit data that satisfies the following conditions:

- It is shared only between the sender and the recipient and no one else.
- The data must be transmitted over and through disparate networks. If one party uses a particular brand of telephone, computer, or application software, there should not be an implicit requirement that the other party use the same brand or product.

The connection may also need to be “reliable.” Reliability refers to the quality that the sender can confirm that the outgoing communication is or is not received by the intended recipient. With a reliable connection, there is no ambiguity as to whether the message is received. It is analogous to sending a registered letter via traditional post: You know that the letter was received by its intended recipient or that it was lost en route.

This ability to transmit data between physically remote nodes requires some sort of network switching capability. Historically, three switching models have been employed: circuit, message, and packet switching. Before tackling the prime topic of packet switching, it is worthwhile to discuss circuit and message switching. This provides a context to understand why packets were invented and remain useful.

Circuit Switching

Circuit switching is easy to understand because its most common example, the voice telephone call, is so pervasive. Each call consists of three phases, establishment or setup, data transfer (i.e., the voice conversation), and termination. Establishment allocates resources to make the telephone call possible. Is the other telephone available? The called telephone could already be busy, or perhaps the line is cut or is otherwise unavailable. Is the desired person available? Are there sufficient resources within the telephone network to construct a route, or circuit, from the caller to the called station? Perhaps a natural disaster, such as a tornado or other usual weather, has caused many other people to attempt phone calls, thus leaving the switches and trunks (the links between the switches) devoid of capacity because they are fully used by others.

The data transfer phase, that is, the actual conversation, is the reason for making the call. The conversation usually has its own (application layer) protocol. Both people say “hello,” engage in some kind of chit-chat, and eventually say “good-bye.” The phones are replaced on their “hooks.” Bills may be prepared, and the electronic facilities, switches, links, and so forth are freed for other calls.

Phone calls are usually metered and billed by measuring their duration in time and sometimes the distance between the stations. The number of phonemes, words, sentences, paragraphs, and information transferred are not measured. Long periods of silence (i.e., no information

transfer) is handled in the same way as intensive information transfer.

We can use the same voice telephone calls to transfer “computer data” instead of analog voice information by using “modems.” The basic paradigm remains: establishment, data transfer, circuit termination, breakdown, and the dedication of facilities by time duration, not information transfer.

Circuit switching is unique in terms of security implications. Although emulated circuit switching networks are becoming increasingly popular (one example is voice-over-IP, or VoIP), true circuit switches are dedicated resources usually supplied by a public telephone company. The supplier tightly controls and secures hardware used for the transmission and switching. A guarantee of secure communication is either explicit or implicit in the contractual arrangement between the vendor and supplier. Vulnerabilities are much more likely near either end of the circuit than in the switching regimes managed by the provider.

Except for an analog portion at each end of the call, today’s (circa 2004) wired telephone communications are almost entirely digital between the central office of the telephone company and the subscriber. The voice conversations are digitized, transferred, and switched as digital signals and then converted back to analog voice just in time to deliver to the receiving party. Broadcast television is now making the conversion to digital transmission. Broadcast radio is also slowly making this same transition. The analog links can be monitored using simple technology and physical access. The digital portions of the circuit require more sophisticated equipment, and the physical access is also more difficult.

Old style, analog mobile telephone systems are extremely easy to monitor because they are simple FM radio systems. A listener, knowing the correct frequencies of the nearby cell phone towers, only has to listen. During their advent, one could simply buy a monitoring receiver and legally listen. Regulations in various countries have attempted to control or criminalize such interceptions.

More important than regulatory changes is the move from analog to digital spread spectrum technology. This makes it far more difficult (but not impossible) to monitor mobile telephone conversations. Digital mobile telephony also opens the door to the employment of encryption technologies, although government agencies in many countries limit the approved encryption algorithms or key lengths so they can reserve the right to wiretap or monitor telephony communications.

Message Switching

The great model for message switching is the paper-based postal system that delivers cards, letters, and packages (which can contain files, books, and even electronic media). At any selected time, the information is in one location, in a vehicle or in a carrier’s bag (moving or not) or in one of the postal stations (being sorted, waiting to be sorted, or waiting to be loaded into a vehicle for transportation). The application layer SMTP (simple mail transport protocol, e-mail) is an old example of electronic message switching that survives into the present.

Let's look at how mail delivery using SMTP works. In addition to the two people sending and receiving the e-mail message, (at least) two kinds of software are involved. Typically the sender employs a UA (user agent) program to compose and address the message and typically sends the message to the sender's local MTA (mail transfer agent) using SMTP. The MTA accepts the message from the UA and promises to try to deliver the message to the recipient. Usually the MTA searches for another MTA, on a distant host, willing to accept the message for the recipient. The two MTAs try to create a connection and negotiate message delivery using SMTP. This can fail for a number of reasons. The sending MTA, which still holds the message, either looks for an alternate, intermediate MTA willing to accept the message, or holds onto it and tries again at a later time. The MTA holding the message is responsible for it until it passes it on to another MTA or until it returns it to the sender as being undeliverable. If the MTA passes a message on to another MTA, its responsibility for the message ends. Final delivery to the recipient's UA is not done by SMTP, but by other techniques (including POP and IMAP, other email-related protocols). This is why we added the parenthetical "at least" at the start of this paragraph.

What's important here? The message travels as a complete unit. At any one time, it exists completely in one place. Of course, we are only speaking about the application layer. What happens on the other layers is entirely another tale.

What can we do with security for this application layer? A message delivered by SMTP contains headers and text. Although headers usually must be transmitted in the clear without encryption, the text portion can be encrypted by the sender and decoded by the recipient.

Table 2 lists some possible protocols used on each layer to transfer an e-mail message using SMTP, using TCP/IP, over a telephone connection. This same TCP/IP connection, at another physical location might be supported by, say, an Ethernet LAN, because the Internet sits on top of heterogeneous networks.

Table 2 can be rewritten to employ a LAN and a privately owned network instead of a dial-up modem and telephone link. In this case, we might select an optical fiber Ethernet over an electrical Ethernet, over a wireless LAN. If we use an electrical network (i.e., metallic wires), we would attempt to shield the cables effectively. We would keep intruders far away from our equipment (to take

advantage of the inverse square diminution of electromagnetic field strength). Ownership and control of a privately owned network, as you expect, is expensive and perhaps not justified. Each of the security-related techniques has monetary and ease-of-usage costs.

Packet Switching

Circuit switching can be inefficient. For example, the circuit switch model we know as the voice telephone conversation is always "on." Signals are always being transmitted even when both parties to the conversation are silent. This is a large waste of dedicated resources.

Think about online computer interactions such as reading e-mail from a server using IMAP (or POP), or obtaining files using file transfer protocol (FTP), or browsing the Web. A user initiates a connection to the Internet. Using IMAP, the user agent (UA) asks the mail server about received messages and gets a list. While the user stares at this list, the Internet connection is normally idle. A particularly interesting message catches the user's eye, and he asks to read it. Now the message is copied in a burst from the server to the UA (i.e., an e-mail program) and can be examined. Typically nothing happens while the recipient peruses the message, which may contain a huge attachment. The reader decides that he wants the attachment, and then, all of a sudden, a long burst of line activity occurs to bring the attachment from the server to the client.

As we can see, computer communications is characterized by short bursts of data transmissions between long periods of idleness. We want a fast link because we don't want to wait. However, most of the time a dedicated, fast, expensive line (or circuit) is idle because we are not using it. Packet switching cost-effectively shares the fast, expensive, high-speed lines with many users. In other words, packets provide something called "multiplexing."

With multiplexing, we chop our messages into units, cells, frames, packets, segments, PDUs (protocol data units). All these words are pretty much interchangeable in general usage. Mostly our packets are of varying size, but there are usually minimum and maximum sizes, that is, the packet cannot be too small or too big.

Along with the advantages of packet switched networks are disadvantages. Because each packet can have an independent path from source to destination, it must contain a header with enough information for the network to route it properly and for the destination to put the message

Table 2 Example of Techniques Used on Different Layers

Layer	Technique	Security Possibilities
Application	SMTP, message switching	Signing, encryption, SSL/TLS
Transport	TCP, virtual circuit	IPSec, IPv6 encryption, encrypted tunnels
Internet	IP, datagram PPP, virtual circuit	IPSec, IPv6 encryption
Data link	Digitization of the analog signal within the telephone plant Modulation of an analog signal using digital data	PPP link encryption
Physical	Modem, telephone circuits, circuit switching	Physical control of circuits, physical layer encryption

PPP = ; SMTP = simple mail transport protocol; SSL/TLS = ; TCP = transmission control protocol.

Table 3 Advantages and Disadvantages of Circuit Switched and Packet Switched Networks

Circuit Switched Network	Packet Switched Network
Dedicated	Shared
Constant, predictable transmission rates	Varying and sometimes unacceptable delays
No overhead, higher maximum throughput	Packet overhead reduces effective throughput
Expensive	Efficient, economical
Often idle	Minimal idle time

back together in sequence. This header information is not part of the message proper and so constitutes “overhead” that reduces the effective transmission rate of the message when compared with dedicated circuits. Additional steps need to be taken to ensure that no malefactor on the network substitutes a bogus packet for a legitimate one.

Finally, there is a statistical risk that all users want to download a large file or use a network simultaneously. Such instances reduce the effective transmission rate far below the nominal rate of the network and may result in unacceptable delays in data transmission. This problem of delays caused by network congestion is a genuine problem in VoIP communication and constitutes a major technical challenge before VoIP becomes widely adopted.

A brief comparison of the relative advantages of circuit switching vis-à-vis packet switching is provided in Table 3.

Two packet switching techniques are commonly employed: datagrams and virtual circuits.

Datagram Networks

Datagrams have no guarantee of delivery: If source A sends out a bunch of datagrams a, b, and c, to destination B, there is no guarantee that any or all the datagrams arrive at their destination. Furthermore, datagrams have no guarantee as to the sequence in which a, b, or c arrive. This is like the Kentucky Derby. If the horses leave the starting gate at approximately the same time, we have no knowledge as to the sequence in which they arrive at the finish line. In fact, with a small probability, one or more of the horses may never cross the finish line. Unlike a horse, should a datagram fail to reach the finish line, we will never know. There is no mechanism to confirm if a datagram ever reached its destination or if it was even expected in the first place.

The Internet protocol employs datagrams, which makes it resilient. One of its original design specifications in the late 1960s, by the U.S. Department of Defense, is nuclear survivability. Although the Internet has not been tested against a nuclear attack, all sorts of other things have been tossed against it. It keeps on working.

Recall that the IP is the layer that connects and sits above the constituent networks. Above the internet layer is the transport layer. There are two Internet protocols on the transport layer, UDP (user datagram protocol), a datagram protocol, and TCP, a connection-oriented protocol. We can select the most appropriate protocol, TCP or UDP, for our application.

Network survivability was tested to a limited degree at the World Trade Center, in New York City, on September 11, 2001. There was significant damage to fiber-optic links

under the towers, the local telephony infrastructure, as well as electrical blackouts and failure of backup power systems. There were serious problems throughout New York City. Most Internet traffic was automatically rerouted and caused little notice. Secondary to the physical damage was the change of Internet traffic patterns caused by users flooding particular Web sites and Internet service providers seeking news about the tragedy that might not be broadcast on radio and television. In addition to general news, people sought information about relatives, friends, and colleagues via the Internet in addition to attempting to reach them via telephone (see Barrett & Silverman, 2001).

Datagrams provide simplicity by avoiding the creation of a circuit. Often, we simply want to send a small amount of information from the sender to the recipient and perhaps receive a reply. We gain by omitting the overhead of circuit establishment, maintenance, and breakdown for only a very short exchange. If we really do want a reply, when we don’t get one, we simply retry the exchange *de novo*.

There are two disadvantages to using datagrams. Each datagram must find its own way through the network; the experience of previous datagrams, for example, how they found a good route, is ignored. It is also possible for a datagram to wander about, to never reach its destination, and to be destroyed. For this reason, datagrams are unreliable. There is no confirmation that they were delivered and no validation that they came from their alleged source.

Datagrams are used for short, noncritical communications such as traceroutes to determine the current optimal route between two network nodes or DNS lookups of a single host or IP address. (If a reply isn’t received from the first DNS server, a secondary DNS server is consulted.) DNS, discussed later, refers to the domain naming system, the method used on the Internet to map domains and URLs (uniform resource locators) to IP addresses.

UDP, transport layer datagrams, rely on IP, internet layer datagrams. The connection-oriented TCP segments also rely on IP datagrams. In the Internet scheme, the internet layer is constructed using datagrams. On the transport layer, there is a choice of using either TCP (virtual circuit connections) or UDP (a datagram, connectionless service).

Another important application suitable for UDP is NTP (network time protocol), which seeks to keep the computer’s clock correct. An intruder who can successfully manipulate a computer’s timekeeping can create all sorts of mischief. Examples can range from improper time stamps on stock market trading or time-critical messages to compressing or expanding the amount of time a

Figure 3: The transmission control protocol three-way handshake protocol.

computer process takes and adjusting billing for the computer's services (McNamara, 2003).

We see that datagrams have advantages and disadvantages. There are times when it is better to use a connection-oriented protocol.

Virtual Circuit Networks

TCP is the connection-oriented protocol on the Internet transport layer, resting on the (datagram) internet or IP layer. Just as in circuit switching, we establish a route (calling it a virtual circuit), we transfer data through it, back and forth, and then we disassemble the circuit and return the resources for reuse. Unlike circuit switching, the physical resources the virtual circuit uses are concurrently available to other virtual circuits as well.

We do the work of allocating, maintaining, and disassembling resources with the expectation that we will make sufficient use of the virtual circuit to pay us back for our effort. What kind of payback can we expect? Because we have constructed a tube, like a garden hose, through the network, when the source sends segments, that is, packets, a , b , and c , into the pipe, we can expect them to arrive, in order, a , b , and c , at the destination. This guaranteed sequencing is an important property. As well, we no longer need the complete source and destination addresses in each packet because this information is managed by the underlying virtual circuit that we initially constructed. Each packet still needs identification, however, saying which virtual circuit it belongs to and what its sequence is in the parade in case it is destroyed in transit.

Packets in a virtual circuit scheme usually employ sequence numbers of some kind because they are part of a parade, with each packet having its own place. Packets are often numbered using three bits, 0, 1, 2, 3, 4, 5, 6, 7; seven bits, 0, 1, 2, ..., 126, 127; or even larger sequences such as the 32-bit TCP sequence number. These sequence

numbers are more overhead but are needed to identify damaged or missing segments so that the receiver can ask for them again using a "negative" acknowledgment. The sequence numbers are also used for flow control, to moderate or slow the sender when the network or the receiver cannot handle the packets as quickly as they are sent.

For reliability and security, establishing a connection uses a technique, the three-step handshake (see Figure 3). First, the initiating host, A, sends a TCP packet to the recipient host, B, containing an arbitrary and random sequence number, x , and a flag, the SYN (for synchronize) flag. On receipt of this first packet, B responds back to A with a second TCP segment containing another arbitrary and random sequence number, y , an acknowledgment field of $x + 1$, and both a SYN and an ACK (for acknowledgment) flag. The last step of the connection setup has A replying to B with a TCP packet containing an acknowledgment field with value $y + 1$ and only an ACK flag. At this point, B can now send data packets to A. The next packet from B to A includes sequence numbers beginning with $y + 1$ and acknowledgments beginning with $x + 1$. The next packet from A to B includes sequence numbers beginning with $x + 1$ and acknowledgments beginning with $y + 1$.

Note that after the first three segments are exchanged, each host knows the initial sequence number of the other host and, by way of the acknowledgment field, has told the other host what number it is expecting in return. Subsequent packets contain increasing sequence numbers where the increase is equal to the number of data bytes in the previous packet.

SECURITY CONSIDERATIONS

Packet switching has provided a fast, efficient, and reliable means of data communication. This efficiency comes with

a cost. Packet-switched communications have security risks not encountered in circuit or message switching. We first discuss how packets are addressed so that they are reliably delivered from a source host to a destination application on the intended recipient host. Only then are we in a position to understand some of the historical attacks and ongoing security concerns inherent in packet-switched environment.

Packet Addressing

Packet addressing is a multifaceted and complex topic. Simplifying the issues for our purposes, we look at four types of addressing: hardware addressing is used to reference machines and hardware on the same physical network. We use TCP/IP addressing to address devices located on other networks or in locations around the world. Machines use IP addresses (numbers), but people prefer a more mnemonic method of naming machines; DNS allows IP addresses to be mapped to the more humane URLs with which we are all familiar. (Some people correctly say that URLs are *not* user-friendly. They may be correct, but alphameric domain names are much nicer than numeric IP addresses!) Finally, we look at port numbering as a convenient way to flag the kind of data contained within a packet and thus what application they should be delivered to on the destination host.

Hardware Addresses

00:05:02:d6:eb:7e, a 48-bit Ethernet address, written using 12 hexadecimal digits, is an example of a hardware address. This unique number is manufactured into each interface card; the first six digits are assigned to the card manufacturer (prefix 00:05:02 is assigned to Apple Computers: cf. <http://www.coe.uky.edu/~stu/nic/nic.cfm>, retrieved May 2004), and the last six digits are a serial number assigned to the card by the manufacturer. Each interface card is made with a unique Ethernet address. The hardware or MAC (media access control) address only identifies the card and not its location or routing paths; therefore, the MAC address is only useful at the local network level. The other computers on this machine's local network as well as its local router know both its IP address and its MAC address. Unless this machine is on our local network, however, we have no idea where the Apple computer with this MAC address is located. Although using MAC addresses is much faster and more efficient than using numeric IP addresses when communicating within the local physical network, communicating with machines outside the local network requires IP addresses. For most of us, we never need to see the MAC address unless there is a problem to solve.

The discussion about hardware Ethernet addresses also applies to wireless IEEE 802.11 addresses. Both sets of addresses are identical in format and are taken from the same pool. Both Ethernet and 802.11 interface cards are manufactured with hardware addresses. Both also have the ability to employ a specified address, supplied by computer software. Thus, an interface card can assume the identity of another card. In a wired network, an intruder need only to learn a valid MAC address, set that address into his or her card, ensure that the real device with this address is powered off and not active, and then physically

connect his or her machine to the network. (Two cards with identical MAC addresses on the same network cause all sorts of problems, thus exposing the stealth attack.) The wireless intruder employs the same steps, except that a physical attachment is not needed. The interloper only needs to be nearby for network access. For this reason, the WEP is provided to offer some limited measure of encryption for wireless networks.

TCP/IP and Other Addresses

Internet, IP version 4 (written as IPv4) addresses are 32-bit numbers specifying a host. A host can have several IP addresses (i.e., one for each interface), but every networked host must have at least one unique IP address. IP addresses are commonly written using dotted decimal format, four decimal numbers in the range 0–255, separated with periods (e.g., 198.169.198.4). Each group of four numbers in an IP address is commonly referred to as an “octet” (because it can be written as a sequence of eight bits).

Numeric IP addresses are grouped into networks. For example, all IP addresses of the form 198.169.198.nnn belong to an organization known as GPFN. When a packet is sent anywhere with these first three octets, it is routed to the GPFN network. The GPFN router's job is to deliver traffic to the correct machine based on the last octet.

For these reasons, IP addresses cannot be arbitrarily acquired. Addresses from the available pool of numbers must be registered with an appropriate agency so that Internet routing is properly able to switch to the correct destinations.

IPv4 addresses are 32 bit numbers, a shortage of addresses was anticipated because of the meteoric growth of the Internet. For this reason and for others, IPv6 was adopted as a replacement scheme. The IPv6 address space is 128 bits in size, a huge increase over today's limits. As well, IPv6 permits a number of other security and other performance enhancements over the IPv4 system employed today.

Domain Naming System

Addressing using IP addresses has two problems: people have difficulty remembering long numeric sequences and the roles of a particular node within a network can change over time. For these reasons the domain naming system was created. The DNS maps numeric IP addresses to domain and host names and vice versa. An example of such a domain name is “gpfm.ca.” These mnemonic names are good for people to recognize and remember. They are not at all like the 32-bit IP addresses that they represent. IP addresses are great—for computers! The DNS is an important scheme implemented through sophisticated Internet applications running on many computers. Additionally significant, the DNS allows us to easily change IP addresses and maintain permanence by retaining the DNS name. The computers are told about the new association, and soon the change is complete.

Three common security attacks subvert DNS employment of datagrams for IP lookups:

- Because DNS heavily relies on UDP datagram packets and because datagrams are unreliable, a rogue DNS server can be positioned to intercept a DNS request for a

domain and then respond with a bogus reply, thus redirecting a user to a fake host.

- Because each datagram is an independent packet with no concept of a request–response session, bogus name-server cache loading relies on the fact that a legitimate DNS server might be fooled into caching a DNS response even if there was no matching DNS request. Thus a legitimate server is loaded with false information using a process known as “DNS spoofing.”
- Finally, an attacker can use UDP flooding to overwhelm a legitimate DNS server with invalid responses, crippling the server’s ability to respond to valid queries from its users. A client requesting a DNS lookup might then accept a response from the attacker as if it came from the legitimate DNS server. A remedy to these problems could use Secure DNS. Secure DNS uses SSL (Secure Socket Layers, which we discuss later) to sign a DNS query with the server’s private key; the client can verify the accuracy of the response by matching the response with the server’s known public key. Secure DNS is available in software such as BIND version 9.

Cybersquatting, purchasing a domain name in bad faith, is another DNS-related issue. The practice is not uncommon. By registering a domain in another jurisdiction or top-level domain, the victim can be cajoled into doing “business” with an unknown entity.

Using the previous example, a user may mistakenly go to `www.gpfn.com` instead of `www.gpfn.ca` (an honest and easy mistake)—especially if a spam e-mail assumed they were a `gpfn.ca` customer and asked them to visit their account and update their profile—a practice known as “phishing”. If the owner of the `gpfn.com` domain is clever enough to mirror the visual identity of `gpfn.ca`, the visitor might be persuaded to divulge credit card information or other personal data from the regular and trusting clients of `gpfn.ca`. Legal redress and diligent protection of a firm’s branding and domain registrations are the most useful remedies for cybersquatting.

Port Numbers

Port numbers in the Internet model are 16-bit numbers specifying communications to a specific process on a host. The host is selected using an IP address (or more commonly, a DNS name that is translated into an IP address). Thus, this combination of two IP addresses (the source and destination IP addresses) and their corresponding two port numbers (again, the source and destination port numbers) uniquely identify any connection. By convention, port numbers less than 1024 are reserved as “privileged” ports and generally used by the system for server-side connections such as Web servers, mail servers, or other services, that is, they are “well-known” ports that are supposed to provide access to an expected application on any host. Ports numbered above 1023 and below the 16 bit limit of 65,535 can be used by servers or clients to initiate or accept connections.

Applications bind themselves to specific ports to request service in the case of client software, or to provide service in the case of server programs. Some “well-known” ports have mnemonic names, for example, FTP (port 21),

HTTP (hypertext transfer protocol; port 80), SMTP (port 25), IMAP (port 143), and POP3 (port 110); the latter two are used for receiving mail from a mail server. The port numbers provide a glue between the Internet transport layer and application processes on the hosts. Firewalls are configured to manage the type of connections permitted by blocking or permitting access by examining combinations of IP and port numbers (i.e., two IP addresses and two port numbers).

For example, a corporate firewall might block internal users from connecting to port 80 on external servers but permit connections to port 80 within the corporate LAN. The result is that employees of that company are not able to surf the Web directly from work but are allowed to view the corporate intranet site. A corporate proxy server might allow internal users to view only those external sites approved by corporate policy. The proxy server is an intermediate computer programmed to accept requests (in this case, from inside the corporate LAN) and perhaps to fetch those Web documents from the outside. The proxy server likely collects statistics on which internal computer accesses which external Web documents.

Encrypted Packet Transmissions

Because packet communications are so pervasive yet easy to intercept, much effort is spent trying to encrypt packet streams so that they are decipherable only to the sender and the recipient. Encryption combines a unique sequence of binary digits called a digital “key” with the data to be encrypted. An encryption algorithm is shared and used by all parties to the communication.

If the same key is used by all parties to encipher and decipher the data, then the encryption protocol is said to be a “symmetric” encryption protocol. Although symmetric algorithms are computationally efficient, they are only as secure as the digital key that all parties must share.

For this reason, another class of cryptographic algorithms known as “asymmetric” protocols are used. Asymmetric protocols have every party to a communication owning two complementary parts of a key: One part is a public key that is shared with the rest of the community, and the second is a private key that is tightly guarded. A data source enciphered with a party’s private key can only be deciphered with that party’s public key, and vice versa. Because each party tightly guards its private key, there is less chance that a single security breach can compromise the entire community than with a symmetric system. Because each party to the system has its own key pair, symmetric encryption also allows for digitally “signing” a message (by encrypting it with the author’s private key), or allowing only one person to view the message (by encrypting it with the recipient’s public key), or both (by encrypting a signed message a second time with the recipient’s public key). Asymmetric protocols require much larger keys for the same level of security, however, and thus much more computational overhead to encipher and decipher messages.

Hybrid cryptosystems were established to address these respective strengths and weaknesses. Using an asymmetric protocol, two parties establish a trusted connection and use it to share a symmetric “session” key used

Table 4 Unsecured Internet Services and Their Corresponding Secure Socket Layer Secure Services

Service	Port	Secure Service	Port
telnet	23	telnets	992
smtp	25	smtps	465
http	80	https	443
pop3	110	pop3s	995
ntp	123	Secure ntp	123
imap	143	imaps	993
BSD rlogin	513	ssh	22

only for the duration of the session. Once the connection is ended, the session key is discarded. On the next connection, a new session key is negotiated in the same manner.

Two of the most common packet encryption schemes are SSL and tunnels, more commonly called virtual private networks (VPNs). One common tunnel protocol is called IPSec and is part of the IPv6 protocol.

SSL Encryption

SSL, an application-level encryption protocol, is a hybrid cryptosystem developed by Netscape Communications. It is only used to encrypt certain types of TCP traffic, such as web (HTTP), e-mail (SMTP), or log-in connections. Because each type of TCP traffic connects to a “well-known” port on the server, many of these ports are duplicated and used for SSL-encrypted TCP sessions through which the same information can pass. In this way, even if someone is able to intercept the data transmission, the encryption shields the meaning of the transmitted information.

For example, whereas HTTP (Web traffic) uses the well-known port 80, port 443 is used for encrypted Web traffic (also known as HTTPS, hypertext transfer protocol secure); similarly, unencrypted traffic over telnet (port 23) can be encrypted and transferred using SSH (secure shell) over port 22. Other examples include SMTP over SSL/TLS (port 465), IMAPS (secure IMAP) on port 993, and POP3S (secure pop3) on port 995. See Table 4 for examples of services and their well-known ports.

If you view the security information with your Web browser when visiting a secure Web site, you see that the key used by the Web server is generated by some trusted vendor of digital certificates such as Thawte™, <http://www.thawte.com/> (retrieved May 2004) or Verisign™, <http://www.verisign.com/> (retrieved May 2004) and matched to the owner of the Web site. This certificate generates browser warnings if it is used by another Web site or if it is not signed by a trusted vendor. Although a site administrator can use an unsigned SSL key on their site, most commercial sites pay an annual fee to a certificate vendor to ensure that these warnings do not appear to the user. Certificate vendors, for their part, exercise due diligence to ensure that the certificate buyer has a legal right to use the name, address, and other details of the certificate and do not misrepresent themselves or their Web sites.

When secure communications is a requirement and packets travel over a hostile or unsecured network, using

SSL-encrypted channels is often the only available means to ensure security.

Virtual Private Networks and Encrypted Tunnels

Another way to enhance security is to create an encrypted tunnel. Although IP header information must be sent in the clear (for the Internet to be able to route it to its destination), any payload data sent into this tunnel is enciphered at its source and deciphered at its destination. Because all data through the tunnel is encrypted, this process uses more computational and network overhead. The benefit, however, is the security of all the information sent through the tunnel. A number of key management systems, both symmetric and hybrid, can be used to create the tunnel; because of the computational overhead of encrypting data streams through the tunnel, pure asymmetric encryption is not used.

Because the tunnel is constructed at the transport layer, any application—even those that do not have any encryption functionality—can use the tunnel and have its data secured in transit. In fact, any application using the tunnel necessarily has its transmission encrypted. Because these encrypted tunnels simulate a secure private network within the hostile public Internet space, they are often called VPNs.

Security Concerns with TCP Packets

Historically, there have been a number of security issues with TCP packets. We discuss six of these because they are, to some measure, still relevant today. The first relates to blocking incoming connections, which is commonly managed by firewalls. The TCP sequence prediction attack relies on the predictability of the acknowledgment numbers used in the TCP three-way handshake protocol. Blind spoofing exploits a common weakness in the random number generator used to generate the initial value in the three-way handshake’s acknowledgment number.

Firewalls and Connection Blocking

Many home and business networks support internal users opening connections to some external Internet services, but they eschew outsiders initiating connections into their internal machines. Firewalls can block incoming connections by scanning the TCP headers. If an incoming TCP header contains a SYN flag but not an acknowledgment number, then the firewall recognizes the first step of the three-step handshake to initiate a connection and discards the packet.

Firewalls can also block outgoing connections to a particular port number regardless of the destination IP. In this way, internal users are prevented from accessing a particular Internet service such as FTP or streaming media sites.

TCP Sequence Prediction Attack

The TCP sequence prediction attack was made famous by Kevin Mitnick’s attack on Tsutomu Shimomura’s computers (Tsutomu Shimomura, n.d.):

- The attacker monitors the communication between two systems, one of which is the target system.

- Next, the attacker ensures that he or she can communicate with the target before the other trusted system responds, usually by overloading the trusted system with a flood of network packets or launching some other form of denial-of-service attack.
- Finally, the attacker issues packets to the target system with the source IP address of the trusted system that is communicating with the target system.

Because the packets issued by the attacker have the sequence numbers that the target system is expecting, the target continues to communicate, unaware that an attacker has now replaced the trusted host (Comer, 1997).

SYN Flooding

Using the three-way handshake protocol, a denial-of-service attack (DoS) is attempted by having one or more rogue hosts attack a target by sending a flood of TCP packets containing only SYN packets to the target, thus initiating a TCP connection, but refusing to respond to the target's attempt to consummate the second leg of the connection. Because the target has finite resources to manage incomplete connections, all of its available connection ports are consumed with "hung" connections, preventing legitimate connections from other users.

Remedies for this type of attack include:

- shortening the time that a host waits for the initiator to respond with an ACK packet;
- simulating the third leg of the handshake to force the connection open and release blocked resources;
- using a proxy server to manage the connection handshake until the connection is consummated, then handing the connection off to the intended host for the data transmission;
- returning connection information to the client in a data packet attached to the SYN response, known as a SYN cookie; and
- restricting the number of simultaneous connections from a single remote host.

Blind Spoofing Attack

The third security issue involves predicting the initial sequence number (ISN) of a target computer. If the ISN can be predicted, an attacker can spoof both the source IP address of a trusted host and the ISN returned by the target machine in the acknowledgment packet. This way, the attacker can force a one-way connection. For this reason, the TCP standard calls for a 32-bit ISN and relies on a strong pseudo-random number generator to ensure that the ISN cannot be easily anticipated. Not all operating system vendors use strong pseudo-random number generators, making the "blind spoofing attack" a topic of ongoing research (Forouzan, 2001).

CONCLUSION

Modern data networks utilize a layered approach to manage data transmissions efficiently and flexibly. The most commonly used layered model, TCP/IP, is the technique used on the Internet.

Data transmission uses switching technology so that information can be correctly and reliably routed between a source and destination. Three such switching models include circuit, message, and packet switching. Although circuit switching, analogous to traditional telephone conversations, is the most secure and robust, it is also the most expensive in that an entire set of resources are allocated for the duration of the communication regardless of how much or how little data are actually being transmitted. Message switching, comparable to traditional postal systems, introduces cost efficiencies compared with circuit switching but also loses some of the inherent security of circuit switching.

In modern networks, packet switching is the most commonly employed switching paradigm. In fact, it is so pervasive that circuit switching and message switching are now emulated by packet switching networks. Packet switching networks come in two flavors: Datagram networks do not promise reliability in that the sender has no guarantee or confirmation as to whether a message is or is not successfully delivered, whereas virtual circuit networks do afford this reliability.

Packet switching relies on addressing to ensure that a packet is correctly routed from its source to its destination. The dominant addressing model employed by the Internet is TCP/IP. The IP address supports a resilient and robust packet delivery paradigm throughout the world. The process of mapping this IP address to the domains and URLs we are all familiar with when accessing the Internet is managed by a system called "Domain Naming System" or DNS.

In addition to IP and hardware addresses, the Internet also uses port numbers. Port numbers allow two nodes to support multiple simultaneous communications. It also supports the concept of "well-known" ports whereby each service provided by the Internet is addressed using a unique port number.

By default, most TCP/IP connections are not encrypted or secured in any way. As such, any interloper can intercept mail, Web, or other data transmissions and use the contents for malicious purposes. Two solutions to this problem are commonly employed: SSL is an encryption scheme employed at the application layer. SSL-enabled servers and browsers work in tandem to encrypt their communication in a way that foils the designs of any interloper. Tunneling technology such as VPNs can also be employed at the transport layer to encrypt all communication between two nodes so that even if the applications using the connection between the two nodes are incapable of encrypting their communications, an interloper is not able to decipher the data stream.

Finally, a number of security considerations exist when using TCP packet switching. These considerations include how to block incoming connection attempts using firewalls and how to ensure that an attacker does not incapacitate a trusted node and then masquerade as that node to intercept communications.

GLOSSARY

Address Something that specifies a location or a unique instance. A person's name, an apartment number, a

- house number and street name, and a telephone number are common examples.
- Address, Hardware** An unchangeable address that is built into a device. An Ethernet address, manufactured into a network adapter, is an example.
- Address, IP** The Internet Protocol address (version IV) is a 32-bit number assigned to a host computer on the Internet. (A host can have more than one address.) The address is used to specify a particular machine. An example is 198.169.198.4, using dotted decimal notation. Four decimal numbers, 0-255, written with dots separating them, is commonly used to write an IP address. IP addresses are used in selecting routes through the Internet from a source to a destination.
- Address, Port** A 16-bit number. Each IP address has two complete pools of these numbers, one for TCP and one for UDP. Thus, at any one time, each IP address can sustain 65,535 TCP connections and 65,535 UDP transactions. The port numbers connect specific application instances, or processes, to the Internet. Each set of two IP addresses and two port numbers, at any specific time, are completely unique and specify one TCP connection.
- Asymmetric Encryption** An encryption scheme in which each party has a private and a public key. Messages enciphered with a private key need the corresponding public key to be deciphered and vice versa. The private key is closely guarded by its owner, whereas the public key is broadly disseminated. If the originator enciphers the message with the recipient's public key, only the recipient can decipher the message. If the originator enciphers the message with his private key, we have a digitally signed message (cf. chapter 184). Popular asymmetric encryption protocols include PGP and RSA.
- Blowfish** A symmetric encryption algorithm designed by Bruce Schneier. It is designed for 32-bit microprocessors, uses as little as 5 kB of memory, uses simple hardware operations, is very fast, and uses keys up to 448 bits. For these reasons, it has become popular for many personal computer applications and utilities. The source code is publicly available.
- Circuit** A route or path through a network. A circuit can exist in a circuit switching network or in a packet switching network. We habitually choose slightly different, and more specific, terms, such as virtual circuit or route depending on what kind of network we are discussing.
- Circuit Switching** The technique of establishing a route through a network that completely dedicates facilities of the links used to create the "circuit" entirely for one connection. The capacity of the circuit can be completely used, completely unused, or anything between. The circuit is dedicated, for example, a telephone call.
- Data Encryption Standard, (DES)** One of the first and most thoroughly tested symmetric encryption algorithms. It was adopted by the U.S. government as a federal standard in November 1976.
- Datagram** An unconnected UDP packet on the transport layer of the TCP/IP model. An unconnected IP packet on the internet layer of the TCP/IP model. A generic

term for a packet that travels through a network independently, from source to destination.

- Digital Certificate** A unique series of bits used by an encryption algorithm to encipher, decipher, or sign a block or stream of data. The uniqueness of the certificate is important to verify that the data was indeed issued by the alleged sender. A certificate is often issued by a certification authority that signs the digital certificate with its own trusted certificate, thus creating a chain of trusted certificates, known as a "certificate chain."
- Digital Signature Algorithm (DSA) or Digital Signature Standard (DSS)** The DSS specifies a DSA appropriate for applications requiring a digital rather than a written signature. The DSA digital signature is a pair of large numbers represented in a computer as bit strings. It is computed using a set of rules (i.e., the DSA) and parameters that identify the signer and the integrity of the data. The DSA provides the capability to generate and verify signatures. Signature generation makes use of a private key, whereas signature verification requires the use of a corresponding public key (cf. private key, public key). See Beyda (2000).
- Encryption** A formula or algorithm that combines a "key" and a unit of information so that only those knowing the key can discern meaning from the information. See also symmetric and asymmetric encryption.
- Hybrid Cryptosystem** A technique combining the advantages of both asymmetric and symmetric encryption schemes. Asymmetric systems effectively transfer information so that it can only be deciphered by the intended recipients, can be verified to be authentically generated by its alleged composer, or both. Asymmetric systems are computationally intensive, requiring keys many magnitudes of bytes larger than symmetric keys to offer the same level of cryptographic security. Symmetric systems are much less demanding in terms of computational power to encipher and decipher messages but lack efficient key management systems; should any malefactor gain access to the cipher key, all communications between any party using that key including archived communications are vulnerable. For this reason, many systems use asymmetric encryption to exchange securely a symmetric session key that is then used to encipher and decipher large data blocks transmitted between the two parties for the duration of that session.
- Internet** The worldwide network of networks employing TCP/IP. The underlying foundation networks are not homogeneous. Note the upper case "I." The Internet is a very public place and thereby has more need of effective security tools than does a physically secured network.
- internet** A network of networks usually employing TCP/IP. The underlying foundation networks need not be homogeneous. Note the lower case "i." A physically secured internet is called an "intranet."
- intranet** See internet.
- Layer** Computer code, hardware, protocols (i.e., rules) that constitute an entity designed to perform a specific job. The layer is supported by lower level layers. In

turn, it supports higher level layers. Ideally (OSI reference model), a layer is totally independent of its higher and lower neighbors, that is, the layer can be entirely replaced without its peers being aware of the swap. Realistically (TCP/IP model), this is not always true: TCP and UDP are useless without IP supporting it. IP has little use without TCP or UDP above it.

Layer, Application The highest layer, associated with human beings and application programs.

Layer, Data Link The layer immediately above the physical layer, concerned with communications on links between nodes (hosts, routers, switches) of a network. This layer exists only between two nodes.

Layer, Internet The layer above supporting networks that creates a uniform internet on top of (likely heterogeneous) networks. This is the IP layer.

Layer, Network The layer above the data link layer. It encompasses the entire network.

Layer, Physical The lowest layer consisting of hardware and its mechanical, electrical, functional, and procedural specifications.

Layer, Transport The layer above the network or the internet layer, depending on context, concerned with the end-to-end delivery of packets (UDP datagrams and TCP segments for an internet).

Local Area Network (LAN) A network in a limited geography, that is, a room, a building, or a campus. Usually LANs are broadcast networks.

Message A complete entity. Examples include the contents of a book between its covers, the contents of an envelope in the paper-based postal system, a computer file, an e-mail (message).

Message Switching The transport of a message through a network as a complete unit. The message is not broken into smaller units (i.e., packets, e.g., a letter in the postal system).

Metropolitan Area Network (MAN) A network typically covering an area the size of a metropolis. The common example of a point-to-point MAN is the local cable TV distribution system. An example of a broadcast MAN is an FM transmitter sending information to the city. MANs are typically constructed as point-to-point networks but can be broadcast networks.

Multiplexing Various techniques for transparently sharing a transmission resource among disparate users. These include frequency and time division multiplexing for electronic signals and wave division multiplexing (WDM) for optical signals. Using packets is a form of multiplexing.

Network, Broadcast A network employing a common medium or “ether.” It consists of nodes and a medium accessible to all the nodes. An example is all CB radio operators tuned to a particular channel in a restricted geographic area. A network can be broadcast on one layer and point-to-point on another layer.

Network, Datagram A network organization that has packets traveling as independent units, that is, uses datagrams. There are no circuits nor connections.

Network, Point-to-Point A collection of nodes or switches, connected with links. The telephone system is a good example. A network can be point-to-point on one layer and broadcast on another layer.

Network, Unconnected see Network, Datagram.

Network, Virtual Circuit A network organization that has the packets in a “connection” follow an established path through the network, in sequence, one after another.

Octet A grouping or unit of eight bits. Those in the field of communications prefer this more specific term over the less specific “byte.”

OSI Reference Model A seven-layer (physical, data link, network, transport, session, presentation, application) pedagogic model for networks developed by the International Standards Organization (ISO). It is an old model that represents no modern network but is useful in categorization.

Packet A “bunch” of data, usually with delimiting headers and trailers, typically tens to tens of thousands of octets, transmitted as a unit.

Packet Switching The technique of breaking information into discrete “packets” and routing them through a network. The routing of the individual packets can be unconnected or connected.

PGP, Pretty Good Privacy A company specializing in asymmetric encryption software products. In addition to its commercial products, it has freeware versions available for private, noncommercial use. For more information, visit <http://www.pgp.com/>, retrieved May 2004.

Port Number See Address, Port.

Private Key A secret key used in asymmetric encryption schemes. It is not shared and is used to sign or decipher electronic documents digitally. By signing a document with one’s private key, the signature can be verified at a later date using the alleged signatory’s public key. By enciphering a document with the intended recipient’s (or recipients’) private key(s), the document can only be deciphered by the recipient using the private key.

Proxy Server A router used to break an Internet connection into two legs. Instead of opening a TCP connection to a remote host, a client opens a connection with the proxy server, supplying the connection details for the remote host. The proxy server then opens this second connection on the client’s behalf and passes the contents from the remote host back to the client. Proxy servers can provide an effective way to filter virus, certain types of files and file extensions, specified port numbers, or content deemed “inappropriate” to the user, or block access to certain hosts or domains.

Public Key A widely disseminated key used in asymmetric encryption schemes. It is used by other parties to validate or authenticate a person’s identity. It should be shared broadly provided that it is distributed or received through a trusted source. A public key corresponds to, but is not the same as, the private key. In this way, anyone can verify a digital signature by employing the alleged sender’s public key. Similarly, anyone can encrypt a message that can only be deciphered by enciphering it with the recipient’s public key. In this case, the recipient would use the private key to decipher the message.

Route See Circuit.

Routing The process of discovering and constructing a path, circuit, or route through the network from the source to the destination.

RSA The first robust algorithmic implementation of a public-key encryption algorithm. The acronym RSA references its three inventors: Ron Rivest, Adi Shamir, and Leonard Adleman. RSA is also the name of a company making commercial encryption software products based on the RSA algorithm (cf. <http://www.rsasecurity.com/>, retrieved May 2004).

Secure Socket Layer (SSL) A hybrid cryptosystem developed by Netscape Communications. It provides an encrypted pathway between two hosts to exchange a session key. These keys are typically 128-bits in length. Anything less is not considered secure. SSL can be used to encrypt any type of Internet traffic. SSL is most commonly used for secure Web sites (given the URL prefix https), secure shell sessions, and secure e-mail gateways (using TLS/SSL) and mail servers (imaps, and pop3s).

Security The process of protecting information so that it is only meaningful to the originator and intended recipient(s) of the information.

Segment A connected, TCP packet on the transport layer of the TCP/IP model.

Symmetric Encryption An encryption scheme in which recipients and originators share the same key, that is, the key used to encipher the information is the same key used to decipher the information. Popular examples include DES, Triple DES, and Blowfish (cf. hybrid cryptosystems, asymmetric encryption).

TCP/IP Model A three-layer (internet, transport, application) model for the Internet. This ad hoc model, developed to create a practical working network, sits on top of a foundation provided by other networks or LANs. Because there is no true standard for this model, it is variously defined as a three-, four-, or five-layer model by including one or more of the lower layers on which the TCP/IP layers rest. TCP/IP is something practical that works and has become popular and widely disseminated.

Triple DES A variation of the DES symmetric encryption scheme which churns the data through the DES algorithm three times, resulting in a much higher level of security. Whereas an exhaustive search for a DES key takes 2^{56} attempts, the same search for a triple DES key requires 2^{112} attempts.

Tunnel A networking construct in which an encrypted channel is formed between two nodes. The encryption is provided by a lower level of the network stack and sometimes by hardware. Applications communicating between these nodes have their data enciphered by the sending station and deciphered by the receiving station without having to incorporate encryption algorithms at the application level.

Voice-over-Internet Protocol (VoIP) A method for transporting voice using the Internet. Whereas traditional telephony environments rely on circuit switching, a growing phenomenon is voice communications using packet switching over IP networks. It reduces costs and allows for new features and options in voice communication. The use of packet switching exposes

voice communications to many of the same security risks inherent in other packet switching environments, however.

Wide Area Network (WAN) A network covering a large region. Usually larger than a metropolitan area. Typically, it is a point-to-point network.

Wired Equivalent Privacy An encryption protocol for use on IEEE 802.11 networks. As the name implies, the protocol is only intended to give 802.11 wireless networks the same level of privacy as hardwired networks; It is not meant to offer any assurance that a wireless transmission is not intercepted and deciphered by a malefactor.

INTRODUCTION

Digital communication is the process of conveying digital information from a transmitter to a receiver across an analog channel. The origin of the binary data is known as a *source*; the destination of the binary data is known as a *sink*. Although binary data may be derived from an analog source such as music or a digital source such as a Web page, the means by which the binary data was created has little influence on the operation of the digital communication system. Digital communication could also be defined for nonbinary sources, but this is not standard for current transmission systems.

The principles of digital communication have been recognized and rediscovered many times during the past few thousand years. Early forms of digital communication used technology such as smoke signals, torch signals, signal flares, or drums. Most of these systems were visual meaning that the message was conveyed based on sight by signaling according to some prearranged code. One of the more successful signaling systems is the heliograph, discovered in ancient times and still in use today, which uses reflections from the sun on a small mirror to convey digital signals. Digital communication using electrical signals is more recent and dates back to the invention of the telegraph by Samuel Morse in the 1830s. The telegraph used Morse code, essentially a mapping from letters to quaternary sequences (long pulses, short pulses, letter spaces, and word spaces), to convey digital information over long distances via cable. Marconi patented a wireless telegraph in 1896—this is the origin of wireless digital communication. The facsimile (fax) machine is a sometimes-surprising example of early digital communication. First patented in 1843 by Alexander Bain, the fax machine both then and now scans documents line by line and digitally encodes and conveys the presence or absence of ink.

Digital communication systems offer a number of advantages over comparable analog systems. Of course, a significant advantage is that they are fundamentally suitable for transmitting digital data. Digital communication systems, however, offer other advantages including higher quality compared with analog systems, increased security,

better robustness to noise, reductions in power, and easy integration of different types of sources, for example, voice, text, and video. Because the majority of the components of a digital communication system are implemented digitally using digital signal processing, digital communication devices take advantage of the reductions in cost and size enjoyed by digital signal processing technology. In fact, the majority of the public switched telephone network, except the connection from the local exchange to the home, is digital.

All aspects of the Internet are enabled by digital communication technology. Digital communication technology is a mix of analog and digital components. The backbone of the Internet uses digital communication over optical fibers. All last-mile access technologies, despite the different transmission media, are fundamentally digital including broadband wireless, voice-band modems, cable modems, and digital subscriber lines. Local area networks use different digital communication technologies such as Institute of Electrical and Electronics Engineers (IEEE) 802.3 (Ethernet) for wired access or IEEE 802.11.16 for wireless access. Digital communication allows remote access to the Internet via cellular systems through CDPD in first-generation systems and General Packet Radio Service (GPRS), High Data Rate Service (HDR), or Enhanced Data Rate for Globalize Evolution (EDGE) in second-generation systems such as wimax. Third-generation cellular systems harmonize voice and data access because they have been designed with Internet access in mind.

This chapter presents the fundamentals of digital communication. Many topics of relevance to digital communication are treated elsewhere in this encyclopedia. A more thorough description of wireline communication media and wireless media are available in (2002–2004). Radio frequency communication is treated in more detail in (2002–2004). Readers who are interested in only a cursory overview can read the next section. Those who want a more thorough treatment beyond this article should read “Fundamentals of Design Communication” and “Important Concepts in Digital Communication” sections 2–3 as well as consult select references in “Further Reading.”

FUNDAMENTALS OF DIGITAL COMMUNICATION

Digital Communication System Overview

Over what is known as the physical layer, a typical digital communication system is illustrated in Figure 1. The physical layer is one of a number of layers of abstraction of a communication network and deals with the transmission and reception of waveforms. There are several steps in the transmission and reception process, some of which involve digital signal processing (DSP) and some of which involve analog processing. So although digital communication involves the transmission of digital information, the transmission and reception process involves both digital and analog processing. In this chapter, we focus on the DSP aspects of digital communication, in particular, the aspects at the physical layer where the analog waveforms are generated and processed.

The block diagram for a typical digital communication system in Figure 1 is divided into three parts: the transmitter, the channel, and the receiver. The transmitter processes a bit stream of data for transmission over a physical medium. The channel is the physical medium that adds noise and distorts to the transmitted signal. It accounts for the propagation medium as well as any analog effects in the transmitter and receiver. The receiver attempts to extract the transmitted bit stream from the received signal.

The first basic transmitter block is devoted to source encoding. The purpose of source encoding is to compress the data by removing inherent redundancies. The input to the source encoder is called $s[n]$, the source sequence. The output of the source encoder is called $i[n]$, the information sequence. Source encoding includes both lossy and lossless compression. In lossy compression, some degradation is allowed to reduce the amount of data that needs to be transmitted. In lossless compression, redundancy is removed, but upon inverting the encoding algorithm, the signal is exactly the same. That is, if f and g are the source encoding and decoding processes, then $\hat{s}[n] = g(i[n]) = g(f(s[n]))$, for lossy compression $s[n] \cong \hat{s}[n]$ and

for lossless compression $s[n] = \hat{s}[n]$. Data compression is treated in more detail in (2002–2004). So, from the source encoder $s[n]$ is transformed into $i[n]$, both of which are in bits. The bit rate R_b is the rate at which information bits are transmitted through the channel.

Following source encoding is encryption. The purpose of encryption is to scramble data to make it difficult for an unintended receiver to interpret. Generally encryption involves applying a lossless transformation to the information sequence $i[n]$ to produce an encrypted sequence $e[n] = p(i[n])$. Decryption reverses this process by applying an inverse transform $p^{-1}(\cdot)$ to produce $i[n] = p^{-1}(p(i[n]))$. Unlike source coding, encryption does not compress the data; rather, it makes the data appear random to an unformed receiver. Methods of encryption and security more generally are discussed briefly in the last section of this chapter and in more detail in Part 3 of Volume II.

The next block is the channel coder. Channel coding adds redundancy to the encrypted sequence $e[n]$ in a controlled way to provide resilience to channel distortions and to improve overall throughput. Using common coding notation, for every k input bits, or information bits, there is an additional redundancy of r bits. The total number of bits is $n = k + r$; the coding rate is defined as k/n . Two types of channel codes are prevalent: forward error correction codes and error detection codes. Forward error correction codes are used to provided redundancy that enables errors to be corrected at the receiver. They come in varieties such as trellis codes, convolutional codes, or block codes (Bossert, 1999). Error detection codes, CRC (cyclic redundancy check) codes being the most common, provide redundancy that allows the receiver to determine whether an error occurred during transmission. The receiver can use this information either to discard the data in error or request a retransmission.

Following channel coding, the bits are mapped to *waveforms* by the modulator. Typically, groups of bits are mapped to *symbols*. Following the symbol mapping, the modulator converts the digital symbols into

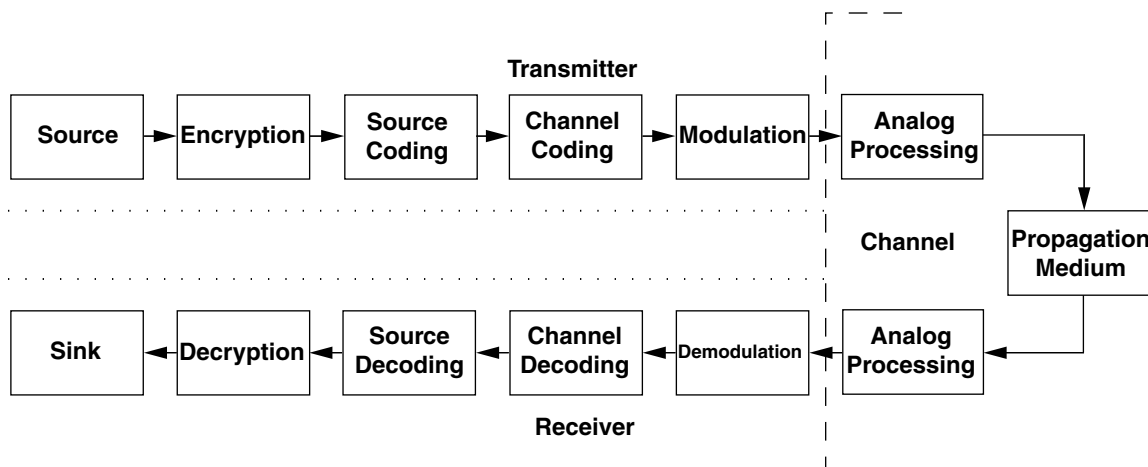

Figure 1: The components of a typical digital communication system.

corresponding analog waveforms for transmission over the physical link. This can be accomplished by sending the digital signal through a digital to analog (D/A) converter into a shaping filter and, if needed, mixed onto a higher frequency carrier. Symbols are sent at a rate of R_s symbols per second, also known as the baud rate; the symbol period $T_s = 1/R_s$ is the time difference between successive symbols. This is the demarcation point at which basic transmitter-side digital signal processing for communications ends. The signal generated by the transmitter travels through a propagation medium, which could be a radio wave through a wireless environment, a current through a telephone wire, or an optical signal through a fiber, to the receiver.

The first block at the receiver is the analog front end (AFE), which, consists at least of filters to remove unwanted noise, oscillators for timing, and analog to digital (A/D) converters to convert the data into the digital regime. There may be additional analog components such as analog gain control and automatic frequency control. This is the demarcation point for the beginning of the receiver-side digital signal processing for digital communication.

The channel, as illustrated in Figure 1, is the component of the communication system that accounts for all the noise, distortion and intersymbol interference introduced by the analog processing blocks and the propagation medium. Noise is a random disturbance that degrades the received signal. Sources of noise include the thermal noise that results from the material properties of the receiver, the quantization noise caused by the D/A and the A/D, and the external interference from other communication channels. Intersymbol interference is a form of signal distortion that causes the transmitted signal to interfere with itself. Sources of intersymbol interference include the distortion introduced by the analog filters as well as the propagation medium. Sources of distortion include clipped non their amplification is the analog elements.

The first digital communication block at the receiver is the demodulator. The demodulator uses a sampled version of the received waveform, and perhaps knowledge of the channel, to infer the transmitted symbol. The process of demodulation may include equalization, sequence detection, or other advanced algorithms to help in combatting channel distortions.

Following the demodulator is the decoder. Essentially, the decoder uses the redundancy introduced by the chan-

nel coder to remove errors generated by the demodulation block. The decoder may work jointly with the demodulator to improve performance or may simply operate on the output of the demodulator. Overall, the effect of the demodulator and the decoder is to produce the closest possible $\hat{e}[n]$ given the observations at the receiver.

After demodulation, decryption is applied to the output of the demodulator. The objective is to descramble the data to make it intelligible to the receiver. Generally, decryption applies the inverse transformation $p^{-1}(\cdot)$ corresponding to the encryption process to produce an estimate of the transmitted information $\hat{i}[n] = p^{-1}(\hat{e}[n])$.

The final block in the diagram is the source decoder that essentially reinflates the data back to the form it was sent: $\hat{s}[n] = g(\hat{i}[n])$. This is basically the inverse operation of the source encoder. After source decoding, the digital data is delivered to higher level communication protocols that are beyond the scope of the chapter.

For Internet traffic, common transmitter–receiver pairs include digital subscriber line (DSL) modems, fiber optic transceivers, local area networks, or even storage devices like a disk drive. Although their physical media are diverse and the speeds at which they transmit may be significantly different, the fundamental model for each of these digital communication systems is the same.

Processing in the Digital Domain

There are three basic classes of signals in digital communication. They are *continuous-time*, *discrete-time*, and *digital*. Continuous-time signals are those whose value at time t is $x(t)$, where t and $x(t)$ can take values on a continuum, for instance the real number line or the complex plane. Discrete-time signals take values only at integer times n , but the signal $x[n]$ takes values on a continuum. Finally, digital signals are those that have value at integer times and take on values on some finite (perhaps countably infinite) set.

The link between the analog and the digital domains is through the D/A and the A/D, as illustrated in Figure 2. At the transmitter, the D/A converts a digital signal $x[n]$ to an analog signal $x(t)$ essentially by letting $x(nT_s) = x[n]$ and interpolating the remaining values. At the receiver, the A/D samples the received signal $y(t)$ at some period T (typically a fraction of T_s) to produce $y[n] \cong y(nT)$, where this is approximate equality because $y[n]$ is quantized to some set of values. This new signal is called $y_d[n]$ and is

Figure 2: The relationship between a continuous-time signal and a discrete-time signal.

the digital waveform derived from the continuous-time waveform $y(t)$.

The Nyquist sampling theorem gives flexibility in the choice of whether to process $y(t)$ or $y[n]$. Ignoring quantization noise, the Nyquist sampling theorem states that if the inverse of the sample rate is greater than twice the maximum frequency in $y(t)$ (or equivalently the bandwidth), then there is no loss in the sampling process. This implies that any processing done on the continuous-time waveform can be done equally well on the sampled waveform given that the conditions stated in the Nyquist sampling theorem are satisfied. Several practical considerations, however, make digital the domain of choice.

The biggest advantage of doing as much processing as possible in the digital domain is that it allows full exploitation of the benefits of digital technology. Many digital platforms exist that are highly customizable and easy to alter; for instance, field programmable gate arrays (FPGAs) and digital signal processors. This hardware has been designed to have very good tolerances and reproducibility. Because the DSP machinery is easy to change, it is also well suited to adaptation if parameters may need to be adjusted over time. Analog circuitry, on the other hand, can be extremely bulky and expensive to produce. Moreover, if a change has to be made to the design, analog equipment may need to be redesigned as well. For these reasons, doing processing in the digital domain has become very relevant to digital communication. This is not to say that all analog processing can be obviated. For instance, the fundamental noise limits for a modem may be the noise produced by the analog components or the A/D converter. Another advantage of processing in the digital domain is a byproduct of the shrinking transistor size. The shrinking of transistor size offers both dramatic increases in processing power as well as significant reductions in overall cost. Thus, doing the majority of the processing in the digital domain improves cost, performance, and flexibility.

Key Resources: Power and Bandwidth

The two primary resources in any communication system, both digital and analog, are power and bandwidth. Systems whose performance is limited by the available power are power-limited, whereas those that are limited by bandwidth are bandwidth-limited. Most practical systems are to some extent both power and bandwidth limited.

The power of a signal is roughly defined as the average energy over time. Mathematically, this is often written as $P = \lim_{T \rightarrow \infty} (1/T) \int_{-T/2}^{T/2} |x(t)|^2 dt$. Power may be measured in watts but is more often measured in decibels relative to 1 watt (dB) or 1 milliwatt (dBm). The decibel is a relative measure that is defined as $(P/Q)_{dB} = 10 \log_{10}(P/Q)$. When used to measure the power of P in dB, Q is assumed to be 1 watt, whereas to measure the power of P in dBm, Q is assumed to be 1 milliwatt.

There are two different but related notions of power in a communication system: transmit power and the received power. Naturally, the transmit power is the average energy over time of the transmitted signal, and the receive power is the average energy over time of the received signal.

The transmitted power in a communication system is limited by the maximum power available to transmit a signal. Generally system performance will be better if there is high transmitted power (and thus received power). Practical constraints on cost, properties of the transmission medium, battery life (in mobile systems), or regulatory constraints, generally imply low transmitted power.

Because propagation media are lossy and dispersive, the received power is a function of the transmit power and the channel. In all media, the loss due to the channel increases as some function of the distance between the transmitter and receiver. Thus, the larger the distance, the smaller the received power.

The minimum received power required at the receiver, known as the *receiver sensitivity*, is determined by the parameters of the system, the quality of the hardware, and the desired operating characteristics. The range of the system can be inferred from the ratio of the maximum transmit power to the minimum received power. Generally, increased data rate in a given *bandwidth* or lower bit error rates increase the required minimum received power requirements.

Besides power, bandwidth is the other design constraint in a communication system. Unfortunately, there are many definitions of bandwidth, and different notions are used in different systems. The most generic definition of the bandwidth of a signal $x(t)$ is the portion of the frequency spectrum $X(f) = \int_{-\infty}^{\infty} x(t)e^{-j2\pi ft} dt$, for which $X(f)$ is nonzero. Because the true bandwidth of a finite duration signal is infinite, systems often use the “3-dB bandwidth,” which is the contiguous range of frequencies over which the power spectrum is at least 50% of the maximum value. Other definitions of bandwidth are also possible; see Couch (2001) for details.

The definition of bandwidth differs depending on whether the communication system is *baseband* or *bandpass*. Baseband communication systems operate at DC, and bandpass communication systems convey information at some carrier frequency f_c . Figure 3 illustrates the different bandwidth notions of absolute and 3-dB bandwidth in these types of systems.

The bandwidth available in a communication system depends on the transmission medium. In wireless systems, bandwidth is a precious and expensive commodity that is regulated by the government. Thus, although in wireline systems, the bandwidth is determined by the type and quality of the cable and the interconnects. Generally, the larger the bandwidth, the larger the potential data rate that can be supported. Exploiting larger bandwidths, however, typically requires more sophisticated receiver processing algorithms and more expensive analog components.

Bandwidth and power are related through the concept of the power spectral density (PSD). The PSD is a measure of the power in a signal as a function of frequency. The integral of the PSD is hence the power of the signal.

Measures of Performance

A number of potential measures are used to evaluate the performance of a digital communication system. The choice of a performance measure depends significantly

Figure 3: Illustration of two notions of bandwidth in baseband and bandpass signals.

on the application and other aspects of the system. Broad classes of performance measures include the probability of error, the outage probability, and the capacity. In this chapter, we discuss the probability of error and the capacity. The probability of error is a measure of the rate at which errors occur, and the capacity is a measure of the maximum data rate that can be supported by a channel with a given *signal to noise ratio* (SNR) and an arbitrarily small probability of error.

Of the two measures, the probability of error is the more pragmatic indicator of system performance. There are various types of the probability of error, including the probability of bit error, probability of symbol error, and the probability of frame error. Equivalently, these measures are known as the bit error rate (BER), the symbol error rate (SER), and the frame error rate (FER).

The BER provides the average number of bit errors. For example, a BER of 10^{-2} means that on average about 1 bit out of every 100 will be in error. The BER can be measured at various places in the receiver but is typically most meaningful after demodulation (the uncoded BER) and after error correction (the coded BER).

The performance needs of the application determine the required BER. For example, voice communication in cellular systems might require a coded BER of 10^{-2} , whereas data communication in the same system might require a coded BER of 10^{-5} . In most communication systems, the uncoded BER is a function of the data rate and the modulation scheme and can be readily related to the SNR. The SNR is essentially the ratio of the received signal power to the noise power in the signal bandwidth. Thus, the BER is a function of both the received power and the bandwidth of the signal, although more generally the channel model will also play a role.

The fundamental limit to data communications can be most simply described by the so-called capacity of a channel, C , which is the maximum average number of bits that can be supported by a channel with a given SNR at an arbitrarily small probability of error. The capacity is measured in units of bits per second and is essentially a bound on the achievable data rate. Often, the capacity is normalized by the bandwidth. The normalized capacity C/B measures the bits per channel use in units of bits per second per Hertz. Unlike the BER, the capacity provides an upperbound (instead of the actual performance) of a communication system because it is optimized over all

possible modulation and coding schemes. Like the BER, the capacity is typically a function of the SNR, the bandwidth, and the channel.

The capacity is a measure for determining the fundamental limit on the data rate imposed by the given communication channel. The BER is more useful for evaluating the performance of an actual coding and modulation scheme. Typically, a target BER will be defined, and a coding and modulation scheme will be proposed to achieve the largest data rate possible R . Naturally, it should be the case that $R < C$. Spectrally efficient digital communication systems have a rate R that closely approaches the capacity C for the desired operating point.

IMPORTANT CONCEPTS IN DIGITAL COMMUNICATION

Modulation

The modulator in a digital communication system maps binary data onto waveforms for transmission over the physical channel. The modulator maps a group of bits (or symbols) onto a finite number of waveforms each symbol period. Binary modulations map each bit to one of two possible waveforms, whereas M -ary modulations map each group of $\log_2 M$ bits to one of M possible waveforms. The analog waveforms are designed with the constraints of the channel such as the bandwidth or the carrier frequency in mind.

There are two basic forms of modulation known as linear and nonlinear modulation. Linear modulation schemes are typically more spectrally efficient, that is, they are able to come closer to the capacity. Nonlinear modulations typically have other properties, such as constant envelope, that make them easier to implement and less susceptible to various impairments in the channel. The choice of a modulation scheme depends on the desired throughput, the target bit error rate, the spectral efficiency of the modulation scheme, the power efficiency of the modulation scheme, robustness to impairments, and the implementation cost and complexity.

Modulations may also have memory or they may be memoryless. When a symbol is only a function of the bits from the current symbol period, it is said to be memoryless. When a symbol is a function of the bits from previous

symbols periods, the modulation is said to have memory. Having memory in the modulation scheme may have some practical advantages such as reducing the peak-to-average ratio of the transmitted signal or simplifying noncoherent detection at the receiver. Modulations with memory can also provide some additional resilience to errors, and thus they are sometimes called coded modulation schemes.

To illustrate the concept of modulation—in particular, linear modulation—let us first define the concept of signal space and then relate that to common modulation formats found in practice. A vector space is defined to be a set of vectors (in this case continuous signals), $\{\phi_i(t)\}$ with two operations: (a) addition of those vectors (i.e., $\phi_i(t) + \phi_j(t)$ is defined and is an element of the vector space) and (b) multiplications of those vectors by a scalar (i.e., $k\phi_i(t)$ is defined and an element of the vector space). Other technical rules for being a vector space can be found in Anton and Rorres (1991). In communications, typically these vectors are orthogonal, that is

$$\int_{-\infty}^{\infty} \phi_i(t)\phi_j(t)dt = \delta_{ij}, \quad (1)$$

where δ_{ij} is 1 for $i = j$ and 0 otherwise. Because these waveform vectors are orthogonal, they are also a basis for the vector space and are sometimes referred to as basis functions.

A digital communication system may be baseband or bandpass depending on whether the symbols are conveyed at baseband (DC) or at some carrier frequency (see Figure 3). ADSL (asymmetric DSL) is an example of a baseband communication system. Most digital communication systems are bandpass, including all narrowband wireless systems, optical systems, and cable modems. Although bandpass systems convey information at a carrier frequency, the modulator and demodulator do not need to generate signals at that carrier frequency. Instead, the modulator and demodulator work with the *baseband equivalent* waveform. At the transmitter, the *upconverter* in the analog processing block converts the baseband equivalent signal to the bandpass signal by shifting it to the desired carrier frequency. At the receiver, the *down-converter* in the analog processing block shifts the bandpass signal down to zero frequency. The advantage of the baseband equivalent notion is that it makes the digital operations of the communication system independent of the actual carrier frequency.

Let us first consider baseband pulse amplitude modulation (PAM). PAM transmission is used in HDSL (high bit-rate DSL), HDSL-II, and optical transmission. It is a linear and memoryless modulation. An M-PAM system is a form of M -ary modulation in which $m = \log_2 M$ bits at a time are mapped to an element of the set of M possible amplitudes \mathcal{C}_{PAM} which is the constellation. For 4-PAM, a set of possible amplitudes is $\mathcal{C}_{PAM} = \{-3, -1, 1, 3\}$, which are equally spaced apart. A pulse-shaping filter $\phi(t)$ with a bandwidth B is modulated to produce the transmitted waveform $x(t) = \sum_n x[n] \phi(t - nT_s)$, where $x[n] \in \mathcal{C}_{PAM}$. So the set \mathcal{C}_{PAM} is the constellation, $x[n]$ is the symbol transmitted starting at time nT_s , and $\phi(t)$ is the basis waveform. The spectrum of the PAM wave-

forms is determined by the pulse-shaping filter $\phi(t)$. The choice of pulse-shaping filter is a complicated one involving several competing requirements including resistance to timing jitter, minimized spectral bandwidth, and noise immunity.

A nice generalization of PAM that is preferable for bandpass systems is known as quadrature amplitude modulation (QAM). As with PAM, QAM is a linear and memoryless modulation. An M-QAM modulation is defined for M that are a power of four. Let $m = 1/2 \log_2 M$ and consider the same set of 2^m possible amplitudes \mathcal{C}_{PAM} and pulse-shaping waveform $\phi(t)$. For M-QAM, at some carrier frequency f_c , the transmitted waveform is

$$x(t) = \left(\sum_n i[n] \phi(t - nT_s) \right) \cos(2\pi f_c t) - \left(\sum_n q[n] \phi(t - nT_s) \right) \sin(2\pi f_c t), \quad (2)$$

where $i[n] \in \mathcal{C}_{PAM}$ corresponds to the symbol transmitted on the inphase component $\cos(2\pi f_c t)$ and $q[n] \in \mathcal{C}_{PAM}$ corresponds to the symbol transmitted on the quadrature component $\sin(2\pi f_c t)$. Assuming that f_c is much greater than $1/B$, the modulated inphase and quadrature components are orthogonal; thus, QAM has double the data rate of a PAM system, which would use only the inphase or quadrature component. Of course, recalling the discussion about Figure 3, note that a bandpass QAM system also uses twice the bandwidth of a baseband PAM system thus the spectral efficiency of QAM at bandpass and PAM at baseband is the same. The ordered pair $(i[n], q[n])$ is the symbol transmitted starting at time nT_s , and $\phi(t) \cos(2\pi f_c t)$ and $\phi(t) \sin(2\pi f_c t)$ are the basis waveforms. For M-QAM, the constellation \mathcal{C}_{QAM} is composed of all possible ordered pairs that can be generated from choosing the $2^m - PAM$ points for the inphase and quadrature components. Thus, the M-QAM constellation has two dimensions. The baseband equivalent of the QAM signal in Equation 2 is a complex function and is given by

$$\sum_n (i[n] + jq[n]) \phi(t - nT_s),$$

where $j = \sqrt{-1}$. Quadrature modulation schemes have complex baseband equivalents to account for both the inphase and quadrature components. The spectrum of the QAM waveform is determined by the pulse-shaping filter $\phi(t)$ and is shifted in frequency by f_c . PAM and QAM modulation are illustrated in Figure 4.

Not all bandpass systems are capable of using QAM modulation. For example, in optical transmission phase information is not available, so the constellations are defined for positive amplitudes only. If the constellations values are 0 and A, this is known as On-Off Keying (OOK).

Another common form of modulation is multicarrier modulation in which several carriers are modulated by QAM modulation simultaneously. These carriers can be thought of as a basis waveform modulated by sinusoids of differing frequencies. This is not easy to accomplish, so an IFFT (inverse fast Fourier transform) is used to approximate this operation. The inverse fast Fourier transform

Figure 4: Signal space illustration of pulse amplitude modulation (white circles) and quadrature amplitude modulation (black circles) signalling. The numbers represent the mapping of bits to the constellation points.

of a set of constellation points is in fact the sum of a set of sampled sinusoids multiplied by the constellation points. In IFFT the digital domain, each of these waveforms can be independently demodulated. These samples are sent through a single pulse shaping filter (basis waveform) and transmitted through the channel. The receiver samples the waveform and performs the inverse operations, an FFT. Multicarrier modulation has become important because of its robustness to impulsive noise, ease of equalization, and its ability to do spectral shaping by independently controlling the carriers. Discrete multitone (DMT) is the most common baseband version of multicarrier modulation, and orthogonal frequency division multiplexing (OFDM) is the most common bandpass version.

Intersymbol Interference Channels

After modulation, the analog waveform $x(t)$ corresponding to an input sequence of bits is transmitted over the communication medium. Communication media, whether fiber optic cable, coax cable, telephone cable, or free space, generally have a dispersive effect on the transmitted signal. The effect of the medium on $x(t)$ is often modeled using a concept from signal processing known as a linear and time-invariant (LTI) system. The linearity implies that if $y_k(t)$ is the response to $x_k(t)$, then $\alpha y_1(t) + \beta y_2(t)$ is the response to the input signal $\alpha x_1(t) + \beta x_2(t)$. Time invariance means that the response to $x(t + \tau)$ is $y(t + \tau)$, that is, the behavior of the channel is not a function of time. Practically all physical channels are time varying (because of changes in environmental factors), especially wireless channels; however, over short periods of time, they can be modeled as time invariant. Optical channels can also exhibit nonlinear behavior, and thus other models may sometimes be appropriate.

The LTI assumption about the communication medium allows the distortion to the input signal to be

modeled using the convolution operation

$$y(t) = \int_{-\infty}^{\infty} h(\tau)x(t - \tau)d\tau.$$

The function $h(\tau)$ is known as the impulse response of the channel and includes all the analog effects such as filtering at the transmitter and receiver in addition to the distortion in the medium. From basic Fourier transform theory, LTI systems have the nice property that in the frequency domain $Y(f) = H(f)X(f)$ where $Y(f)$ is the Fourier transform of $y(t)$, $H(f)$ is the Fourier transform of $h(t)$, and $X(f)$ is the Fourier transform of $x(t)$. Essentially, the channel acts as a frequency-selective filter that operates on the input signal. LTI systems induce distortion that is multiplicative in the frequency domain.

In an ideal channel, $|H(f)| = 1$, and there is no distortion (only a delay) of the input signal. Equivalently, in the time domain an ideal channel produces $y(t) = x(t - \tau)$, where τ is an arbitrary delay. When the channel is not ideal, a more serious problem is encountered known as intersymbol interference. To illustrate this concept, suppose that $x(t)$ is generated at baseband using PAM as described in the previous section.

In the absence of a channel, ideal sampling of $x(t)$ at the receiver at time mT_s (more details on this in the next section), results in $\sum_n x[n] \phi(mT_s - nT_s)$. The pulse-shaping filter $\phi(t)$, however, is often a Nyquist pulseshape, which means that $\phi(0) = 1$ and $\phi(nT_s) = 0$ for $n \neq 0$. Thus sampling at time mT_s yields symbol $x[m]$. Now consider a nonideal channel. Let $\tilde{\phi}(t)$ be the convolution of $\phi(t)$ and $h(t)$. For a nontrivial channel, it will generally be the case that $\tilde{\phi}(t)$ is no longer a Nyquist pulseshape, and thus $y[m] = \sum_n x[n]\tilde{\phi}((m - n)T_s)$. In this case, there are multiple superpositions of symbols at each sampling instant—thus, the notion of intersymbol interference. Compensating for intersymbol interference is known as equalization and is an important part of the receiver processing when intersymbol interference is present.

Noise and Interference

Noise and interference are the most ubiquitous forms of degradation in any communication system. Essentially, both can be modeled as random disturbances that are unrelated to the desired signal. Intersymbol interference also results in degradation; however, the effect is different because it causes the signal to interfere with itself. Noise usually refers to the disturbances generated in the receiver as a result of the analog components, analog to digital conversion, and material properties of the receiver. Generally, noise can be reduced, but never eliminated, by using higher quality materials. Interference generally refers to disturbances generated by external signals. Typically, interference has more signal structure than noise, and thus it can be mitigated by more complex processing at the expense of higher cost.

There are various sources of noise in communication systems. Common examples include thermal noise, shot noise, and quantization noise. Thermal noise is a result of the Brownian random motion of thermally excited electrons. It is generated by resistors and the resistive parts

of other devices such as transistors. Shot noise is more impulsive and may be more related to the signal, for example the random arrival rates of photons in optical systems. Quantization noise is a result of digitizing the amplitude of the discrete-time signal. Because thermal noise limits the performance in most systems (with the exception of optical system), we focus our explanation there.

Because noise is fundamentally not deterministic, it is often modeled as a random process. For thermal noise, the Gaussian random process has been found to be adequate for the job. When applied to model thermal noise, the process is assumed to be zero mean, uncorrelated from sample to sample, and have a variance σ^2 that is generally proportional to kBT_e , where k is Boltzman's constant ($1.23 \times 10^{-23} \text{ J/K}$), B is the signal bandwidth, and T_e is the effective noise temperature of the device. The latter, T_e , is a parameter determined by the analog portion of the receiver. Essentially for thermal noise the variance increases linearly as a function of the bandwidth. Thus signals with larger bandwidths incur an additional noise penalty while enjoying a higher signaling rate.

The effect of thermal noise is additive; therefore, the received signal can be written $z(t) = y(t) + v(t)$, where $v(t)$ is a realization of the noise process. Because $v(t)$ is unknown to the receiver, its presence degrades the performance of subsequent processing blocks. The severity of thermal noise is quantified by the SNR.

The origin of interference is usually an undesired communication signal. Examples include adjacent channel interference, crosstalk, and cochannel interference. Adjacent channel interference refers to the interference caused by signals operating in adjacent frequency bands. Because practical signals cannot have a finite absolute bandwidth, when the carrier frequencies of two signals are close together, there is often leakage from one signal to the other. Crosstalk is a form of interference in wireline systems. It results from the electromagnetic coupling among the multiple twisted pairs making up a phone cable. Cochannel interference is the wireless equivalent of crosstalk. Because of the limited availability of frequencies, wireless cellular systems reuse each carrier frequency. Essentially, cochannel interference is the interference among users sharing the same communication frequency.

Like thermal noise, interference is also additive. Thus a signal with interference may be written $z(t) = y(t) + \sum_k y_k(t)$, where $y_k(t)$ refers to the distorted interfering signals. Performance degrades because $y_k(t)$ is both random and unknown at the receiver. More generally, noise is also present, and thus

$$z(t) = y(t) + \sum_k y_k(t) + v(t).$$

In some cases, the interference is modeled as another Gaussian noise source. Then performance is characterized by the signal to interference plus noise (SINR) ratio, which is essentially $P_s/(P_i + P_v)$, where P_s is the power in the desired signal, P_i is the power in the sum of the interfering signals, and P_v is the power in the noise. Systems for which $P_i \ll P_s$ are called noise limited, and those for which $P_v \ll P_i$ are called interference limited. If the

source of the interference is crosstalk or cochannel interference, then the interfering signals $\{y_k(t)\}$ all have a structure (modulation, coding, etc.) similar to the desired signal. In this case, advanced signal processing algorithms can be used to mitigate the impact of the interference. Examples of algorithms include joint demodulation in which all the signals are demodulated simultaneously, interference cancellation in which the interference is partially cancelled, and optimum filtering in which filters are constructed that partially eliminate the interference. Removing or mitigating interference improves performance by reducing the required transmit power to achieve a given BER for a given data rate or by allowing the data rate at a given BER to be increased for a given transmit power.

Timing and Synchronization

Prior to demodulation and symbol recovery at the receiver, a number of timing and synchronization tasks need to be performed, including phase synchronization, frequency synchronization, symbol timing, and frame synchronization. Synchronization is performed to ensure that the transmitter and receiver operate in a synchronous manner. The process of synchronization typically consists of first estimating the synchronization error then correcting this error. Typically the processing required for synchronization is done in a mixture of the analog and digital domains.

In bandpass systems, information is modulated onto sinusoids as illustrated in the QAM example in Equation 2. To demodulate this signal at the receiver, these sinusoids must be exactly reproduced. The problem of ensuring the phases are accurate is known as phase synchronization. The problem of estimating the transmitted carrier frequency is known as frequency synchronization. Estimating and tracking the phase of the sinusoid is typically more difficult than the frequency; however, phase differences can sometimes be included as part of the channel and removed during equalization.

At the receiver, the A/D samples the analog waveform for subsequent digital processing. Optimal processing requires two aspects of symbol synchronization: symbol timing and sampling clock recovery. Symbol timing is the problem of knowing exactly where to sample the received signal. Even in systems with ideal channels, symbol timing errors can lead to intersymbol interference because of timing errors. Often the symbol timing problem is solved by oversampling the received signal and choosing the best subsample. Sampling clock recovery refers to the problem of ensuring that the sampling period T_s at the receiver is identical to that at the transmitter. Sampling clock recovery is typically more important in baseband systems because in bandpass systems the sampling clock can be derived from the carrier.

In systems where the fundamental unit of information is a frame and not a symbol, an additional synchronization step is required. This process, known as frame synchronization, is required to determine where the beginning of the frame is located. Frame synchronization is often assisted by the presence of synchronization sequences that mark the beginning of the frame.

Demodulation

The goal of the demodulator is to convert the sampled received waveform back into a sequence of bits. Of course, demodulation is highly dependent on the modulation and the channel therefore this section provides only a cursory overview.

The first step in the demodulation process is to sample the waveform. Typically, this is done via a frontend filter that removes unwanted noise, followed by a sampler. The sampled data comes from an A/D converter, so the data is in the digital domain. The sampled signal includes residual noise left after filtering, the noise from the sampling device, and the signal of interest. For example, assuming perfect timing, synchronization, and no interference, in the presence of an ideal channel the sampled PAM signal at the receiver $y(nT_s)$ is

$$y[n] = x[n] + v[n],$$

where $x[n]$ is the transmitted PAM symbol and $v[n]$ represents the sampled thermal noise and the quantization noise. The samples $y[n]$ are sent through a decision device that processes the data to make a decision. Typically, the decision device determines the most likely symbol from the given constellation that was transmitted. An inverse symbol mapping operation then converts the symbols to bit form.

Because the noise is unknown to the receiver, the role of the decision device is to produce its best guess about the transmitted data. One common criterion is to find the symbol that is the most likely input given the observations. If X and Y are vectors representing the input $x[k]$ and the output $y[k]$ respectively, then

$$\hat{X} = \arg \max_X P(X|Y),$$

where $P(X|Y)$ is the probability that $x[k] = X$ given that observation of $Y = y[k]$. The maximization is taken over all possible points in the constellation to find the point with the maximum conditional probability and is called the maximum a posteriori decision. When the source data are equally likely, it turns out that this is equivalent to the maximum likelihood detection rule which is given by:

$$\hat{X} = \arg \max_X P(Y|X).$$

In this case the decision rule determines the symbol that was most likely to have produced the observation. For the additive white Gaussian noise channel (AWGN), the conditional probabilities we have described have a known form.¹ For instance, when the input symbols are equally likely, it turns out that the detection principle is simply to minimize the Euclidean distance between the observation and the set of possible inputs

$$\hat{X}[k] = \arg \min_{x[k] \in \mathcal{C}} \|y[k] - x[k]\|^2. \quad (3)$$

¹ In the AWGN channel, there is no intersymbol interference and the only source of degradation is uncorrelated Gaussian noise.

In this case, the detector is known as a slicer. The operation of the slicer can be described by Figure 4. For a QAM/PAM waveform, if a received sample is within a decoding boundary of a point, it is mapped to that point. Because of the simple decoding boundaries, the test is essentially a series of threshold tests, and hence the name slicer.

In the absence of an ideal channel, even with perfect timing and synchronization, there will be intersymbol interference and thus the sampled PAM signal may have the form

$$y[n] = \sum_{l=0}^L h[l]x[n-l] + v[n],$$

where $h[l]$ is the sampled equivalent channel impulse response. Optimum decoding requires considering the channel response in the decision device. Because of the memory in the channel, it is no longer possible to make a decision on a symbol by symbol basis. Instead, sequences must be decoded. Thus, given a sequence of observations $\{y[p]\}_{p=0}^{P-1}$, we must determine the sequence $\{x[n]\}_{n=0}^{N-1}$, that was most likely to have been transmitted. We allow for $P \geq N$ at the receiver to account for multiple observations of the received signal via oversampling or multiple antennas, for example. Clearly, the complexity of the search grows with both N and P . Using the fact that memory of the channel is finite, however, allows lower complexity approaches such as the Bahl, Cocke, Jelenick, and Raviv (BCJR) algorithm to help in maximum a posteriori decoding and the Viterbi algorithm for maximum likelihood decoding (see, e.g., Wicker & Kim, 2002).

Alternatively, to correct for intersymbol interference, many transmission systems use equalizers that attempt to remove the effect of the channel before the slicing operation. Some common equalizers are zero-forcing equalizers (ZFE), which invert the channel; minimum mean square error (MMSE) equalizers, which include the effects of noise; and decision feedback equalizers (DFE), which use the detected symbols to remove some portion of the trailing intersymbol interference. Equalization generally gives inferior performance relative to sequence decoding but offers much lower complexity.

A PERFORMANCE EXAMPLE

The AWGN channel provides an analytically tractable baseline case by which performance in other channels can be compared. First consider the capacity of the AWGN channel. It can be shown in this case that the capacity expression is remarkably simple

$$C = B \log_2(1 + SNR), \quad (4)$$

where B is the channel bandwidth. The theoretical spectral efficiency that can be achieved in this channel is thus C/B bits per second per Hertz. The normalized capacity as a function of SNR is illustrated in Figure 5.

The capacity expression in Equation 4 provides an interesting means for evaluating system performance. For instance, if a coded system provides 3 dB increased immunity to noise, the SNR will increase by a multiple of

Figure 5: The normalized capacity of an additive white Gaussian noise channel as a function of the sound to noise ratio (SNR).

two ($10 \log_{10} 2 \cong 3 \text{ dB}$). Hence, the amount of information that can be transmitted will increase by about 1 bit per transmission for high SNR because $\log_2(1 + 2 \cdot \text{SNR}) \cong \log_2(2 \cdot \text{SNR}) \cong \log_2(\text{SNR}) + 1$.

Unlike the capacity, the symbol error rate in an AWGN channel is a function of the modulation scheme that is employed. For uncoded M-PAM or M-QAM transmission, the probability of symbol error is given by

$$P_e = 2 \left(1 - \frac{1}{M}\right) Q \left(\sqrt{\frac{3 \text{ SNR}}{M^2 - 1}} \right) \text{ for PAM} \quad (5)$$

and

$$= 4 \left(1 - \frac{1}{\sqrt{M}}\right) Q \left(\sqrt{\frac{3 \text{ SNR}}{M - 1}} \right) - 4 \left(1 - \frac{1}{\sqrt{M}}\right)^2 \times \left(Q \left(\sqrt{\frac{3 \text{ SNR}}{M - 1}} \right) \right)^2 \text{ for QAM}, \quad (6)$$

where $Q(x) = 1/\sqrt{2\pi} \int_x^\infty e^{-t^2/2} dt$ for $x \geq 0$ is the area under the tail of the Gaussian probability distribution function. The probability of symbol error for QAM transmission is illustrated in Figure 6 as a function of SNR. Notice how the error rate is exponentially decreasing as the SNR increases. For a given probability of error (at high SNR), observe that there is approximately a 6 dB difference between the SNR required for 4 QAM and 16 QAM or between 16-QAM and 64-QAM.

By inverting the formulas in Equations 5 and 6, for a target probability of error, a useful expression for the maximum spectral efficiency obtained is

$$R = \log_2 \left(1 + \frac{\text{SNR}}{\Gamma} \right), \quad (7)$$

where the gap, Γ , can be calculated as a function of M and the target probability of error. Conveniently, Equation 7

Figure 6: The symbol error rate for quadrature amplitude modulation (QAM) transmission in an additive white Gaussian noise channel as a function of sound to noise ratio (SNR).

allows direct comparison with the capacity in Equation 4. The gap, Γ , effectively determines the loss in capacity, that is, the gap between the actual spectral efficiency and the maximum spectral efficiency. Coded modulation schemes generally reduce the gap (toward the ultimate limit of $\Gamma = 1$). The effect of coding is most often expressed in dB as the coding gain, ϕ_{dB} , making the effective gap smaller, so that $\Gamma_{dB}^{new} = \Gamma_{dB} - \phi_{dB}$.

CONNECTIONS WITH SECURITY

Owing to their versatility and efficiency, today's digital communication systems are the targets for various threats, malevolent actions, and attacks. Security, the general subject of this *Handbook*, is an essential component of any digital communication system.

The provision of security services for digital communication systems can be accomplished at various levels of the communicating entity. In this chapter, we consider security implemented at the physical layer, as illustrated in Figure 1. In this figure, the *encryption* block follows the source coding block of the transmitter and the *decryption* block precedes the source decoding block of the receiver. These functional blocks permit encryption and decryption of the source. This processing, in turn, provides a confidentiality service and, if appropriate management of encryption keys are implemented, it also provides authentication. An example of this type of processing, offering both confidentiality and authentication, is the Wired Equivalent Privacy feature of IEEE 802.11b wireless communication (, 2004).

The actual primitives that implement the encryption and decryption functions can be divided into two general classes:

- 1. Symmetric (secret) key encryption.** This encryption scheme employs the same encryption key at both the transmitter and receiver. The scheme is characterized by its efficiency. It provides large data rates in converting *plaintext* to *ciphertext* while requiring minimal

memory resources. Examples of symmetric ciphers include the Data Encryption Standard (Schneier, 2004) and the Advanced Encryption Standard (Schneier, 2004). Symmetric ciphers are implemented algorithmically, employing sequences of permutations and substitutions based on the key. Although efficient, symmetric methods require that the secret key be available at both transmitter and receiver. After generation by one party, the secure communication of the key to the other party represents a significant logistical problem; in other words, the key sharing assumes a secure means of communication to establish a secure means of communication. In a mesh network of N duplex entities, $N(N - 1)/2$ secret keys are required to implement secure communication and each of these keys must be securely communicated between the entities that share it. From a security perspective, such a network employs $O(N^2)$ shared secrets.

2. **Asymmetric (public) key encryption.** This encryption scheme employs two encryption keys, a *public key* and a *private key*. Either can accomplish a transformation from plaintext to ciphertext (encryption), with the other key being required to accomplish the inverse transformation (decryption). In other words, if a message is encrypted with one of the keys, for example, the *private key*, then the message can only be decrypted with the corresponding *public key*. In operation, one of the keys, the *private key*, is known only to the entity that generates it. A second key, the *public key*, is universally advertised as being associated with the generating entity.

If Party A wishes to communicate a message confidentially to Party B, then A obtains B's public key, encrypts the message, and sends it to B. Because only B's private key can decrypt the message, and B alone possesses that key, B can be assured that the contents of the message are not available to any third party.

Because the private key remains in the exclusive possession of its owner, if a message is encrypted with this key, the resulting ciphertext requires that the owner of the private key perform the encryption, and therefore this operation is called signing the message and the ciphertext can be considered the digital signature. If A encrypts a message with its private key and sends it to B, then when B decrypts the message with A's public key, then B is assured that the message originated with A. Note that because A's public key is available to anyone, encryption with the private key only provides proof of origin (authentication) and not confidentiality.

Asymmetric key schemes are significantly less efficient than symmetric key methods. They are implemented via mathematical functions as opposed to algorithms. Examples include RSA, named for its inventors, Ron Rivest, Adi Shamir, and Ken Adleman (Schneier, 2004) and elliptic curve (Schneier, 2004). Unlike symmetric key methods, an N node mesh network only requires $O(N)$ asymmetric keys to secure communication and no shared secrets are necessary.

In addition to symmetric and asymmetric cryptographic operations, another tool is frequently employed in cryptographic processing. This tool, the message digest function, associates a number having a fixed maximum magnitude with a message of arbitrary length. The

association between a message and its digest is assumed to be unique. Therefore, the digest can be employed as an abbreviated form of the message. For example, the message digest of a message, encrypted with the originator's private key, represents one form of digital signature for the message. Today's message digest functions typically are 128 or 160 bits in length, for example, message digest version 5 (MD5) or secure hash algorithm (SHA-1; Schneier, 2004).

The taxonomy of communication system attacks is hierarchical: Passive attacks monitor communications. In the most subtle instance, traffic analysis, the eavesdropper simply learns that two parties are communicating. A more aggressive passive attack, message disclosure, causes the communication between two parties to be disclosed to other, unauthorized, parties.

Active attacks modify or deny communications. Modification involves changing the content of a communication, whereas masquerading involves fraudulently changing the origin of the communication. Replay causes a valid communication to be sent, one or more times, after the original communication was received. Denial of service simply prevents communication.

Communication security is responsible for providing a systematic countermeasure for each type of threat or attack against the communication system. These countermeasures are articulated by the International Telecommunication Union in their Recommendation X.800—Security Architecture for OSI. The countermeasures are considered security services that are provided by the communication system. Each service is intended to address one or more threats:

Access Control. This service guarantees that resources can only be accessed by appropriately authorized parties.

Authentication. This service makes it possible to prove the identity of a communicating party.

Availability. This service ensures that communication is possible between appropriately authorized parties.

Confidentiality. This service ensures that information will not be disclosed to unauthorized entities.

Integrity. This service guarantees that information will not be altered in transit.

Nonrepudiation. This service prevents a participant in a communication from denying participation in the communication.

In general, each service may employ a combination of cryptographic primitives and the implementation of one service may automatically provide another. For example, the nonrepudiation service employs both asymmetric key cryptography and message digest functions as noted earlier. Consider a transmitter with a large message, for example, several gigabytes, that must be communicated in such a manner that its origin can not be repudiated. The transmitter would first compute the message digest function of the message. This relatively small value is uniquely associated with the larger message, and it can be encrypted using the transmitter's private key far more efficiently than the message it represents. The transmitter

then transmits the message and its encrypted message digest to the receiver. At the receiver, the message is again processed through a message digest function, and the result is compared with the decryption, using the transmitter's public key, of the appended encrypted message digest. Upon equality, the receiver is assured that the message was sent by sender (nonrepudiation) and that it was not altered in transit (integrity).

Frequently, the implementation of the communication security service is accomplished beyond the actual digital communication system. In the earlier example, the message and its encrypted message digest could easily be regarded as source input to the digital communication system. Similarly, the secure socket layer (SSL) or transport layer security (TLS) used to provide authentication, confidentiality, and integrity security services for Web-based digital content is implemented as part of an application that would provide source input to a digital communication system.

SSL is noteworthy both because of its broad usage in securing Web-based financial and purchasing transactions and because it effectively makes use of a combination of cryptographic primitives to provide its security services. As an example, when a Web browser initiates an SSL session with a server, a unique session key is initially generated via asymmetric methods. This key is then employed with a symmetric algorithm and message digests to achieve processing efficiency.

As one might expect, communication security services implemented at different levels of a system may duplicate services. For example, a Web session employing SSL may be served by an operating system that provides Internet Protocol security (IPsec) services, which, in turn, may employ a WEP enabled wireless communication interface. In this example, the confidentiality service may be redundantly provided by all three components of the system.

The security of digital communications may also be provided incidentally to communication function itself. For example, code division multiple access (CDMA) wireless communications rely on the transmitter and receiver possessing a common sequence of bits, or pseudo-noise (PN). The PN is necessary to separate a specific signal from other similar signals sharing the same frequency band. However, because the PN is effectively a shared secret between the transmitter and receiver, it is capable of being employed to provide both confidentiality and authentication services.

CONCLUSION: FURTHER READING

Digital communications is a broad area that draws on many different but related aspects of electrical engineering. Perhaps the standard academic references for digital communication are *Digital Communications* by John G. Proakis (2000) and *Digital Communication* by Edward Lee and David Messerschmitt (1994). The text *Digital Communications* by Bernard Sklar (2000) provides an intuitive presentation of the concepts of digital communications. A good online manuscript by John Cioffi (n.d.-a, n.d.-b, n.d.-c) is available online. A good technical discussion of digital communication in wireless systems is found

in *Principles of Mobile Communication* by Gordon L. Stuber (2001). The *Coding Theory and Cryptography—The Essentials* reference edited by Darrel Hankerson (2000) provides a good introduction to cryptography, which is perhaps the most relevant aspect of security for digital communications. The standard reference for digital signal processing is *Discrete-Time Signal Processing* by Alan V. Oppenheim and Ronald W. Schaffer (1999). For a basic reference on vector spaces, *Elementary Linear Algebra: Applications Version* by Howard Anton and Chris Rorres (1991) is a good text.

There are many advanced concepts in digital communication that were just barely covered. For example, *Elements of Information Theory* by Thomas M. Cover and Joy A. Thomas (1991), provides a more thorough introduction to information theory. The book *Synchronization Techniques for Digital Receivers* by Umberto Mengali and Aldo N. D'Andrea (1997) provides a current treatment of synchronization in digital communication systems. Forward error correction is a topic that was only briefly mentioned yet is of significant importance. A classic reference is *Error Control Coding: Fundamentals and Applications* by Shu Lin and Dan J. Costello (1982). A text that treats some current topics is *Fundamentals of Codes, Graphs, and Iterative Decoding* by Stephen B. Wicker and Saejoon Kim (2002).

Current research in digital communication appears in a variety of journals including the *IEEE Transactions on Communications* (<http://www.comsoc.org/pubs/jrnal/transcom.html>), the *IEEE Transactions on Signal Processing* (<http://www.itsoc.org>), the *IEEE Transactions on Information Theory* (<http://www.ieee.org/organizations/society/sp/>), among others. Research in the areas of security and digital communication appears in these journals as well as the *ACM Transactions on Information and System Security*.

GLOSSARY

A/D Analog to digital converter.

Asymmetric Key Encryption An encryption process that employs one key for the encryption process and a separate key for the decryption process.

Bandpass A type of communication signal that has information modulated onto a carrier.

Baseband A type of communication signal that does not have information modulated onto a carrier.

Capacity The maximum data rate for which nearly errorless transmission can occur.

Carrier A high frequency sinusoid that shifts the spectrum of a baseband signal to higher frequencies, making it bandpass.

Channel Coding The process of adding redundancy to the transmitted data stream for the purpose of improving resilience to errors caused by the channel.

Ciphertext The information produced by the process of encryption.

D/A Digital to analog converter.

Decryption The process of transforming encrypted data to its original unencrypted form.

Demodulation The process of extracting the transmitted digital data from the continuous waveform observed at the receiver.

Digital Signature An encryption-based authentication method employing secret information used to affirm the origin of electronic documents.

Downconversion Process of converting a bandpass signal to a baseband signal by removing the carrier frequency.

Encryption The process of encoding data to prevent unauthorized access during transmission.

IP (Internet Protocol) Security An Internet network layer security protocol providing authentication, confidentiality, and message integrity services.

Message Digest Function An assumed one-way function, for which the domain is all positive integers and the range is a set of fixed length integers.

Modulation The process of converting digital data to continuous waveforms for transmission on a communication medium.

Plaintext Information before the process of encryption.

Private Key A key employed in asymmetric cryptography that is available only to its owner in the protocol.

Public Key A key employed in asymmetric cryptography that is shared with all participants in the protocol.

Receiver Sensitivity The minimum required signal level for a receiver to be able to demodulate the received signal.

Secure Socket Layer (SSL) An Internet application layer security protocol providing authentication, confidentiality, and message integrity services.

Signal to Noise Ratio (SNR) Essentially the ratio of the received signal power to the noise power.

Source Generic name for the component that generates the information stream that is the input to the transmitter.

Source Encoding The process of removing redundancy from the information stream provided by the source.

Symbol A representation of a set of bits in the digital or analog domain.

Symmetric Key Encryption An encryption process that employs the same key for both encryption and decryption.

Synchronization The process of ensuring that the transmitter and receiver operate in a synchronous manner.

Upconversion Process of converting a baseband signal to a bandpass signal by increasing the carrier frequency.

INTRODUCTION TO LOCAL AREA NETWORKS

A network is a collection of two or more devices linked together. Typically the connection is a physical connection using wires or cables, although wireless connections are also possible for networks. In addition to the hardware required for this connection, there is communication software necessary to allow the communications to occur. Networks facilitate the sharing of resources, including hardware, software, and data, as well as providing a mechanism for enhancing communications between computers and users of computers.

Networks can be primarily classified as local area networks and wide area networks (WANs). The main distinction between these classifications of networks is the radius of the network. A Local Area Network is a network where the computers are physically close together. This may mean that the computers are in the same room, the same building, or even at the same site. Computers in a Wide Area Network are often distributed beyond metropolitan areas. The Internet is an example of a WAN. Other classifications of networks may include metro area networks (MANs) and storage area networks (SANs).

Why Do We Want to Network Computers?

In the early days of computing, there were a small number of computers, which could be used by only one person at a time. With the emergence of time-sharing in the 1960s, individual computers were able to be used by more than one user simultaneously. This significantly expanded the functionality of computers but had several limitations. Chief

among the limitations was that as more users connected to the shared computer, the amount of resources available to each user's transaction became less. In the late 1970s and early 1980s, the personal computer (PC) resulted in the return of one computer/one user (Figure 1). Finally in the 1990s, hardware and software became available to network multiple PCs (Figure 2). Before LANs, copies of data needed to be kept by every user of the data on each computer, copies of software or application programs used by each user had to be installed on each computer, and every computer needed its own printer. Networking computers alleviates some of this need for redundancy, although there will also be some redundancy needed for backup purposes.

Data in a networked environment can be shared. Each user can access the data from other computers via the network. This feature of networks helped speed the transition from mainframe computing to networked computing. Networked computers allow important information to be shared among different computer users. Rather than keeping copies of data on each computer, one copy of the data can be kept on a server and accessed remotely via the network. Changes to the data can be made once and then accessed by all.

Rather than installing software on every computer, software can be shared in a network environment. Application programs can be stored on one computer and run remotely from another computer. In an office configured with multiple nonnetworked computers, each computer must have installed a copy of each application program that is used. In addition to the need to purchase copies of the software for each computer, the software must be

Figure 1: Before networks.

installed and maintained on each computer. Network versions of many application programs can be purchased. A networked version of software is typically much cheaper than purchasing large numbers of a particular piece of software. Network software needs to be installed only once on a server, allowing users on the other computers to access the software. When it is time to upgrade the software, it needs to be done only once on the server, instead of on all of the computers. Installing software on multiple computers simultaneously can be facilitated using a computer network.

Networks facilitate the sharing of hardware. Hardware can be installed in one location and accessed over the network from other computers. Printers can be networked so that multiple users can share the same printer or other hardware device. Other peripheral devices, including modems, CD and DVD ROMs, and networking devices, such as routers, can all be shared using a LAN.

Before LANs, computer users who needed to communicate with others had to use traditional methods, such as physically visiting another user, calling on the telephone, or have a letter delivered to the other person. Communications has been enhanced tremendously with e-mail and instant messaging (IM). E-mail and IM are facilitated by the use of a LAN.

TYPES OF LANs

A computer that can access a network are often referred to as a computer workstation or host. Any device (workstation, printer, modem, etc.) that connects to a network is called a node.

Many of the early networks allowed simply the sharing of resources among PCs. These types of networks are called peer-to-peer networks. Each computer has the same potential for sharing files and hardware devices. A peer-to-peer network is easy to design and maintain but is limited in its capabilities.

Most networks today are classified as client/server networks. In a client/server network, one or more of the computers function as servers, whereas the remainder of the computers functions as clients. A server is a computer that provides a service, whereas a client computer makes use of the service provided. Examples of servers include print servers, file servers, mail servers, and Web servers. A print server (Figure 3) is a computer or peripheral device that provides access to one or more printers across the network. Print servers were among the earliest type of servers. A file server provides a repository for files that can be accessed by other computers over the network. A mail or communication server manages the flow of incoming and outgoing electronic mail for users accessing the server from client workstations. A Web server runs software that provides access to World Wide Web documents.

Computers on a network can run more than one type of server software and can function as multiple types of servers. For example, a computer can have both Web server and e-mail server software installed and function as both a Web server and a communications server. A workstation can be both one type of server and a client for another type of server. For example, a computer can be running Web server software but print through the network using another computer that functions as a print server. It is generally not recommended that one computer

Figure 2: After networks.

Figure 3: Print server.

function as more than one server. Doing so increases the likelihood of one point of attack on the network. However, using a separate computer for each server results in more potentially vulnerable computers. This increases the points of attack and needs to be taken into consideration. Running only one main service (e.g., e-mail) can significantly increase the reliability of the network as instability and maintenance associated with that service will typically not affect other services running on separate servers.

Similarly, it is recommended that servers not function as clients. Using a server as a client increases the opportunity for introducing security vulnerabilities that might compromise the security of the server.

Difference between LANs and WANs

As mentioned under Introduction to Local Area Networks, the main distinction between LANs and WANs is the radius of the network. A LAN is a network where the nodes are physically close together. In most cases, the nodes are in the same room, although they may be in the same building or in nearby buildings. Historically, networks with a radius greater than a kilometer or two are typically classified as WANs. Other ways of distinguishing between LANs and WANs include transmission speed and ownership. LANs are typically faster networks with speeds of at least 10–1000 megabits per second (Mbps). WANs are generally significantly slower, with most connections to WANs at around 1.5 Mbps, although there exist very high-speed WANs. LANs are owned by the organization where the network is used. WANs generally use hardware that is owned and operated by a network provider, although there are public agencies that do own and operate their own WANs. A final distinction is with the difference in protocols used by LANs and WANs. The next section describes two of the protocols (Ethernet and token ring) used by LANs. WANs typically use different protocols, including frame relay, ATM, and X.25. Recently Ethernet has started to be deployed in WANs as Metro Ethernet. These distinctions continue to blur significantly over the last several years as WANs get faster and LANs get larger.

LAN Topology

LANs can be organized in a variety of ways. One way to classify networks is by their electrical configuration or **logical topology**. This is often called the signal topology

and is determined by how the nodes communicate with each other. This is basically the way that the data is transmitted between nodes. The main two logical topologies are **bus** and **ring**.

In a bus network, the data is broadcast from one node to all other nodes in the LAN even though the data may be intended for only one node. Each of the nodes receives the data but they are “read” only by the node where the data is intended. The data include an address for the destination node or nodes. Ethernet is the primary protocol that supports the bus logical topology.

In a ring network, the data are sent from one node to the next in sequential order in a circular fashion. Each node inspects the destination address of the data packet to determine if the data are meant for it. If the data are not meant for the node, the data packet is passed along to the next node in the logical ring.

LANs can also be classified by the physical layout of the network. The way that the nodes are physically connected to the network is known as the **physical topology**. The physical topology of the network can have a significant influence on a LAN’s performance and reliability. The three main physical topologies are **bus**, **ring**, and **star**. There are also hybrid networks, including star-bus and star-ring, which incorporate parts of both types of networks.

In a bus topology (Figure 4), the nodes are arranged in a linear fashion, with terminators (Figure 5) on each end. The nodes are connected to the “bus” with connectors. Bus networks are easy to install but not very reliable. Any break in the connection, or a loose connection, will bring down a portion of the network and possibly the entire network.

Figure 4: Bus network.

Figure 5: Terminator and BNC T-connector.

In a ring topology (Figure 6), each connected node is an active participant in the ring network. Each data packet is received by a node, and, if it is not intended for the node, it is passed along the ring to the next node. If one of the nodes or its network card malfunctions, a portion of the network stops functioning.

In a star network (Figure 7) each connected node is attached to a central device. Typically this device is a hub or a switched hub, but it could also be other devices, including a multistation access unit (MAU). Star networks are more economical and easier to troubleshoot. Star networks do require an additional hardware device, such as a hub or switch, and additional cable. Because each node is independently connected to the central device, a failure affects only the single node. Of course, if the central device fails, the entire network fails.

A network's physical and logical topologies are not necessarily the same. For example, a twisted-pair Ethernet network is physically arranged with a star topology although the data are transmitted via a bus topology.

LAN Architecture

The most popular network architecture for LANs today is Ethernet. Ethernet was developed by Robert Metcalfe and others at the Palo Alto Research Center (PARC) around 1973. Ethernet uses the carrier sense multiple access with collision detection (CSMA/CD) access method. Carrier

Figure 6: Ring network.

Figure 7: Star physical network.

sense refers to each node being able to “listen” for other users using the network, only attempting to use the network if it is not being used. Multiple access means that any node on the network may use the network without requiring further permission. Collision detection lets the node know if a message was not delivered and controls the mechanism for retransmitting the data packet. CSMA/CD is most efficient when there are a limited number of nodes requesting access to the network.

In 1981, the first Ethernet standard was developed by a consortium composed of Digital, Intel, and Xerox. This was followed by a second Ethernet standard in 1982, called Ethernet II. Ethernet II (Figure 8) had the following characteristics:

- Bus topology
- Coaxial cable using baseband signaling
- 10 Mbps data rate
- Maximum station separation of 2.8 kilometers
- 1024 maximum number of stations

In addition, the IEEE developed a standard, also often referred to as Ethernet, called the IEEE 802.3 standard (Figure 9). The two standards are very similar and have similar frame layouts as shown.

Ethernet can run over a variety of media types, including several types of coax cable, twisted pair cable, and fiber optic cable, as well as wireless formats, including radio signals and infrared. Table 1 lists several of these media types. The first number indicates the speed in megabits

Destination MAC Address 6 octets	Source MAC Address 6 octets	Type 2 octets	Data Unit 46-1500 bytes	Frame Check Sequence 4 octets
-------------------------------------	--------------------------------	------------------	----------------------------	----------------------------------

-------------------------------------	--------------------------------	--------------------	--	----------------------------------

Figure 9: IEEE 802.3 frame layout.

Table 1 Types of Network Media

Standard	Popular Name	Speed (Mbps)	Media	Maximum Segment Length (Meters)
10Base2	Thinnet; cheapnet	10	Thin coaxial cable RG-58	185
10Base5	Thicknet, yellow hose	10	Thick coaxial cable RG-8 or RG-11	500
10BaseT	10BaseT twisted pair Ethernet UTP	10	Unshielded twisted pair CAT3, CAT5	100
100BaseT4	Fast Ethernet	100	4 pair telephone grade cable	100
100BaseTX	Fast Ethernet	100	2 pair data grade cable	100
10BaseFL	Fiber Ethernet FOIRL	10	Multimode fiber optic cable	1000
100BaseFX	Fast Ethernet	100	2 strands fiber cable	412
1000BaseT	Gigabit Ethernet	1,000	Cat5e	100
10GBase	10 Gigabit Ethernet	10,000	Fiber	300

per second; the *base* refers to **baseband transmission**, meaning that the entire bandwidth is dedicated to just one data channel; and the last number or letter indicates the approximate maximum segment length or the media type.

A second network architecture, token ring (Figure 10), was developed in early 1970s by IBM. A token ring is often preferred for time-sensitive and mission-critical applications. Token ring uses the token passing access method. Only the computer that has the 24 bit packet of data called the token may use the network. This token is generated by a designated computer, called the active monitor, and passed around the ring until one of the computers wishes to use the network. When a computer wants to use the network, it seizes the token, changes the status of the token to busy, inserts its data frame onto the network and releases the token only when it receives a confirmation that the data packet has been received. A token ring network uses a sequential logical topology, which was traditionally a ring physical topology but now is typically a star topology. IBM specified two architectures that operated at 4 and 16 Mbps. Ethernet and token ring standards are typically associated with the Data Link Layer of the OSI model.

LAN HARDWARE AND MEDIA

There are a variety of media choices for connecting computers to a local area network. Early networks used copper wires, either coaxial or twisted pair. The standards detailing the LAN hardware and media are associated with the physical layer of the OSI model.

Copper Wire

Coaxial cable consists of a center wire surrounded by insulation and then a grounded shield of braided wire. The

shield minimizes electrical and radio-frequency interference. Coaxial cable was typically either **thinnet** or **thicknet**. Thicknet (Figure 11) was the original standard for Ethernet and is defined by the IEEE 10Base-5 standard and uses 50-ohm coaxial cable (RG-8 or RG-11 A/U) with maximum lengths of 500 meters. Thinnet (Figure 12) is defined by the IEEE 10Base-2 standard and uses 50-ohm coaxial cable (RG-58 A/U) with maximum lengths of 185 meters. RG-58 is similar to the coaxial cable used with cable TVs. Cables in the 10Base-2 system connect to other devices with BNC connectors (Figure 13).

Twisted pair networking cable also has two different forms: **UTP** (unshielded twisted pair) and **STP** (shielded twisted pair). Both types of cable consist of either two or four pairs of wire. Each pair is twisted together. Shielded twisted-pair cable has an additional layer of conducting material surrounding the twisted pairs of wires. Unshielded twisted pair cable has no additional layer. Telephone companies use UTP cable with two twisted pairs of wires. UTP is the most common and least expensive method for networking computers (Figure 14). There are six categories of unshielded twisted pair cabling ranging from **Category 1 (CAT1)**, which is ordinary telephone cable used to carry voice, to **Category 6 (CAT6)** (Figure 15), which is designed for high-speed networks. CAT6 uses 23 AWG copper as opposed to the 24 AWG used in Cat5e and lower; therefore the signal attenuates less with speed and distance. Cat6 also uses a tighter twist ratio that cuts down on internal crosstalk. UTP uses RJ45 connectors (Figure 16) to plug into the different networking devices.

Fiber Wire

Fiber-optic cable (Figure 17) is becoming more common as demand increases for higher transmission speeds. Fiber optic cable transmits data using pulsating laser light

Starting delimiter 1 octet	Access Control 1 octet	Frame control 1 octet	Destination address 6 octets	Source address 6 octets	Optional Routing Information Field up to 18 octets	Optional LLC Fields 3 or 4 octets	DATA Unlimited size	Frame Check Sequence 4 octets	Ending delimiter 1 octet	Frame status 1 octet

Figure 12: RG-8 coaxial cable.

Figure 13: BNC connector.

Figure 14: CAT5 patch cable.

Figure 15: CAT6 twisted pairs of wires.

Figure 16: RJ45 connector.

instead of electricity. Fiber optic cable consists of a thin glass or plastic filament protected by thick plastic padding and an external plastic sheath. A light signal travels faster, farther, more reliably, and more securely than electricity. Fiber cable can send reliable signals at speeds of 100 GB/s as far as 10 kilometers. Unfortunately, fiber-optic cable is expensive to buy, install, and maintain. Although not impossible, it is more difficult to intercept data carried by fiber optic cable.

Wireless

Wireless LANs are rapidly becoming commonplace in businesses and homes. Early wireless LANs were light based using infrared light to transmit the data. Wireless LANs that are light based require line of sight for all devices on the network. Because of this limitation and the slow data speed, there are few light-based infrared wireless LANs.

Most wireless LANs use radio waves to transmit the data. Each device in a wireless network requires an antenna to receive and transmit the radio signals. Wireless LANs can be peer-to-peer or ad hoc networks (Figure 18) that require only that each device be equipped with a wireless network card that contains the antenna or a more complete network called an infrastructure network that requires an **access point** (Figure 19). The access point contains an antenna, a radio transmitter, and a wired network interface, typically an RJ45 port. The access point acts as a base station (similar to a hub) for the wireless network and also as a bridge between the wireless and wired networks.

Figure 17: Fiber optic cable.

Figure 18: Peer-to-peer wireless network.

Regardless of whether the network is wired or wireless, every device on the network must be connected to the network with a network adapter or network interface card (NIC) (Figures 20–22). The card must be physically connected to the device, either installed directly into a slot in the computer or connected via a port, such as a USB port. The network card provides the interface between the node on the network and the network media. Because communication in a wireless network occurs through the air, it is easier for the signal to be intercepted. As wireless becomes more pervasive, security has become a significant issue.

Hardware Devices

Several factors limit the radius of a local area network. The farther a signal travels along a twisted pair or coaxial cable, the more likely it is to be degraded by noise. As the signal travels, it loses energy and becomes weaker, thus becoming difficult to read. As the network cable comes longer, it becomes more likely that two or more machines will transmit at the same time, causing a “collision.” It will take longer for the machines to detect the collision. There are several ways to increase the radius of a network.

The simplest is to use a repeater. A repeater (Figure 23) is an electronic device used to extend the distance of a network by amplifying the signal and reducing the electrical interference within the network. The repeater relays the data from one segment of the network to another without inspecting or modifying the data. Repeaters can also be used to connect segments of the network that use different cable media. Repeaters operate at the physical layer of the network.

Figure 21: Network interface card with RJ45 connection.

Figure 22: PCMCIA wireless NIC.

Figure 23: Repeater.

Figure 24: Four-port hub.

A hub (Figure 24) is a multiport repeater that allows the distance of the network to be extended as well as allowing multiple devices to connect to the LAN. A hub is a device that brings all of the connections together (Figure 25). Like a repeater, the hub does not inspect or modify the data. Ethernet networks with only hubs and repeaters are constrained by the 5-4-3 rule, which limits the connections between two nodes to no more than five segments with no more than four repeaters where no more than three of the repeaters connect additional nodes.

Repeaters and hubs boost the signals on a network but do not solve problems involving collisions. Other devices, however, alleviate this problem by limiting traffic on the network. A bridge (Figure 26) is an electronic device that connects two or more networks typically running the same network protocols. It allows the isolation of the different networks. The different networks may have different topologies. Bridges are used to increase the efficiency of a network by limiting the collision domain to “one side” of the bridge. By doing this, networks can be expanded with no significant increase of traffic. Bridges operate at the physical and data link layers and make use of the physical addresses associated with the network cards.

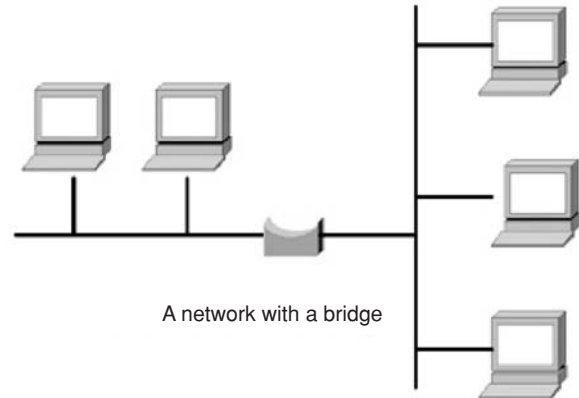

A switch (Figure 27) is a multiport bridge. Switches are often referred to as switching hubs. A switch combines the appearance and functionality of a hub with the additional functionality of a bridge. Switches provide full duplex transmission between nodes eliminating collisions and enhancing the performance of the networks. Switches have typically replaced hubs in most local area network installations. A specialized type of bridge or switch called a *translating bridge* can be used to connect two or more networks using different protocols (i.e. Ethernet and token ring).

Although typically not part of a LAN, routers provide the interface between a LAN and WAN or between dif-

Two hosts connected with a hub.

Figure 25: Hub connecting two hosts.

A network with a bridge

Figure 26: Bridges.

ferent LANs. Routers route the traffic between different networks by maintaining tables of networks and their addresses. Routers forward Layer 3 IP datagrams between different Layer 2 broadcast domains. Routers are more sophisticated than switches and bridges and work at a higher level of the network.

LAN SOFTWARE

Local area network software can be classified into three categories: network operating systems, network utilities, and network applications. Not too long ago, operating systems and network operating systems were distinct. Today almost all operating systems have the functionality of a network operating system built in. In other words, you do not need to add any additional software to the operating system to get the computer to function on a network. All of today's popular operating systems, including all recent versions of Microsoft Windows, all versions of Linux and UNIX, and all versions of the Macintosh OS, will support the connection of a computer to a network right out of the box. In addition to the usual computing tasks performed by an operating system, a network operating system also

- Manages the network connection
- Directs data traffic onto and off of the network
- Manages the flow of data between the different devices
- Manages communication and messages between the network users
- Provides for security of the data and other resources available the network

8-port switch

Figure 27: Switches.

The network operating system provides the interface between the LAN hardware and the applications running on the host.

Included with most of the network operating systems are specific network utilities, such as ping, ARP, and traceroute, which provide network functions. Ping sends an Internet control message protocol (ICMP). ECHO_REQUEST and ECHO_REPLY packet data to another device to indicate the time it takes to reach a target machine. Ping is a useful utility for troubleshooting networking problems. Address resolution protocol (ARP) is used to map the physical address of a networked device to the corresponding network IP address that has been assigned to the device. Traceroute uses the ping utility to map the route packets of data taken from a source to a destination machine. Network operating systems typically include drivers for most network adapters so the adapter can be plugged into the computer and the computer can be functioning on the network without too much additional configuration.

Network application software includes client front-end software that is specific for use by client computers. This would include programs such as Web browsers and e-mail software clients that would be run when needed. Hosts functioning as servers would have server software that would be constantly running, waiting for connections from clients (e.g., Web servers and e-mail servers). Other types of network application software include database client and server software as well as groupware software.

ROLE AND APPLICATIONS OF LANs IN THE INTERNET, INTRANET, EXTRANET, AND E-COMMERCE WORLDS

One of the major uses of local area networks is to facilitate connections by users to the Internet. This requires the connection of the LAN to the Internet via a dial-up telephone connection, a broadband connection, or a leased line. A dial-up connection requires a modem that converts the network's serial digital signal to the phone line's analog signal. A broadband connection typically requires a digital subscriber line (DSL), integrated digital services network (ISDN) or cable modem and a router and hub. A leased line connection requires a router that is then connected to another hardware device called a CSU/DSU (channel service unit/data service unit). The CSU/DSU in turn connects the network's router to the end of the leased line (e.g., T1) and converts the network's serial data signal to and from the leased line's digital signal. The leased line provides a high-speed Internet connection for the organization owning the LAN. The leased line is typically leased from a telecom provider through an Internet service provider (ISP). The ISP maintains the actual connection to the Internet using its own router.

Connecting a LAN to the Internet requires that the devices on the LAN support the TCP/IP suite of protocols that provide the foundation of the Internet. These protocols are necessary for computers on the LAN to be able to communicate with devices in other parts of the Internet. The TCP/IP suite of protocols include the following:

- Transmission control protocol (TCP) establishes and maintains the Internet connection
- Internet protocol (IP) handles the routing of packets of data across the Internet
- Simple mail transfer protocol (SMTP) receives and delivers e-mail messages
- Hypertext transfer protocol (HTTP) facilitates the delivery of Web documents
- File transfer protocol (FTP) transfers files
- Telnet allows users to remotely connect to other computers over the Internet

Many organizations have set up their own internal Internet called an intranet. An intranet is a private network that uses many of the same protocols as the Internet. An intranet appears to the user like the Internet, but it is typically not open to anyone outside the organization. An intranet is not a replacement for a LAN but rather runs within a LAN and supports many of the same applications as the Internet, typically Web servers and browsers, and e-mail servers and clients, as well as additional groupware software. The core of most intranets is the Web site, which typically contains most of the internal documents that need to be disseminated among the organization's members. Setting up an intranet site on an organization's LAN requires a lot of organization and planning in selecting the hardware, software, and data needed to create a functional intranet.

Some organizations have taken the intranet concept one step further and linked distributed parts of the organization together through the Internet via an extranet. An extranet is basically an intranet that may include access by customers, suppliers, and trusted partners.

WIRELESS LOCAL AREA NETWORKS

Wireless local area networks (WLANs) are rapidly becoming commonplace in offices and homes. WLANs provide the freedom to access data without being tethered to the network with wires. WLANs enable users to take laptops and handheld computers anywhere, anytime, and still be able to access the network. This is becoming more important in today's world of information.

Wireless networks are easier and less expensive to install. Wireless networks require spending less money on cable and not needing to spend additional money and time installing the cable. Wireless access points and NICs have become much cheaper in the past year. Installing a wireless network involves turning on the access points, installing the software for the access points and NICs, and identifying the access points for the NICs to connect to. Modifying a wireless network is easier but does have its issues. There is no need to remove and/or relocate cable. There is no longer a concern for network cable failure.

Companies are using WLANs for keeping track of inventory in warehouses. Workers who need to be constantly in contact with their network are more frequently using WLANs. WLAN devices have become commonplace among workers in the health care industry. One area where WLANs are beginning to have a great impact is in education. Students and faculty no longer need to find

wired computer labs to communicate and work. With wireless devices, students and faculty can access the networks in any buildings where wireless access points have been installed.

Wireless networks still have some drawbacks. Chief among them are the limitations on distance and bandwidth. The radius of a WLAN can be extended by adding additional access points and RF repeaters to the network. Adding additional access points on the same channel can also help increase the bandwidth of the WLAN. There are also new standards and associated wireless devices emerging that support increased bandwidth. 802.11b and 802.11g use the unlicensed 2.4-GHz ISM band and support transmission speeds up to 11 and 54 Mbps respectively. A third standard, 802.11a, uses the 5-GHz UNII band and supports transmission speeds up to 54 Mbps.

The other major drawback for WLANs is security. A WLAN transmits radio signals over a broad area. This allows an intruder to lurk anywhere and intercept the signals from the wireless network. One way of inhibiting access to wireless network is to turn on wired equivalent privacy (WEP). WEP relies on a secret key that is shared between a mobile station and the access point. The secret key is used to encrypt packets before they are transmitted, and an integrity check is used to ensure that packets are not modified in transit. Even though WEP is easily compromised, it is still useful for home-based LANs as a first line of defense. Additional levels of security are now being developed and implemented to protect the transmission of data.

LAN INSTALLATION

Before a LAN is installed, a lot of planning needs to take place. The process can typically be broken down into seven steps as follows:

1. Needs analysis
2. Site analysis

3. Equipment selection
4. Site design
5. Server configuration
6. Installation schedule
7. Installation

Needs Analysis

The first aspect of installing a local area network is determining the needs of the organization and the users. Is a local area network needed? What aspects of the network are needed? Who will be using the network? What will they be using the network for? Will a local area network help the bottom line of the organization?

Reasons for installing a local area network might include the following:

- Need for improved communication
- Need for centralizing data
- Need for sharing hardware
- Need for application sharing
- Need for automating work flow
- Need for enhanced security of data

Site Analysis

Once a need has been established, it is necessary to determine where the LAN will be installed. What parts of the organization's site will be networked? Where will the servers be located? A site plan will need to be drawn. If a fire escape plan is available, it can be used as a template for the building and location of rooms and doors. It is best if the architectural plans can be found. The site plan (Figure 28) is a map of the location where the network is installed and should include the following:

- The dimensions of the site, including the location of each employee

Figure 28: Sample site plan.

Figure 29: Sample site design.

involve moving furniture, installing new outlets, and removing equipment that will no longer be used. Do not forget to back up any data on systems that will be affected by the move.

Installation

Before the installation begins, it is best to discuss everything with someone who has been through a LAN installation before. Have this person look over the designs, schedules, and forms to ensure that nothing has been forgotten. Depending on the size of the installation, it may take anywhere from a couple hours to a couple of days. Be prepared for delays. If this is a wired network, conduit needs to be installed and the cable media will need to be pulled. This is the part that typically takes the longest time. While the cable media are being pulled or shortly thereafter, the remaining components will need to be installed. This would typically include the patch panels in the communications rooms and the wall outlets for each device that will be networked. Once this is completed, the electronic devices (hubs, switches, etc.) will need to be installed. If network cards need to be installed in the older computers, this will be done next. Finally, the software for the network cards will need to be installed on each workstation and server if it hasn't already been done. Be sure to install the appropriate network software.

The final two stages of the installation are the testing and training. Every device will need to be tested to ensure

that its network connection works. This should be done before any of the users access the network. Be sure to test all of the network devices and the networked printers. Applications, service, and end-to-end testing must be performed. The final phase is training. Users will need to be trained in the procedures they will need to follow to use the network.

LAN ADMINISTRATION

Once the LAN has been installed, there are several key aspects of administering the network.

Configuration List

Using the equipment inventory forms developed during the installation along with similar documentation for the new devices, a set of configuration lists needs to be developed. These would include a list of all computers similar to the equipment inventory form, directory lists for each server that is installed, a list of all server users, a list of all printers and other shared devices. It is also very important to keep copies of the network plans developed for the installation of the network.

System Log

The system log is documentation for the network. It provides a detailed history of the network's hardware, software, and configuration features. As changes are made

to the network, these changes need to be documented in the system log. As problems arise with the network, these also need to be documented in the system log. This log needs to be maintained from the beginning. The system log should include all hardware and software warranties, hardware and software information, current setup structure, backup and recovery plan, backup logs, and error/downtime logs.

Training

Training does not end after the network has been installed. The network is a dynamic part of an organization's computing system. As changes are made, employees will need additional training.

Backup

As more and more data are kept on networked servers and shared by more than one user, it becomes critical that a procedure be established for backing up critical data. This may be the most important task for a network administrator. Hardware and software can be replaced. New employees can be hired. But it is difficult to recreate large amounts of data. The network administrator must establish a schedule for backing up all critical data. Separate SANs or NASs may be needed to provide added storage protection. Critical software may not necessarily be replaced and should be backed up as well. Configuration files should be backed up also.

Security

Once computers become accessible to other individuals, security issues need to be considered. In a networked environment, users will need user ids and passwords. If security is extremely important, then encryption of data might also need to be implemented. If the local area network is attached to another network, then a firewall may be necessary to control access to critical data between the two networks.

LAN SECURITY

In today's world of ubiquitous local area networks, security is of the utmost importance. This is true whether the LAN is a peer-to-peer or client/server network. Security is all about confidentiality, integrity, and availability. Where necessary, information should be confidential. The information should be only available to those who are authorized to access it. The integrity of the information must be maintained. We need to be assured that the information has not been altered. The availability of the information must be preserved. Authorized users need to be able to access the information and computing resources when needed.

Securing a LAN requires a multilayered approach. One of the main themes in security is "defense in depth," where multiple layers of technology and multiple procedures need to be implemented to minimize the threats to the local area network.

Physical Security

"I touch it, I own it!" Without physical security, there is no security. Having physical access to the devices and computers on a network is the greatest vulnerability in network security. No matter how strong other facets of security, if an attacker can physically access computers and other devices, the LAN can be easily compromised.

All LAN servers must be locked in a physically secure area. Network devices and cable need to be protected from intentional and unintentional disruption. To avoid inadvertent compromises, servers should not be used as client workstations. It is too easy for client-based vulnerabilities to be compromised and affect the server software running on the same computer. Securing a LAN includes more than preventing attacks. An inadvertent loss of power to the computers and network devices can be catastrophic. All devices should be protected by surge protectors. Power to servers and other critical hardware needs to be stabilized using uninterruptible power supplies (UPS). The UPS battery needs to be checked regularly. An alternate power supply, such as a generator or second utility grid, should be available, especially for mission-critical LANs.

Access Security

The first line of defense is access control. Access to servers and data needs to be controlled. This can be implemented by instituting controls at the network level as well as individual controls at the directory and file levels. Connections to all servers and the network should be controlled through authentication procedures. All users must be registered and authenticated. There should be no guest accounts. Minimally the use of user ids and passwords should be required for all connections to the network. All users need to use nontrivial passwords that are difficult to "guess." These passwords should be frequently changed and checked. Unfortunately, too many passwords can create operational issues. Often, users will forget their passwords. A mechanism needs to be in place to address this problem. All default passwords for servers, operating systems, and applications must be changed immediately. All obsolete user accounts need to be terminated immediately. It may also be necessary to restrict user access to certain days and times to better control access to sensitive data.

There should be several levels of access to directories and files. These typically would include read, write, and execute. Users need to be given the minimum privileges to access all their files and directories. All data must be protected from access by unauthorized users. It is important that authorization is carefully planned. Audit logs of successful and unsuccessful access to systems and files may need to be kept to allow for tracking of problems that have arisen.

Data Security

Where necessary, critical data need to be protected. In addition to those mechanisms discussed above, additional layers of security may be necessary. In the case of

databases, views need to be provided to permit users to access only the minimum that is necessary.

Data confidentiality is especially important. Where necessary, encryption software needs to be used to protect confidential and sensitive data. Controls need to be implemented to protect all confidential and sensitive data stored and/or processed on the LAN. These controls should include any removable media associated with the LAN. It is important that all confidential and sensitive data be removed before disposing of the media on which the data reside. Remember that simply deleting a file that contains the data may not be enough. Be sure to delete any copies of the files stored on backup media.

Backup procedures need to be implemented. All files servers need to be automatically backed up on a regularly scheduled basis. The backup media need to be kept on-site for immediate recovery. Copies of the backup media need to be kept off-site in case the on-site backups are compromised. Both sets of backups need to be tested and audited to ensure recovery.

Network Security

There are two major approaches to securing a local area network: host-based security and network-based security. Typically, both approaches are combined to provide multiple levels of security.

In host-based security, selected hosts are separately protected. This could range from installing antivirus software or personal firewalls on each computer in the network to installing a host-based intrusion detection system on each server. Minimally, every server should be protected with antivirus software and a personal firewall. If possible, the important servers should also be shielded by a host-based intrusion detection system.

Network-based security is equally important. Hardware-based security devices such as firewalls and intrusion detection devices can be placed at the perimeter of the network, typically inside the router, where they can monitor all traffic coming in and out of the local area network. Intrusion detection and intrusion protection devices can also be set up with agents installed on those hosts needing the most protection. These agents can then be monitored and managed from a central location. In more secure environments, there may be layers of network-based security both at the perimeter of the LAN as well as internal to the network. One layer of security is the placement of a firewall device (Figure 30) between the LAN (trusted network) and the outside (untrusted networks).

The network should be audited for illicit use of inappropriate software (e.g., sniffers and traffic monitors.) No unauthorized connections to the network should be permitted. This would include rogue wireless access points and modems connections.

Malware

Malware includes programs such as viruses and worms. To protect against most malware attacks, antivirus software needs to be installed on all servers and clients. It is imperative that this software be kept up to date on all computers. Most antivirus software vendors have proce-

Figure 30: Placement of a firewall.

dures for automatically updating the software. The auto-update feature should be configured to the shortest time that is tolerable by the users. All foreign media and all files downloaded from the Internet must be scanned for malware. The antivirus software needs to be running continuously. In addition to updating the antivirus software, it is mandatory that all operating systems and applications running on all computers in the network be patched. "Patching host software is probably the single most important thing companies can do to improve their security" [Panko, 2004]. Users should be trained in how to disconnect their device from the network in the event of a virus attack to isolate their host. One vulnerability in an operating system or application can destroy the entire network of computers.

Policy, Procedures, and Awareness

"Security is not a product, it's a process" [Schneier, 1999]. Using any security product without understanding what it does, and what it does not protect against, is a recipe for disaster. Keep in mind that added security features tend to increase the complexity of the system and may decrease the degree of usability of the systems. Usability needs to be balanced with the increased need for security.

Any organization implementing or using a LAN must have a well-documented security policy. The policy should incorporate physical security procedures, e-mail, Internet acceptable usage, and network usage procedures. The policy should include procedures for incident response and a LAN risk analysis. The policy should include a focus on software use to ensure compliance with license agreements. All unauthorized copies of software should be removed from workstations and servers. The policy needs to outline what additional response is necessary when unauthorized software is discovered.

The policy must include procedures for ensuring that all software is patched on a regular basis. This is especially important for all security software, including antivirus software and any intrusion detection and prevention software protecting the LAN and its resources.

As mentioned, audit logs need to be invoked. These logs should not only document successful and unsuccessful access to resources on the LAN but also should record any and all anomalies. These audit logs must be reviewed regularly with procedures in place for addressing any security alerts or identified anomalies. All attacks and breaches of security need to be investigated immediately and followed up with appropriate responses.

“The most potent tool in any security arsenal isn’t a powerful firewall or a sophisticated intrusion detection system. When it comes to security, knowledge is the most effective tool...” [Schweizer, 2003]. There needs to be a regular training program for administration and users. Administrators need to be trained on their responsibilities in managing the security of the LAN and its components. Regular security awareness sessions need to be scheduled and required for all employees, including training against social engineering attacks. An important policy is to train before deploying any component in the network.

CONCLUSION

Local area networks have played a very important role in providing computer access to large numbers of users. They have allowed users to share hardware, software, and, most importantly, data. They now also provide access to the Internet as well as organizations’ intranets and extranets. With the emergence of wireless local area networks, the applications of local area networks will continue to expand. It is imperative that we secure the local area networks to ensure confidentiality, integrity, and availability of the data stored and processed by the LAN.

GLOSSARY

Access Point A hardware device consisting of one or more antennae, a radio transmitter, and a wired network interface. Used as a bridge between a wireless network and a wired network.

Bridge A network device for connecting two or more local area networks that typically use different media but the same network protocol.

Bus Network A network where the nodes are connected to the same wire. Data are broadcast from one node to all other nodes in the LAN even though the data may be intended for only one node.

Ethernet A common data link layer protocol for networking computers in a LAN.

Extranet A private portion of the Internet treated as an extension of an organization’s intranet and allowing access to the organization’s data by the organization’s partners, customers, and so on.

Hub The central device in a star network for connecting multiple nodes to a network. It functions as a multipoint repeater.

Internet A worldwide collection of networks linked together and built around the TCP/IP suite of protocols. It was originally conceived in 1969 by the Advanced Research Projects Agency (ARPA) of the U.S. government.

Intranet An organization’s private internal network based on the TCP/IP suite of protocols.

Local Area Network (LAN) A data communication network of computers, peripheral devices and other network devices allowing data to be communicated at high speeds over short distances.

Logical Topology Based on how the devices of the network are electrically configured; also called electrical topology.

Network An interconnection of two or more computers or devices.

Network Interface Card (NIC) An adapter for connecting a computer or device to the network media.

Physical Topology Based on the way the nodes are physically configuration in the network.

Repeater A network device that retransmits the communication signal and is used for extending the radius of a network. It operates at the OSI physical layer.

Ring Network A network where the nodes are arranged in a closed loop where each device is connected directly to two adjacent devices.

Router A special-purpose network device that connects two or more networks at the OSI network layer.

Star Network The nodes are arranged so that each device is connected to a central device, typically a hub or a switch.

Switch A network device operating at the OSI data link layer that connects multiple network segments. It functions as a multiport bridge, allowing two devices to communicate only with each other at that moment.

Wide Area Network (WAN) A data communication network spanning geographically dispersed areas.

INTRODUCTION

In today's social, political, and economic environment, individuals and organizations communicate and operate over ever-increasing geographic distances. This means that access to and sharing of information and resources must extend beyond the "local" office, building, or campus out across cities, states, regions, nations, continents, and even beyond the planet. Bridging this diversity of distances in ways that satisfy application requirements for speed, capacity, quality, timeliness, and so on at reasonable cost is no simple task from either a technical or a business perspective. Additionally, increasing use of shared, public resources such as the Internet raises levels of concern over security. In this chapter we concentrate on the main elements required to meet such challenges in wide area and metropolitan area networks.

HISTORY AND CONTEXT

Definitions

The public networking arena has typically been divided into two segments with the following characteristics:

- Metropolitan area networks (MANs) are built and operated by service providers (SPs) who offer network services to subscribers for a fee, covering distances up to tens of miles, often within or surrounding a major city. MANs are often built by telecommunication companies, utility companies, or municipal agencies.
- Wide area networks (WANs) are built and operated by SPs who offer network services to subscribers for a fee, covering distances up to hundreds or thousands of miles, such as between cities, across or between countries, across oceans, and so on. WANs designed for voice are usually built by telecommunication companies. WANs for data are also called public data networks (PDNs).

Enterprises may choose to build private MANs and WANs instead of subscribing to public services. If it does not own its own cable or transmission facilities to all network locations, the enterprise can lease cable or transmission capacity from an SP but provides and operates all its own network equipment at the ends of each transmission link. Private networks may provide a higher degree of security when the traffic travels over dedicated cable or connections rather than through shared links or switching equipment.

Local area networks (LANs) are usually built and operated as private networks by individuals or enterprises for their own use. In addition, landlords may offer LAN services to tenants. In either case, the geographic scope of a LAN is typically limited to a building or campus environment, where all rights of way for cabling purposes belong to the individual/enterprise/landlord. The boundaries among LANs, MANs, and WANs began to blur as geographic limitations of networking technologies were extended with increasingly capable implementations over fiber optic cabling. Even the distinctions between private and public networks became more difficult to draw with the advent of "virtual private network" equipment and services.

Challenges

The number of options available to network designers in both the enterprise and SP communities continues to grow for both MANs and WANs. Multiple technologies and standards, increasing numbers and types of applications, higher expectations for MAN and WAN performance comparable to (or at least approaching) that found in a LAN environment, and pressure to keep unit costs low all combine to create enormous challenges for MAN and WAN builders. Infrastructure choices must last long enough, not just for cost recovery but also to achieve return on the investment. Designers must marry new

Figure 1: Connectivity.

technologies to their existing installed base, create smooth transitions (e.g., for network upgrades and new service rollouts) with minimal disruption to customer services, and add or enhance services to meet advancing customer expectations, all in an environment of economic and competitive pressure. Many SPs have begun to recognize that their long-term survival depends on a strategy of reducing the complexity (e.g., fewer technologies, fewer equipment vendors, fewer equipment types, and fewer management systems) of their infrastructure while maintaining the flexibility to adapt to changing application, user, and competitive requirements.

Functional Requirements

The basic function that subscribers seek from MAN and WAN providers is the ability to deliver traffic from one place to another (point-to-point) or to multiple others (multipoint). This begins with *connectivity*. For the network in Figure 1, traffic can flow from A to C and/or D but not to B. Once connectivity is established, the network must have sufficient *capacity* in bandwidth, switching, and routing to get the traffic from the source to its intended destination. Subscribers want services that are reliable, as measured by the percentage of time network resources are available when needed and by the amount of traffic (preferably none) that gets lost. Subscribers also want services that perform well enough so that their traffic gets delivered in a timely fashion, with minimal delay (low latency is particularly important for delay-sensitive traffic such as voice or video). Providers, conversely, want an infrastructure that is cost-effective, manageable, and capable of supporting revenue generation and profits. This especially includes adaptability to support a variety of new services as markets and technology develop.

Another characteristic of particular interest for subscriber traffic traversing shared resources in a public MAN/WAN (e.g., switches, transmission links, and storage) is security. Subscribers wishing to ensure data integrity and privacy can take responsibility for security by themselves implementing appropriate mechanisms (such as encryption) at their end points, or can contract with providers for security services.

Evolution and Coexistence

The first WANs were built from circuit-switched connections in the telephone system because that is what was available to cover the distances involved. Circuit switching continues to be useful, particularly when the computer devices being connected need to exchange messages in real time or with guaranteed delivery. For occasional traffic, dial-up connections similar to an individual telephone call are used. For continuous traffic or when applications cannot tolerate the delay involved in call setup, circuits are leased from a telephone company and “nailed up” into permanent connections that effectively become private as well as dedicated. For two connected locations the leased line is called a *point-to-point* connection (Figure 2a). More than two locations can be connected with a *multipoint* link (Figure 2b) if a sharing discipline is imposed to prevent traffic from one source interfering with traffic sent from another at the same time. With leased lines being dedicated to a particular subscriber, security is improved because traffic does not traverse any shared facilities among the SP’s public network resources.

Two devices connected by a leased line may or may not send traffic continuously, wasting capacity when the line is idle. If there are multiple devices in one location to be connected to one or more devices in a destination location, a single leased line may be shared using a device at each end of the line called a multiplexer. Statistical multiplexing allows more devices to be connected than the capacity of the line could support in real time if all were to transmit simultaneously. This is called oversubscription. On average, it is quite likely that only some devices will be active, and the line is shared effectively with little traffic delay and less wasted capacity. However, when many devices are active, performance can be degraded. The sending multiplexer adds a label to each unit of traffic transmitted; the receiver reads (and removes) the label to figure out which device is the intended recipient and switches the traffic onto the appropriate output link. Packet switching is a form of statistical multiplexing, sharing network resources as packets are forwarded to their destinations. Each shared element is a potential point of security risk where eavesdropping could occur or where packets could be misdirected to an unauthorized or unintended destination.

Originally, circuit switching was designed to carry analog voice traffic and packet switching was designed for digital data. Today, however, public networks convert all types

Figure 2: Connections.

of traffic into digital form for cost-effective transport. We could say that “bits are bits,” whether they belong to voice, data, video, or some other application (an oversimplification, as we shall see later). The same network might well be used to deliver multiple types of bits, instead of having distinct networks dedicated for voice, data, and so on. This is the concept of *convergence*, where a single network carries various types of traffic. In the context of convergence, the important question shifts from whether circuit or packet switching is better to what support a network must provide so that traffic delivery meets user expectations and application requirements. The concept of convergence is certainly not new. Early WANs transformed digital data into analog signals and used time-division multiplexing (TDM) to carry it over public networks that had been designed for voice. Today, convergence is based on statistical multiplexing and offers many more options for what traffic to combine and how to do it.

FACILITIES AND INFRASTRUCTURE

Digital Transmission

The heritage of digital WANs dates from the early 1960s, when the Bell System first introduced the T-carrier system of physical components to support transport of digital signals in the United States. The accompanying TDM digital signal scheme, called a digital hierarchy, was based on a standard 64-kilobits per second (Kbps) signal designed to carry one analog voice signal transformed by pulse-code modulation (PCM) into digital form. This basic unit is known as *DS0*. The International Telecommunication Union (ITU) now supports an entire set of digital signaling standards (Table 1), incorporating elements from the North American (United States/Canada), European, and Japanese standard hierarchies.

The traditional U.S. multiplexing hierarchy began with combining 24 DS0-level signals into one DS1. It is commonly called a *T1* stream and consists of a sequence of 24 channels combined to create 1 frame. Each channel is filled with 8 bits (an octet or byte) representing one PCM sample. A particular challenge of the time was to ensure synchronization between transmitter and receiver, which can be accomplished in several ways. For example, each frame could be introduced by a unique starting sequence

Table 1 Digital Signal Hierarchy

Designation	Capacity (Mbps)	Number of DS0s
DS1	1.544	24
E1	2.048	32
DS2	6.312	96
E2	8.448	128
J3	32.064	
E3	34.368	512
DS3	44.736	672
J4	97.728	
E4	139.264	2,048
DS4	274.176	4,032

Note: Abbreviations: DS, North America; E, Europe; J, Japan.

Table 2 Basic SONET Levels

Designation	Line Rate ^a	SDH Equivalent
OC-1	51.840 Mbps	
OC-3	155.250 Mbps	STM-1
OC-9	466.560 Mbps	STM-3
OC-12	622.080 Mbps	STM-4
OC-18	933.120 Mbps	STM-6
OC-24	1.24416 Gbps	STM-8
OC-36	1.86624 Gbps	STM-12
OC-48	2.48832 Gbps	STM-16
OC-96	4.97664 Gbps	STM-32
OC-192	9.95328 Gbps	STM-64

^a1Gbps = 1,000 Mbps; 1 Mbps = 10⁶ bits per second.

of 12 bits to allow receiver synchronization to be renewed on a frame-by-frame basis. The U.S. designers decided instead to distribute the 12 bits over 12 frames, reducing transmission overhead at the expense of receiver complexity. The 12-frame sequence was called a superframe. With improved hardware, synchronization is more easily maintained over longer periods, and an extended superframe (ESF) has replaced the superframe. ESF comprises 24 frames but needs only 6 bits for synchronization, freeing up 4 Kbps that have been used to improve management and control.

In the European scheme (also used by many other countries around the world), the basic *E1* stream aggregates 32 PCM channels. Rather than adding synchronization bits, E1 dedicates the first PCM channel for synchronization and the seventeenth for management and control signaling.

Optical Fiber Systems

Service providers first used digital multiplexing within their own networks (e.g., trunking between central offices) to improve the return on and extend the life of their copper cable infrastructure investments. By the 1980s, however, interest had shifted to fiber optics for longer distance, higher speed communications. Standards were defined for the Synchronous Optical NETWORK (SONET in the United States, equivalent to the Synchronous Digital Hierarchy, SDH, in Europe and elsewhere) to carry TDM traffic cost-effectively and reliably over metropolitan and wide area distances. Today SONET specifies both a standard optical interface signal and a digital signaling hierarchy tailored to the fiber transmission environment. The hierarchy is based on an 810-octet frame transmitted every 125 microseconds (μ s) to create synchronous transport signal-level 1 (STS-1) for electrical signals. Each octet is equivalent to a 64-Kbps PCM channel. For fiber transmission, the STS-1 equivalent is optical carrier-level 1 (OC-1). Higher level signals are formed from specific multiples of OC-1 (Table 2). Each SONET frame is structured into transport overhead and a synchronous payload envelope (SPE), which consists of both path overhead and payload. It is only the payload portion that carries subscriber traffic to be routed and delivered through the SONET network.

Figure 3: SONET Ring Survivability.

The major building blocks for SONET networks are the point-to-point multiplexer and, for point-to-multipoint configurations, the add-drop multiplexer (ADM). In particular, the ADM allows traffic to be dropped off and the resultant free capacity to be reused to carry traffic entering the network at that point. SONET ADMs can also be employed to create highly survivable networks that maximize availability using diverse routing and self-healing, survivable ring structures. Figure 3a shows a dual-ring structure where the network accommodates loss of a link by looping traffic back on each side of the break, and Figure 3b shows how loss of a network node can be handled similarly. SONET has been deployed extensively by service providers in metropolitan areas to create highly reliable and scalable transport capabilities. Once the fiber and switching equipment are in place, transport capacity can be increased by installing higher speed signaling interfaces.

Another approach to increasing the capacity of fiber systems has become available with advances in optical component technology. Rather than using the entire range of wavelengths that can be carried over fiber as a single transmission channel, newer equipment allows us to divide the range into multiple channels for simultaneous transmission using wavelength-division multiplexing (WDM). This is quite similar to sending multiple television channels over a coaxial cable. Channels must be spaced far enough apart to limit the interference between adjacent signals that would degrade signal quality. In *coarse* WDM (CWDM) the channels are widely spaced; for *dense* WDM (DWDM), they are very close together (spacing $\leq 25\text{--}50$ GHz). By combining WDM and high-speed signaling, transmission capacities of OC-192, OC-768, and greater become possible, limited primarily by the quality of existing fiber installations.

Access Technologies

To get traffic in and out of a MAN or WAN, subscribers must have physical connections, or *access*, to the appropriate SPs or enterprise network resources. In the regulated telecommunications environment of the United States, this typically means acquiring connectivity from a local exchange carrier (LEC) to tie the subscriber's physical premises to a WAN service provider's (i.e., interexchange carrier, IXC) equipment as physically located in a point of presence (POP). In a metropolitan area, a single company may be allowed to provide both local exchange connections and MAN services. The primary means of accessing MAN and WAN service provider networks are described below.

Dial-up access is appropriate for occasional connections of limited duration, as for making a telephone call. Where the physical facilities used for dial-up were designed and installed to support analog voice traffic, two characteristics are particularly important for data networking:

- Digital data must be converted to analog using a modem at the subscriber end and reconverted to digital by a modem at the provider end of the connection.
- Data rates are limited by the analog frequency range accepted at provider receiving equipment and by the signal modulation techniques of the modem devices. The most widely accepted standards today support maximum data rates of 56 Kbps.

Leased-line access is more appropriate for connections that need to be continuous and/or of better quality for higher speed transmission. Such facilities are dedicated to the use of a specific subscriber. For example, a business may lease a T1 access line as its basic unit of connection capacity (1.544 Mbps), particularly for access to Internet service providers. Fractional-T1 and multiple-T1 lines are also available in some areas. A newer technology designed to be digital from end to end over copper cabling, called digital subscriber line (DSL), is becoming more popular and prevalent as a lower cost alternative to the traditional T-carrier. Leased-line access requires matching equipment at each end of the line (subscriber and service provider) to ensure transmission quality suitable to the desired data rates.

Wireless access is growing in popularity, both for mobile individuals who do not work from a fixed location (e.g., salespeople, customer service representatives, and travelers) and for business connections to MAN or WAN resources (e.g., "first-mile/last-mile" alternative to cabled connections). From a data perspective, the IEEE has two groups focused on wireless access: the 802.16 working group published its WirelessMAN standard for broadband wireless access (BWA) to wireless MANs in April 2002 and the 802.20 mobile broadband wireless access (MBWA) working group, chartered in December 2002, is developing a packet interface optimized for transport of IP-based services.

The cellular industry is also working to improve wireless access beyond the low-speed data transport capabilities of second-generation (2G) technologies (e.g., cellular

modems or data cables connecting computers to cellular phones) with packet-switched, third-generation (3G) capabilities that grew out of an early effort by the ITU for international mobile telecommunications called IMT-2000. Unfortunately the international representatives were unable to agree on a single approach to creating such a standard and multiple technologies or modes of operation developed. IMT-2000 thus includes five different radio interfaces, some based on code-division multiple access (CDMA) and some on time-division multiple access (TDMA). These are taking hold in different areas of the world according to support by various telecommunication companies. For example, wideband CDMA (W-CDMA or universal mobile telecommunications system, UTMS) is popular for its ability to interoperate with the 2G standard called GSM (global system for mobile communications). However, in the United States the designated frequency spectrum has already been used for other services, so support for CDMA-2000 is more prevalent. Typical wireless access speeds are up to 144 Kbps for mobile users and 2 Mbps for fixed connections.

Wireless access methods depend on broadcasting signals through an open, shared medium, making user authentication and privacy of data major concerns. The IEEE has addressed these security issues through its 802.1x standard, based on the extensible authentication protocol (EAP) for both user authentication and encryption key exchange. Once a user is authenticated (e.g., by password, token, or digital certificate), keys are generated and exchanged for encrypting data transfers.

Cable modem access is typically provided by cable television companies who have expanded their business into data networking. A modem designed to transmit data signals over coaxial, broadband television cable is connected, usually via Ethernet technology, to the subscriber's internal network or computer equipment. In residential applications, subscribers in a neighborhood typically share data networking capacity on the aggregate cable that carries traffic back to their provider's central service location. This is different from a leased-line approach, where access capacity is dedicated from each subscriber location all the way to the provider's POP. Enterprise use of cable modem access is often supplemented by virtual private networking (VPN) technology to counteract the security risk of shared transport.

Cable modems in the Americas are predominantly based on the DOCSIS (data over cable service interface specification) standard from CableLabs, whereas in Europe DVB/DAVIC (digital video broadcasting/Digital Audio-Video Council) competes with a European version of DOCSIS (EuroDOCSIS). An important characteristic that distinguishes cable modems from most other access methods is the difference in bandwidth for traffic *from* the subscriber (typically 3 Mbps shared by all on the same cable leg) and *to* the subscriber (27–52 Mbps, again, shared).

Management

Management for MANs and WANs typically began with proprietary systems sold to service providers by each manufacturer of telecommunications switching equipment. Networks composed of equipment from multiple

vendors thus contained multiple management systems. Equipment management and service management functions are often tied together by an *operations support system* (OSS) to automate operations (e.g., performance monitoring), *administration* (e.g., ordering and billing), *maintenance* (e.g., diagnostics, fault detection, and isolation), and *provisioning* (OAM&P) functions. Many SPs tailored what they could acquire as a basic OSS to accommodate their own specific sets of equipment and services, making it difficult to share information, provide consistent management data in a multiprovider environment, and keep up to date with new functional requirements. This often leaves customers who need services from multiple providers without a single, coherent view of their enterprise WAN resources.

Beginning in 1988, the Telecommunication Standardization sector of the International Telecommunication Union (ITU-T, formerly the Consultative Committee on International Telephony and Telegraphy, CCITT) set about establishing the precepts for a standard *telecommunications management network* (TMN). Although the concept of a TMN encompasses the entire set of OAM&P applications in the network, what they do, and how they communicate, ITU-T standards focus on the information required and how it should be communicated rather than how it is processed (M.3000 recommendation series). Two types of telecommunications resources are encompassed: managed systems (such as a switch), which are called network elements (NE), and management systems, usually implemented as operations systems (OS). TMN standards are organized into interface specifications that define the interconnection relationships possible between resources. Figure 4 shows the relationship between the TMN and the telecommunication network for which it is responsible.

TMN is based on the open systems interconnection (OSI) management framework, using object-oriented

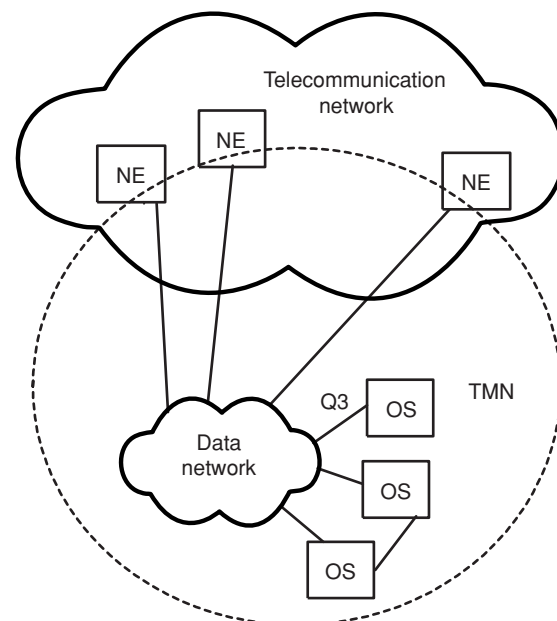

Figure 4: TMN and the Network It Manages.

Table 3 TMN Architecture

Logical Layer	Functional Responsibilities
Business management	Provides an enterprise view that incorporates high-level business planning and supports setting goals, establishing budgets, tracking financial metrics, and managing resources such as products and people.
Service management	Provides the basic contact point for customers (provisioning, billing and accounting, troubleshooting, quality monitoring, etc.) as well as for service providers and other administrative domains.
Network management	Provides an overall view of the network resources, end to end, based on the information from below about network elements and links. Coordinates activities at the network level and supports the functional requirements of service management.
Element management	Provides a view of individual network elements or groupings into subnetworks. Element managers (OSs) are responsible for subsets of all network elements, from the perspective of TMN-manageable information such as element data, event logs, activity, and so on. Mediation devices belong in this layer, communicating with OSs via the Q3 interface.
Network elements	Presents the TMN-manageable information of individual network resources (e.g., switches, routers, and Q-adapters).

principles and standard interfaces to define communication for purposes of managing the network. The primary interface specification, Q3, allows direct communication with an OS. Any network component that does not implement Q3 may not access an OS directly, but must go through a mediation device (MD) instead. Legacy equipment and systems that rely on proprietary ASCII messages for communication are accommodated by means of a Q-adaptor (QA) that can translate between messages representing the legacy information model and the object-oriented representation expected in today's TMN.

TMN defines a layered architecture (ITU-T standard M.3010) as a logical model for the functions involved in managing a telecommunication network effectively (Table 3). The object is to create a framework for interoperability across heterogeneous operation systems and telecommunication networks that is flexible, scalable, reliable, easy to enhance, and, ultimately, inexpensive to operate. Standard management services have been defined for alarm surveillance (Q.821), performance management (Q.822), traffic management (Q.823), ISDN Service Profile Management (Q.824), call detail recording (Q.825), and routing management (Q.826).

Despite the standards for TMN, an organization using multiple SPs cannot necessarily get a single, coherent view of their entire network because not all carriers implement all of the required network interfaces. Worse yet, if the network/network interface (NNI) specifically is not in place, data cannot even be transferred from one carrier's network to another.

Differences around the World

Creating and operating WANs or MANs in different countries may present challenges well beyond identifying a service provider and getting connections established. A particular type of service may not be available in the desired location, a single provider may not offer services in every location, or the capacity required may not be

available. Such differences may be because of telecommunication infrastructure of varying ages and technologies or different regulations on service offerings in various countries. For example, T1 service is readily available in most U.S. cities. Mexico, however, employs the European standard hierarchy and would thus offer E1 service. To communicate across such boundaries, a lower common-denominator service might need to be selected and the differences in capacity and framing would have to be handled appropriately by the network equipment at each end of the link.

In most countries, telecommunication is a regulated industry subject to many government-imposed rules, and there may be no or a limited choice of carriers. Some countries have begun to deregulate, resulting in multiple carriers competing for subscriber business, often creating more choices in technology and services, as well as better pricing. In either case, service availability may differ from one location to another: DSL access might be easily obtained in greater Boston but not available in a rural area; T1 service might be acquired readily in Singapore but perhaps not everywhere in New York City.

Do not make the mistake, however, of assuming that more highly developed areas or countries always have better service options than developing ones. An established metropolitan area experiencing rapid growth in demand for telecommunications may be less able to adapt or expand existing cable and switching capacity to meet new orders than a new suburban business park where there is plenty of room to install new cables and switches to provide higher speed services. Similarly, developing countries that have very little investment in old infrastructure may be able to skip generations of technology, installing the latest where there was previously none. Economics tend to dictate that this does not happen uniformly, but rather emphasizes locations more likely to provide rapid payback for the particular technology investment (e.g., urban rather than rural, business rather than residential, and high-density population areas). Often it is the access

infrastructure that lags behind, because the upgrade costs cannot be amortized across multiple subscribers the way backbone investments can. This is especially true where the end points are individuals with more limited budgets than business or organizational enterprises.

SWITCHING, ROUTING, AND SIGNALING Network Architecture

MANs and WANs are usually divided into three logical segments (Figure 5). *Access* typically includes the customer premises equipment (CPE) located in a subscriber's building or office area and the link that physically connects from there to the SP's point of presence. This link is connected to a device at the *edge* of the SP's network, and the edge device is connected to devices that compose the *core* (also called the backbone) of the SP's network. Different technologies are often used in the access and core portions, with the edge required to translate between the two. The ratio of the aggregate input capacity from all subscriber connections to an edge device to the output capacity from the edge into the core describes the degree of oversubscription. For example, if the sum of all access links is 200 Mbps and the core link is 100 Mbps, then the oversubscription ratio is 2:1. A ratio less than or equal to 1 is called nonblocking; the network performance for values greater than 1 depends on the bursty nature of data traffic to minimize the probability that traffic will be delayed excessively (by buffering) or discarded (when buffers become full).

Some form of packet switching is employed in most core data networks today. Various techniques are used to meet customer expectations for reliable, timely, and effective delivery of traffic to its intended destination. For example, a *virtual circuit* can be established to approximate the service characteristics available in a circuit-switching environment, such as guaranteed delivery of packets in the same order as they were transmitted. However, virtual circuits do not dedicate resources along the path from source to destination, so the network must have sufficient

intelligence to keep traffic moving well enough to meet subscriber expectations.

Choosing the best place to put network intelligence (at the edge or in the core) has been a subject of ongoing discussion among SPs for many years. For enterprises, however, the question becomes what intelligence performing which functions resides in their own equipment as opposed to what happens within the SP network. In particular, where security functions such as access control, encryption, or other firewall capabilities are handled may be important both to network performance and the user's degree of confidence in data protection.

Switching Technologies

In the OSI reference model, layer 2, the data link layer, is responsible for switching traffic point-to-point based on the layer 2 destination address (see the Routing Technologies section for layer 3 switching). However, much of the WAN switching technology for data networking was developed from experience with X.25, an ITU-T packet-switching protocol standard developed in the 1970s to support public data networking that is still in use today. X.25 creates a connection-oriented network out of packet-switching resources by employing virtual circuits to handle packet flow, keeping the data link layer simpler but requiring circuits to be established before packets can be sent. Circuits that are prebuilt from a source to a particular destination and then left in place are *permanent* virtual circuits (PVCs), whereas *switched* virtual circuits (SVCs) are established only on demand. SVCs are like dial-up connections, requiring circuit establishment to the specified destination for each call before traffic can flow, an end-to-end function beyond the capabilities of layer 2.

X.25 is a three-layer protocol suite (Figure 6). The OSI network layer equivalent is the Packet-Layer Protocol (PLP), which has operational modes for call establishment, data transfer, and call termination, plus idle and restarting operations. These functions are implemented through the services of a data link protocol called the Link Access Procedure, Balanced (LAPB), which is responsible for framing data and control commands and for basic

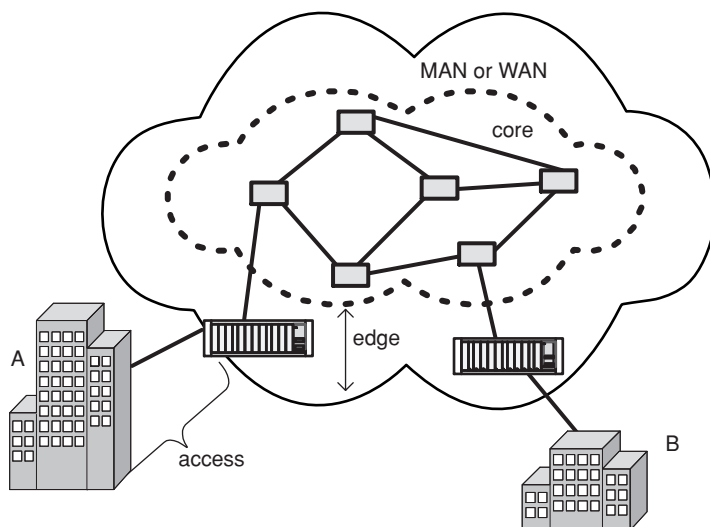

Figure 5: WAN/MAN Architecture.

OSI Reference Model	

Figure 6: X.25 Protocol Suite.

error checking through use of a frame-check sequence (Figure 7). During call establishment, the PLP sets up SVCs using X.121 standard addresses. These include the international data number (IDN), made up of a four-digit data network identification code (DNIC, to specify the packet-switching network containing the destination device) and a national terminal number (NTN) consisting of as many as 10 digits. The NTN specifies the exact destination device to which packets will be forwarded.

Frame relay is the most widely used packet-switching WAN technology. As WAN facilities became more reliable during the 1980s, interest rose in streamlining X.25 to improve performance and efficiency. The CCITT thus began work on frame relay (FR) in 1984. However, it was not until 1991, when several major telecommunication equipment manufacturers formed a consortium called the Frame Relay Forum (FRF) to work out interoperability issues and foster acceptance, that frame relay began to be more widely deployed. In particular, FRF defined extensions to the CCITT work called the local management interface (LMI) to improve SPs' abilities to provision and manage FR services.

Frame relay networks (Figure 8) are based on the concepts of data-terminal equipment (DTE) and data circuit-terminating equipment (DCE) first defined by X.25. Subscriber hosts, servers, workstations, personal computers, and terminals connected to an FR network are all considered to be DTE. The DCE is usually built as an interface into the SP's packet-switching equipment (PSE) rather than just being a modem at the edge of an X.25 network. Frame relay also uses virtual circuits to create a bidirectional communication path between a pair of DTE devices. FR virtual circuits are distinguished by data link connection identifiers (DLCIs), which may have local

Figure 8: Frame Relay Network Elements.

significance only, meaning that each end of a single virtual circuit could have a different DLCI assigned by the FR service provider.

The format for FR data combines LAPB's address and control fields into one 16-bit address field that contains the 10-bit DLCI, an extended addressing indicator bit (for future use), a command/response bit that is not used, and congestion control information. To minimize network overhead, the congestion control mechanisms are quite simple:

- One forward-explicit congestion notification (FECN) bit that tells a DTE that congestion occurred along the path in the direction *from* the source *to* the destination
- One backward-explicit congestion notification (BECN) bit that tells a DTE that congestion occurred along the path in the direction *opposite* to the transmission from the source to the destination
- One discard-eligibility (DE) bit to indicate whether this is a lower priority frame that may be discarded before others (those not marked DE) in a congested situation.

As a packet-switching technology, FR also depends on the bursty nature of data traffic to make efficient use of its transmission facilities for larger numbers of subscribers than could be served with physically dedicated connections. The ability to overbook resources is fundamental to a SP's business model, as well as being a benefit to subscribers, who may be able to insert traffic occasionally at a higher rate than nominal for their access link (called bursting). For enterprises that build private FR networks by leasing private lines and installing their own FR equipment at each end, bursty traffic means more users can be served with less capacity (as in statistical multiplexing).

Flag (frame delimiter)	Address (command or response indicator)	Control (frame type, sequence #, function)	DATA	FCS (frame check sequence)	Flag (frame delimiter)
1 byte	1 byte	1 byte	variable	2 bytes	1 byte

Figure 7: LAPB Frame Format.

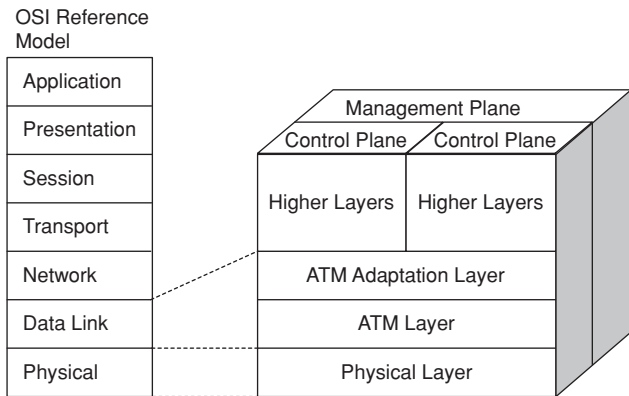

Figure 9: ATM Reference Model.

Integrated Services Digital Network (ISDN) is a set of telecommunication standards first developed from the perspective of telephony networks to accommodate multiple types of traffic such as voice, fax, data, alarm systems, video, and so on, all in digital format, over a single network. The goal was to develop standard interfaces, both for access and within the network, that would allow all types of digital traffic to be transported end to end, reliably, and in a timely fashion according to the needs of its application. The best known elements of ISDN are the user interface definitions for connecting subscriber equipment to the network: the primary rate interface (PRI), intended to replace T1 and E1 services, and the basic rate interface (BRI), designed with multiple channels for voice or data traffic from an individual subscriber.

Asynchronous Transfer Mode (ATM) was selected as the OSI layer 2 transport technology for broadband ISDN (B-ISDN) in 1988. It was designed to be useful across WAN, MAN, and LAN communications, as well as to accommodate multiple types of traffic in a single network (voice, data, video, etc.) and scale for very large networks. Other design goals included support a variety of media types (e.g., fiber and copper), leverage signaling standards already developed for other technologies, promote low-cost switching implementations (potentially one-tenth the cost of routing), adapt readily to future requirements, and enable new, large-scale applications. The challenges inherent in such a diverse set of goals brought together designers from many different backgrounds and resulted in a rather complex architecture (Figure 9).

Basically, ATM is a connection-oriented technology that switches fixed-length packets called *cells*. The 53-byte cell size (5 bytes of header information and 48 bytes for the payload) was chosen as a compromise between the optimal size for voice traffic and the larger size preferred for data applications. The fixed size and format mean that very fast cell switches can be built across a broad range of transmission rates, from megabits to gigabits per second and beyond. ATM interfaces are often characterized by their equivalent optical-carrier levels whether they employ fiber or copper media. The most popular interfaces tend to be OC-3, OC-12, and OC-48 (Table 2), according to their application in WANs, MANs, or LANs.

An important feature of ATM is the definition of service categories for traffic management:

- *Constant Bit Rate (CBR)* was designed to emulate traditional circuit-switched connections. It is characterized by minimum and maximum cell rates specified at the same, constant value. Typical CBR applications include uncompressed voice and video or television, all sensitive to both delay and delay variation.
- *Variable Bit Rate* real-time (VBR-rt) and non-real-time (VBR-nrt) are characterized by specified minimum and maximum cell rates, much like frame relay. Typical applications include compressed voice or video and multimedia e-mail. VBR-rt handles applications sensitive to delay variation, whereas VBR-nrt is suitable for bursty traffic.
- *Unspecified Bit Rate (UBR)* handles traffic on a best-effort basis, without guaranteeing delivery or any particular rate. This is used to carry data (such as store-and-forward e-mail) that is not sensitive to delay. In a highly congested network situation, UBR cells may be discarded so that the network can meet its traffic contracts for the other types.
- *Available Bit Rate (ABR)* is characterized by a guaranteed minimum cell rate but may offer additional bandwidth when network resources are available. Rate-based flow control provides the adjustment mechanism. When it is offered, ABR is often preferred for data traffic.

ATM's service categories are crucial to meeting user demands for *quality of service (QoS)*, which generally means guaranteed, timely delivery of traffic to match the needs of particular applications. An ATM end system will request a particular level of service for traffic entering the network, forming a traffic contract with the network. The ATM switches throughout the network are responsible for meeting the terms of the contract by traffic shaping (using queues to smooth out traffic flow) and by traffic policing to enforce the limits of the contract. The capabilities of ATM to provide QoS end to end across a network for multiple types of traffic simultaneously are the most sophisticated to date and distinguish ATM from other packet-switching technologies. Its suitability by design for LAN, MAN, and WAN applications made ATM especially popular with SPs, because they could use one technology throughout to manage their own infrastructure and to support a large variety of service offerings to their customers. For enterprise LANs, however, ATM has been superseded by higher speed versions of Ethernet.

Ethernet became the dominant LAN technology in the latter 1990s, as extensions from the original 10 Mbps were defined for 100 Mbps and then 1,000 Mbps (= 1 Gbps) and 10 Gbps, and shared media gave way to switched networks. As physical layer definitions for Ethernet over copper were supplemented by fiber standards, Ethernet became practical over longer distances. New communication companies with no telephony heritage began laying optical fiber and leasing capacity for short-haul (i.e., MAN) or long-haul (i.e., WAN) connections rather than selling services, as was typical in public networks. This meant that customers could specify the technology used to put bits on the medium rather than subscribing only to specific services offered by providers. As advances in optics and use of switching allowed Ethernet to cover

Figure 10: Routing within and between Autonomous Domains.

even greater distances, the geographic limits that distinguished LAN from MAN technologies began to disappear. In fact, new providers sprang up offering Ethernet connectivity from the business doorstep to other locations across town or beyond, taking Ethernet from the access layer right into the network core. The great competitive question was whether Ethernet MANs could be made as reliable and fault-tolerant as more traditional MAN/WAN technologies built over SONET.

Resilient Packet Ring (RPR) is an effort begun by the IEEE 802.17 working group in late 2000 to design a high-speed access protocol combining familiar Ethernet interfaces with the fault-tolerance and rapid restoration capability of ring-based MAN technologies like SONET. RPR defines a new medium access control (MAC sublayer of OSI layer 2) protocol that extends Ethernet framing from the LAN into the MAN/WAN environment. As seen by the RPR Alliance (an industry consortium designed to promote adoption of RPR), this approach combines the cost-effective scalability of Ethernet access interfaces with a MAN that can be optimized for rapidly increasing volumes of data traffic. Because it focuses on the MAC sublayer, RPR is independent of the underlying layer 1 technology, making it suitable to run over much of the MAN infrastructure already in place.

Routing Technologies

In the OSI reference model, routing takes place at layer 3, the network layer. Essentially routing consists of three major functions: maintaining information about the network environment, finding a path through the network from particular sources to destinations, and forwarding packets at each relay point. Layer 3 switching is a shortcut through the traditional OSI protocol stack that allows packets to be switched on the basis of their (layer 3) network destination address. The Internet protocol (IP) is the dominant method of interconnecting packet-switched networks (i.e., for internetworking) at layer 3. It provides connectionless network services (CLNS), with no guarantee of delivery or packet ordering, and is widely used

today for private and public LANs, MANs, and WANs, including the Internet. The IP is primarily concerned with the format for packets (also called datagrams), the definition and structure of addresses, a packet-forwarding algorithm, and the mechanisms for exchanging information about conditions in and control of the network.

Routing responsibility in an internetwork is divided between intradomain or interior routing protocols (IRPs) and interdomain or exterior routing protocols (ERPs) as shown in Figure 10. IRPs are used for internetworks that belong to a single administrative authority, such as an enterprise LAN, a single service provider's MAN, or a private WAN. ERPs are used when routers tie together networks belonging to multiple independent authorities, as in the Internet. These protocols differ in how much information is kept about the state of the network and how routing updates are performed using the mechanisms defined by IP.

IP version 4 (IPv4) was defined by the Internet Engineering Task Force (IETF) for the original ARPANet and published as (Request for Comments) RFC 791 in 1981. It specifies that each interface capable of originating or receiving internetwork traffic be identified by a unique 32-bit address consisting of an ordered pair containing a network identifier (net_ID) and a host/interface identifier (host_ID). Three primary classes of network addresses (A, B, and C) were designed to promote efficient routing, with additional classes defined for special or future uses (Figure 11). Although the Internet is not centrally managed, it was necessary to establish a single authority to assign addresses so that there would be no duplicates or conflicts.

As the Internet grew through the 1980s, a number of limitations in the design of IPv4 became apparent. The allocation of addresses, especially classes A and B, tended to be wasteful. For example, a single class B address assigned to one organization accommodates one network with over 64,000 IP interfaces—much larger than is practical or needed for most, meaning that a lot of address space can be wasted. Conversely, a single class C address accommodates only 255 interfaces, which is too small for most organizations, requiring them to have more than

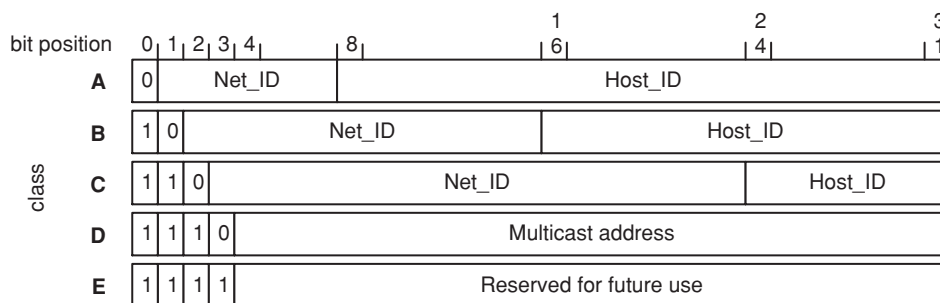

Figure 11: IPv4 Addressing Format.

one. From a routing perspective, the two-level hierarchical address structure means that routers need to keep track of over 16 million net_IDs just for class C networks, as well as calculate paths through the Internet to each one. A number of schemes were developed to solve some of the addressing and router problems (subnet masking, classless interdomain routing or CIDR), but those were not the only issues. Rising interest in using the Internet to carry voice, video, multimedia application, and commercial transaction traffic increased the demand for security and quality of service support, neither of which were built into IPv4. Consequently, the IETF began work on a new version, IP-ng, to handle the next generation.

IP version 6 (IPv6) represents that next generation of network layer services. It extends the addressing space from 32 to 128 bits, simplifies the packet header and allows for future expansion, and adds new capabilities to label flows of packets (same source to a single destination), to assign packets priority in support of QoS handling, and to provide authentication and security. Several of these features (CIDR, DiffServ, and IPsec) were designed so they could be added onto IPv4. In fact, such retrofitting solved IPv4 problems well enough in the late 1990s that people began to question whether a move to IPv6 was necessary. Upgrading the large numbers of routers involved with Internet traffic would be expensive, time consuming, and require careful coordination. Transition strategies and mechanisms would likely be needed over a considerable period of time. Unfortunately, retrofits cannot do much about the size of IPv4 addresses. Sufficient growth in the numbers and types of devices people want to connect to or through the Internet (e.g., handheld devices, household appliances, and automobile systems) and international pressure from countries without enough addresses will eventually make IPv4 addressing inadequate. The only question seems to be when.

Border Gateway Protocol (BGP) is the exterior routing protocol used by independent or autonomous systems (ASs) to exchange routing information throughout the Internet. Published in 1995 as RFC 1771, it defines procedures to establish *neighbor* relationships and to test the *reachability* of neighbors and other networks. A router at the edge of an AS uses BGP to work with adjacent (i.e., directly connected) routers in other ASs. Only after two routers (one in each AS) have agreed to become neighbors can they exchange routing information or relay traffic for each other's AS. Unlike IRPs, which use the services of IP to accomplish their communication, BGP uses the reliable

transport services of TCP (transmission control protocol, running over IP). In this way, BGP can be simpler because it depends on the error control functions of TCP and its messages are not limited in size by the constraints of an IP datagram.

BGP is purposefully designed to allow an AS to control what detail of internal information is made visible outside the AS (aggregating routes using CIDR, for example). Typically each BGP router screens potential routing updates or reachability advertisements against a configuration file that specifies what type of information it is allowed to send to each particular neighbor. This approach promotes policy-based routing, but at the expense of needing to calculate paths from incomplete detail about the network topology. Thus BGP will not always choose the optimal path across an internetwork to reach a particular destination. It does, however, allow a country or company constituting an AS to make appropriate political or business decisions about when and where to route its traffic.

Questions about the scalability of BGP have been raised in light of predictions for continued substantial growth in Internet traffic, and particularly as more organizations consider deploying delay-sensitive applications over the Internet (e.g., voice, video, and conferencing). Intelligent route control, virtual routing, and new approaches to traffic engineering are among the options being explored to solve performance problems before they become serious impediments to effective use of the Internet.

Multiprotocol Label Switching (MPLS) has been designed by the IETF to improve the performance of routed networks by layering a connection-oriented framework over an IP-based internetwork. MPLS requires edge routers to assign labels to traffic entering the network so that intermediate routers (called label switched routers, LSRs) can make forwarding decisions quickly, choosing the appropriate output port according to the packet's label and rewriting that label (which is intended to have local significance only) as necessary (Figure 12). MPLS represents a significant shortcut from the usual IP approach, where every relay node must look deeply into the packet header, search a routing table for the best match, and then select the best next hop toward the packet's destination. All packets with the same MPLS label will follow the same route through the network. In fact, MPLS is designed so that it can explicitly and flexibly allocate network resources to meet particular objectives such as

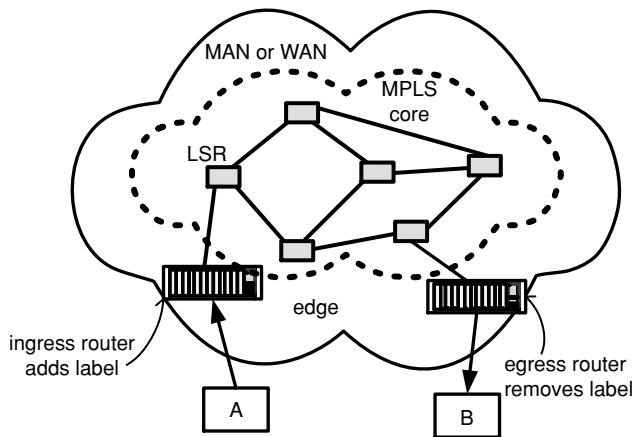

Figure 12: MPLS Architecture.

assigning fastest routes for delay-sensitive packet flows, underutilized routes to balance traffic better, or multiple routes between the same end points for flows with different requirements. This is called *traffic engineering* and serves as the foundation for both optimizing performance and supporting QoS guarantees.

Nothing about the MPLS design limits its use to the IP environment; it can work with suitably equipped ATM and frame relay routers as well. In fact, it can coexist with legacy routers not yet updated with MPLS capabilities, and it can be used in an internetwork that contains a mix of IP, ATM, and FR. Another powerful feature is the ability to stack labels on a last-in/first-out basis, with labels added or removed from the stack by each LSR as appropriate. This allows multiple label-switched paths to be aggregated into a tunnel over the common portion of their route for optimal switching and transport. MPLS is also a convenient mechanism to support virtual private networks, especially when multiple Internet SPs are involved along the path from one end to the other.

Signaling and Interworking

Connection-oriented networks require specific mechanisms for establishing a circuit (physical or virtual “connection” through which all traffic subsequently travels) prior to traffic flow and for terminating the circuit afterwards. In the circuit-switched telephony environment,

call setup and termination are part of a well-developed set of telecommunication system control functions referred to as *signaling*. MANs and WANs that were built for voice included signaling as an integral part of their designs, because resources were dedicated to each call as it was established and needed to be released after call completion.

The ITU-T began developing standards for digital telecommunication signaling in the mid-1960s; these have evolved into common channel interoffice signaling system 7 (CCIS7, known in the United States as Signaling System 7, or just SS7 for short), currently in use around the world. SS7 is an out-of-band mechanism, meaning that its messages do not travel across the same network resources as the conversations it was designed to establish and control. In fact, SS7 uses packet switching to deliver control messages and exchange data, not just for call setup, but also for special features such as looking up a toll-free number in a database to find out its real destination address, call tracing, and credit card approvals. Out-of-band delivery of the messages allows SS7 to be very fast in setting up calls, to avoid any congestion in the transport network, and also to provide signaling any time during a call.

In packet-switched MANs and WANs, signaling had been associated primarily with establishing and tearing down switched virtual circuits (SVCs) that required no further control during the data transfer phase. With a rising interest in multimedia communications (e.g., video and especially voice over IP, VoIP), however, the ITU-T quickly recognized a need for additional capabilities. Their *H.323* recommendations encompass an entire suite of protocols that cover all aspects of getting real-time audio and video signals into packet form, signaling for call control, and negotiation to ensure compatibility among sources, destinations, and the network. *H.323* takes advantage of prior ITU work (such as ISDN’s Q.931 signaling protocol) and defines four major elements (Figure 13):

1. *Terminals* are the end-user devices that originate and receive multimedia traffic.
2. *Gateways* primarily handle protocol conversions for participating non-*H.323* terminals, as would be found in the public switched telephone network (PSTN).
3. *Gatekeepers* are responsible for address translation, call control services, and bandwidth management.

Figure 13: H.323 Network Elements.

4. *Multipoint Control Units* (MCUs) provide multiconferencing among three or more terminals and gateways.

The IETF took a simpler approach to signaling with the *session initiation protocol* (SIP), which was designed as a lightweight protocol simply to initiate sessions between users. SIP borrows a great deal from the hypertext transfer protocol (HTTP), using many of the same header fields, encoding rules, error codes, and authentication methods to exchange text messages. Like H.323, SIP assumes that the end-point devices (i.e., terminals) are intelligent, running software known as the user agent. The agent has two components: the *User Agent Client*, which is responsible for initiating all outgoing calls, and the *User Agent Server*, which answers incoming calls. In the network itself, SIP provides support with three types of servers:

1. *Registration* servers keep track of where all users are located.
2. *Proxy* servers receive requests and forward them along to the next appropriate hop in the network.
3. *Redirect* servers also receive requests and determine the next hop, but rather than forwarding the request, they return the next-hop server address to the requester.

An alternative approach to multimedia communication control developed by the IETF is called the media gateway control protocol (MGCP). It is quite different from H.323 and SIP because it assumes that the end-user devices are not very intelligent. Consequently MGCP takes a central server approach to communication coordination and control. Two elements are defined: the *Media Gateway Controller* (also known as the call agent), which provides the central intelligence and controls all of the *Media Gateways*, which perform a variety of interface functions such as with the PSTN, residential devices, business private branch exchanges (PBXs), and so on. MGCP defines the communication that takes place between the call agent and the Gateways that execute its commands.

In practice H.323, SIP, and MGCP will likely coexist to support multimedia communication in the Internet environment because each has advantages for specific applications or coverage. MGCP is particularly useful to MAN/WAN service providers with large installed bases of unintelligent end-point devices, and its gateway approach allows for tailored interfaces to each different underlying technology. The simplicity of SIP is more attractive to enterprise networks designed primarily for data traffic with smaller requirements for supporting voice and video. Finally, H.323 is the most mature and most comprehensive. As usual in the telecommunication industry, vendor support and suitability to customer business models are likely to determine which, if any, one approach becomes dominant.

PROVIDERS AND SERVICES

Carriers and Service Providers

The public provision of telecommunication services to subscribers for a fee has a history of being government

regulated in most parts of the world (the term *common carrier*, for example, dates back to public transportation for people, first by stagecoach, then by trains, buses, etc.). Regulation was required because access to telecommunication services depended on cabling that was run from subscriber premises (residential or business) across public property (e.g., along roads) to a provider's central office as a service point. Governments could also impose standards to ensure that services offered by providers in different locations would be compatible enough to interoperate. In some countries, infrastructure was built and services operated by the government itself (e.g., PTTs that provided postal, telegraph, and telephone services nationwide). In the United States, telephone industry regulation was divided between LECs, whose cabling and local services go to individual premises, and IXC, who provided the interconnection (i.e., long-distance services) between LECs.

The Internet as a means of public data communication has grown up rather differently, driven largely by the U.S. regulatory environment, where telecommunication companies were prohibited from providing unregulated data services (e.g., participation in the Internet). Consequently, a new type of company called an Internet service provider (ISP) was born. Data would move from a subscriber's premises across cables belonging to an LEC to ISP equipment in a point of presence, where it was transferred onto Internet resources. The subscriber thus had to be a customer of both the LEC and the ISP unless a private (non-LEC) link could be installed directly to the ISP's POP. The Internet connections from one ISP location to another are most often lines leased from an IXC. As telecommunication services have been increasingly deregulated worldwide, the distinctions among voice and data service providers have become blurred.

It is important to remember that "the Internet" is not really a single entity but rather an interconnected set of autonomous networks whose owners have agreed to cooperate and use a common set of standards to ensure interoperability. *Peering* is a form of interconnection where ISPs agree to exchange traffic for their respective customers, based on a specific set of business terms. Peering points are where the networks actually connect to effect this exchange. The number and location of peering points and partners is decided by each ISP according to customer demand and its own business criteria. Subscribers may need to be aware of these agreements to understand fully the performance they can expect end to end across the Internet. Multiple providers may also influence a subscriber's choice of security mechanisms.

Just as the background and emphasis of traditional voice and traditional data SPs differ, so do their business models and their choices of technology. Some offer only transport for traffic, either between subscriber sites or to the Internet. Others offer access to applications or management services. Local telecommunication carriers tend to offer MAN services over an ATM and SONET infrastructure, whereas data providers would be more likely to offer IP services or simply Ethernet access and transport. Cable television and wireless SPs also offer access services according to the characteristics of their infrastructure

technologies. The options available will likely continue to grow as technology progresses.

Class of Service, Quality of Service

As interest in carrying multimedia or multiple-service traffic (i.e., voice, data, video) over MANs and WANs has grown, managing the traffic to provide performance appropriate to each application has become more important. Quality-of-service techniques are expected to guarantee performance and delivery, usually in terms of bandwidth allocation, timeliness of delivery, and minimal variation in delay (e.g., ATM service categories). Class-of-service (CoS) techniques do not make such guarantees, but rather attempt to meet user requests on a best-effort basis. Typically CoS works by grouping together traffic with similar requirements (e.g., voice or streaming video) and using a priority queuing system so that switches and routers forward the traffic accordingly. Connectionless network services such as IP offer CoS traffic management, whereas connection-oriented services such as ATM provide QoS.

QoS cannot really be guaranteed unless it is available all the way from end to end of the connection. This creates a challenge for MAN and WAN environments where multiple technologies from one or more SPs may be involved in delivering user traffic and especially when the traffic originates or terminates in a LAN of yet another different technology. Several groups are involved in developing standard techniques for CoS and QoS. The problem is making sure that appropriate translation mechanisms can carry user application requirements across network and SP boundaries:

- IEEE 802.1p is a layer 2 tagging mechanism to specify priority using three bits in the layer 2 frame header.
- IETF's differentiated services (DiffServ) indicates how packets are to be forwarded using per-hop behavior (PHB) queuing or discarding if there is not sufficient bandwidth to meet performance requirements.
- ATM traffic management defines service categories and traffic classes.

Data flows may need to be mapped across mechanisms multiple times as they travel from edge to core to edge.

Virtual Private Networks

A virtual private network (VPN) is a special service that amounts to establishing a closed user group capability over a shared or public network infrastructure. This means that access is restricted to authorized users only; traffic belonging within the VPN does not get out or become visible to unauthorized users, and outside traffic does not get in. Additional mechanisms may be needed to assure data privacy, such as use of IP security (IPsec) or secure sockets layer (SSL). VPNs are becoming a very attractive way for organizations to reduce the cost of private WANs while improving the security for traffic that travels over public networks. Where high-speed MAN and

WAN services are available, long-distance performance can even be kept reasonably close to what the remote users would experience if they were directly connected to the LAN. VPNs may also be built to send traffic across the Internet, with one or more SPs providing the access links between the Internet and various geographically dispersed customer sites. Internet VPNs can be significantly less expensive than the private lines or networks they replace.

Management and Security

The OSI model for network management encompasses five functional areas: configuration management, performance management, fault management, accounting management, and security management. A MAN or WAN service provider must cover these both from the perspective of operating the entire network effectively and balancing the needs and expectations of paying customers who could always choose to take their business elsewhere. Operation must be reliable, there must be sufficient capacity to meet traffic needs and performance expectations, and privacy must be maintained not only for the content of the traffic carried but also for data about the customers. At the same time, subscribers typically want the ability to manage the performance and flow of their own traffic through their allotment of SP resources. SP operation systems must be capable and sophisticated to meet all these requirements.

A primary mechanism used to establish and manage expectations between customers and providers is the *service level agreement* (SLA). SLAs are the defining documents (contracts) that spell out what services and levels of support will be provided to the customer at a specified price. Successful SLAs are built on a solid, shared understanding of business priorities and service impact for both the service user and the service provider. Detail about roles and responsibilities, metrics and reporting, added cost for incremental services or enhancements, escalation procedures, and change management are just some of what should be covered in an SLA. Many customers also build in penalties in case the SP fails to deliver services at the level specified in the SLA. This may be necessary legally to protect the service user's interests, but it is important to remember that failure of the provider to deliver service typically means that the user has failed to meet a business requirement as well. Consequently it is in both the customer's and SP's best interests if the penalty clause is never invoked.

CONCLUSION

The boundaries among local area, metropolitan area, and wide area networks have become less clear over time, because of the increasing variety of implementation choices available to network designers. For MANs and WANs in particular, classifying equipment, services, and management responsibilities by architectural category (access, edge, and core) may help to distinguish among options so that choices can be made in alignment with the business priorities of each designer's organization. Flexibility to accommodate change and growth, reliable service delivery,

and optimal cost/performance ratios are the major characteristics typically desired for every network design. The tension between network users wishing to maximize cost-effectiveness and service providers trying to maximize profit continues to work with technological developments to create opportunity for new business approaches. The primary challenge always seems to lie in balancing expensive, long-term infrastructure investments with new technologies and services that meet changing application requirements.

GLOSSARY

Circuit A complete connection between a source and destination for the purposes of transferring information (i.e., for communication).

Circuit Switching A *connection-oriented* approach to networking where the entire path from source to destination is determined and sufficient resources are allocated along the path to carry the traffic before any traffic can flow.

Local Area Network (LAN) A network covering a single office, building, or campus that is built and operated as a private network, by an individual or organization, for his/her/its own use.

Metropolitan Area Network (MAN) A network covering distances up to tens of miles, often within or surrounding a major city. Public MANs are built and operated by service providers who offer network services to subscribers for a fee.

Packet A portion of a message to be carried from a source to a destination.

Packet Switching A *connectionless* networking approach where each packet is routed through the network independently.

Private Network A network built, owned, and operated by a single individual or organization for his/her/its own use.

Public Network A network built to offer resources or services to a set of subscribers who are typically independent from each other and from the owner of the network. Most people think of the Internet as the only truly "public" network.

Routing Determining where a packet should go next to get it closer to its intended destination (i.e., deciding what is the next hop along the path).

Service Provider (SP) Builds and/or operates a network for the purpose of selling capacity or services to subscribers for a fee.

Service User Subscriber to the offerings of a public network.

Switching Placing a packet on the appropriate transport mechanism to get it to the network device representing the next hop.

Wide Area Network (WAN) A network covering distances up to hundreds or thousands of miles, such as between cities, across or between countries, across oceans, and so on. Public WAN facilities are built and operated by service providers who offer network capacity or services to subscribers for a fee. Private WANs are built by organizations for their own use.

INTRODUCTION

Home area networks (HANs) facilitate communication among appliances, home systems, entertainment products, and information devices in a home so that they can work cooperatively and share information. A device connected to an HAN gains the capabilities of other networked devices, and as a result the device can provide a service or function that it would have otherwise been incapable of providing alone (CEA, 2004). Several factors are pushing for the development and adoption of HANs. These include the advancement in telecommunications technologies, the wide proliferation of personal computers, the decreasing costs of smart devices that allow users to control and monitor events in consumer-based appliances, and consumer demand for content rich applications.

HANs enable users to get information about the home's condition, to remotely control home systems and appliances, and to gain access to information and entertainment resources both from inside (such as a computer hard drive) and outside the home (for instance, from the Internet) (Bose, 2001). To provide these benefits to home consumers, different devices of the home network must be able to communicate with each other to provide services despite their implementation differences. This requires the management and coordination of discovery methods that work across heterogeneous device technologies and complex home networking architectures. To achieve this management and coordination transparently without user intervention is a complex task that until now has been the major factor responsible for impeding the wide acceptance and delivery of advanced services into the home. A common solution is to exploit a central connection point often referred to as a residential gateway. The residential gateway acts as a "bridge" between the wide area network (e.g., Internet) and the home network as illustrated in Figure 1. The gateway provides users access to home devices and control over the contents and leverages two technological trends, namely the ubiquity of broadband connectivity and Internet access in homes, offices,

vehicles, and mobile/portable devices and the emergence of new applications and services. As Figure 1 illustrates, the residential gateway provides a central coordination connection point for different heterogeneous communication technologies such as Jini and UPnP using physical Ethernet or IEEE 802.11 network connectivity (Marples & Kriens, 2001).

In this chapter, we discuss the design and implementation of such a residential gateway based on the Open Services Gateway Initiative (OSGi) (Gong, 2001; OSGi Forum, 2004). We place special emphasis on the development of an architecture that enables seamless interoperability among different device technologies by exploiting the OSGi architecture.

RELATED WORK AND NOVELTY OF CONTRIBUTION

Related Work

The OSGi expert group (OSGi Forum, 2004) is currently focusing on the development of drivers for all possible and probable protocols to be used in home networks. Saif, Gordon, and Greaves (2001) discussed the design and implementation of a residential gateway in the context of the AutoHan project. Dobrev et al. (2002) proposed a framework to extend the OSGi framework to enable redefining gateway services and to provide a smart querying technique for users and devices to look up services with particular attributes. The authors also addressed the interoperability feature and proposed implementing it through the extension of OSGi services. Wils et al. (2002) discussed the integration of Universal Plug and Play (UPnP) (UPnP Forum, 2004) and Jini (Sun Microsystems 2004 a, 2004b) with the OSGi framework.

Novelty of Contribution

As mentioned previously, one of the main goals of this work is to investigate the *interoperability* feature of OSGi by design and implementation. In doing so, our proposed

Figure 1: Remote Internet access to a heterogeneous home area network via an OSGi-based residential gateway.

design architecture enables different devices using different technologies (e.g., UPnP and Jini) to seamlessly operate with each other to provide services to home network users. In this work, we focus on OSGi to provide this capability and in this context this work differs from Saif and colleagues who do not use OSGi in their architectural design. In contrast to Wils and colleagues' work that merely proposed support for OSGi-Jini services and OSGi-UPnP services, our work *unifies* Jini and UPnP, and we demonstrate the seamless communication between Jini and UPnP via actual implementations of Jini and UPnP drivers within the OSGi framework. In contrast to other previous works, our implementation also deals with the security issues involved during remote Internet access to an HAN.

SECURITY IN HOME AREA NETWORKS

One of the main concerns for HAN users is the need to create and maintain a secure working environment. Two distinct approaches in addressing the security issues include *security prevention* and *security detection*. An example of *security prevention* would be a firewall device that restricts specific traffic/ports to or from specific hosts. Although this provides protection against unauthorized traffic, it has no means to determine if an attack is being attempted via some authorized port. An example of *security detection* could be an intrusion detection system (IDS) device that contains a signature to identify a specific attack via authorized or unauthorized ports. Different security services (authentication, confidentiality, integrity, access control, and possibly nonrepudiation) need to be provided to different players (e.g., end user, operator, and service provider). Furthermore, the nature of the network infrastructure technology has an impact on the security of the entire system. Certain network infrastructure technologies are inherently more secure than others. Similarly, the security mechanisms incorporated within certain communication protocols are more sophisticated than those in others. The two network infrastructure categories include infrastructure technologies and communication protocols used to interconnect the various

devices within the home network and infrastructure technologies and communication protocols used to *interconnect a home area network to a wide area network (WAN)*.

Securing Networked Devices within the HAN

Session Initiation Protocol Security Applied to Networked Appliances

The session initiation protocol (SIP) (Handley, Schulzrinne, Schooler, & Rosenberg, 1999) provides simple application layer signalling for setting up, maintaining, and terminating multimedia sessions such as voice calls, videoconferences, and instant messaging sessions. SIP can also be used between the external access device and the residential gateway and can be used for naming, addressing, routing of messages, and for secure access to HAN-based networked appliances. SIP leverages the standard SIP capabilities to communicate directly with appliances even when they are behind firewalls, as compared to NATs or other entities that prevent direct end-to-end communication. The primary advantage of using SIP for networked appliances is its ability to provide connectivity across a WAN. For general SIP security some form of public key (Galvin & Murphy, 1995) technology must be employed to provide security. In the case of remote access to devices and appliances within the home, however, shared secrets (Algesheimer, Camenisch, & Shoup, 2002) can be used to provide privacy and authentication. In this case, a one-to-one (or few-to-one) correspondence exists between authorized users and the home area network devices with which they will be communicating. Users will have the opportunity to designate a shared secret (Handley, Schulzrinne, Schooler, & Rosenberg, 1999) for use in their communication with the HAN devices. The secret may be shared either with the home residential gateway or firewall in the case where the user directly communicates with the home devices. In general, secret key methods are preferable to public key because of their higher level of security and increased efficiency. SIP describes two methods of achieving privacy: by

encrypting either *end-to-end* or on a *hop-by-hop* basis. In the case of remote access to an HAN, end-to-end encryption is more efficient when the home user and the home residential gateway/firewall (or service provider proxy) share a secret key.

Securing HAN Devices

An HAN typically has many devices on the network, some belonging to the entire household and others belonging to individuals within the home. The security domain for HANs can be defined as a set of objects (a user can also be an object) that are allowed to interact with each other. However, a security policy is the specification of how objects in a security domain are allowed to interact. The security policy and domain taken together can be used to control and administer privileges to the various HAN devices. For example, a networked home alarm system might be in a security domain with one particular control application on the family personal computer that can only be accessed by one user (such as the head of the family). Other family members or other applications on that computer would not be allowed access to it.

To ensure that actions and access to devices residing on the home network have the proper authorizations, we can support device authentication using various key distribution mechanisms (Ellison, 2004; Strategis, 2001):

- **Passwords:** Since passwords are used for authentication, similar to keys, they are considered as part of the key distribution mechanism. Most often passwords are converted by algorithms to cryptographic keys. The disadvantage of password is that, if it is too simple, then it is easy to crack the password. But if the password is complex people tend to have a tendency to write it down and therefore it is subject to being leaked.
- **DES, AES, or WEP keys:** There are symmetric encryption algorithms, such as Data Encryption Standard (DES) and Advanced Encryption Standard (AES), and protocols using symmetric algorithms, such as wired equivalent privacy (WEP). The keys for these algorithms and protocols are similar to passwords in that both ends of a communication need to know the key. These are typically expressed in hexadecimal digits and have the advantage that they can carry more entropy (information) than a typical password but have the disadvantage that they are not memorable. They must therefore be written down, which makes them potentially available to someone other than the user although not to attackers on the Internet.
- **Public Keys:** Public key (PK) cryptography differs from symmetric key cryptography in that one encrypts with a different key from the one used to decrypt. It is also a characteristic of PK systems that one key, called the private key, can easily be used to generate the other key, called the PK, but the reverse is not true. As only the PK is made available, this is a more secure method.
- **PKI:** A traditional public key infrastructure (PKI) is a mapping from names to PKs and the mapping being created by some trusted third party (usually called a certification authority or CA).

Once a user or device has been authenticated the next step is to identify the privileges that the device or user has been granted (Bergstrom, Driscoll, & Kimball, 2001). This is important as different users may have different privileges for different devices. Some of the main authorization mechanisms (Ellison, 2004) include the following:

- **Access Control List (ACL):** An ACL (one per device) is a protected table residing in memory in the same device as the resource whose access is being protected. Access to a device can be controlled by using just the ACL. It is an array of entries, and each entry contains the following: subject (an identifier of the entity being granted access), authorization (an indicator of the rights being granted that subject), delegation (a flag, indicating whether the subject may further delegate these rights), and validity (optional conditions on validity of the entry, such as a “not-after” date and time). The disadvantages are that ACL need time and space because of editing if the number of ACLs or subjects is large. ACLs also require persistent storage as they must survive a power failure.
- **Authorization Server (Strategis, 2001):** In the case of a large number of devices, all of which need the same ACL, if that ACL is large because of many entries, and if network costs are low, then it might make sense to move the ACL from each local machine to a server, often called an authorization server. This does not eliminate the need for an ACL in each device. The device needs an ACL listing the authorization server. That ACL, in effect, grants all access rights to the server and allows it to delegate rights to others. Even though each device needs an ACL, there might still be advantages to using a server because the ACL in each device is very small (one entry) and should rarely have to change. But this system is unlikely to find acceptance in HANs, as it is very complex implement. We can delete this section as it does not seem very viable for HANs and is in more line with the corporate environment.
- **Authorization Certificate:** This is a digitally signed ACL used to administer authorization. A subject listed in the device ACL might be given the right to delegate some set of permissions.

Securing the Interconnection between the HAN and the WAN Using Addressing and Firewall

Private Addressing

Private addressing can be used to secure devices and communication protocols within the HAN. Private IPv4 addresses may be assigned to devices within an HAN to cope with limited IPv4 address space. Because assignment of private IP addresses comes with no extra cost to the user, it is attractive from a pricing perspective as well. A clear division of public and private hosts and the resulting need to renumber makes uncontrolled outside connectivity difficult.

When a device within the HAN needs to communicate with a device that is outside the HAN, we can

adopt one of following two possible approaches for addressing:

1. **Network Address Translators (NATs)** (Sengodan & Ziegler, 2001): NATs residing at the boundary of the home area network replace the private IP address with a public address when the packet leaves the home network and vice versa.
2. **Realm-Specific IP (RSIP)** (Borella, 1999): A realm-specific IP implementation involves the creation of servers and clients running the realm-specific IP (RSIP) protocol. RSIP is a new protocol developed (as an alternative to the NAT), with the additional requirement to preserve end-to-end packet integrity. RSIP enables an enterprise to keep many private Internet addresses behind a single public Internet address. RSIP functions by leasing public IP addresses and ports to RSIP hosts located in private addressing domains. The RSIP client requests registration with an RSIP server or gateway. The server in turn delivers either a unique public IP address or a shared public IP address and a unique set of transfer control protocol/user datagram protocol (TCP/UDP) ports and attach the RSIP host's private address to this public address. The RSIP host uses this public address to send packets to public destinations. The packets contain both the public and private addresses, and the RSIP server strips off the private address header and sends the packet on with a public IP header.

Firewall

A firewall for a HAN requires access to all traffic into and out of the HAN. The firewall monitors the flow of data, regulating traffic between the HAN and the Internet. It uses a set of packet filtering rules that specify traffic that should be permitted or denied. But a firewall cannot protect devices that bypass the firewall's protection. Devices on the HAN that access the external world (using a modem, wireless adapter, Ethernet over power line, or broadband connector) all require the protection of a firewall and should not set up connections to the Internet that bypass the firewall. Typically, firewalls can be classified in the following categories:

- **Packet Filters** (Pike, 2002; Sengodan & Ziegler, 2001): There are of two kinds – *static* packet filters (Cheswick & Bellovin, 1996) and *stateful* packet filters (Bosworth & Kabay, 2002). Static packet filters have a static configuration based on which packets are either granted or denied access. They do not maintain any state about the session and handle packets on a per-packet basis. Stateful packet filters maintain information on session state, and based on this information, packets may dynamically be granted or denied access. The nondynamic nature of static packet filters makes them unsuitable for home networks because of the typical dynamic nature of port assignment for several home network sessions. Stateful packet filters are neither adequate nor economically feasible, and the performance requirements are too high for a low-end single-point-of-access gateway. Unfortunately,

it is difficult for the average consumer to correctly administer policies at the packet level. Firewall configuration requires detailed information about the communication characteristics of applications—information that is not apparent to most consumers. In addition, new applications may be installed that change the communication characteristics of the home and require an update to the packet-filtering rules. Some home PC firewalls address the packet-filtering configuration problem by generating an alarm that asks the user for approval to allow the communication. This works well for a single machine, but when there is a central firewall on the home gateway, there is no standard way to reflect the firewall activity back to the application initiating the activity.

- **Circuit Gateways** (Cheswick & Bellovin, 1994): The most common circuit gateway is SOCKS. SOCKS is a networking proxy protocol that enables hosts on one side of a SOCKS server to gain full access to hosts on the other side of the SOCKS server without requiring direct IP reachability. SOCKS are often used as a network firewall, redirecting connection requests from hosts on opposite sides of a SOCKS server. The SOCKS server authenticates and authorizes requests, establishes a proxy connection, and relays data between hosts. A SOCKS server normally resides at the edge of the HAN. The SOCKS server establishes a TCP connection (or circuit) to each of the communicating endpoints and relays the session data. The SOCKS client within the HAN authenticates the establishment of such a virtual circuit. However, the complexity associated with this mechanism, and its dependence on TCP (and therefore not possible for UDP traffic), make it unsuitable for home networking solutions.
- **Application-Level Gateways** (Oppliger, 2002): Application-level gateways (also known as proxies) operate by being aware of the application. Although this approach can be very secure, it is not scalable because such a solution would require that each application require a proxy at the edge of the home network. In addition, this is an expensive solution.

Based on the previous observations, it can be seen that traditional firewall solutions are unsuitable for home networks, and novel security solutions are needed for HANs. One such new technique that shows great promise is based on the concept of a firewall control interface (Mercer, Molitor, & Hurry, 1999) between a device within the home network and the firewall. This interface provides the gateway the ability to manage the firewall, opening specific TCP permissions for well-known or registered ports, in support of VoIP services and applications, and opening only the negotiated TCP and UDP port permissions necessary to allow relevant applications. A firewall control interface opens a single "pinhole" in the firewall implemented by a filtering device. The application logic remains in the end systems and requests are made over a secure channel to the firewall to open and close pinholes and to manipulate or read NAT table entries. This allows the use of both encrypted signaling traffic and address translated endpoints.

A combination of the authorization mechanisms along with firewall solutions can be used to guard against malicious attacks.

DESIGN AND IMPLEMENTATION OF AN OSGI-BASED RESIDENTIAL GATEWAY

The complex diversity of home networking architectures and device technologies need to be coordinated to enable home users to fully exploit and reap their benefits. As mentioned earlier, management of these network architectures and services frequently burden most homeowners and is one of the main reasons impeding the proliferation and acceptance of sophisticated networking services into the home (Dobrev et al., 2002). The advent of OSGi simplifies management of home networks composed of multiple heterogeneous communication technologies. It is worthwhile noting that OSGi specification provides only the application programming interface (API) rather than the underlying implementation making OSGi-based gateways both platform and application independent. This independence gives considerable freedom and flexibility to application developers and designers in their service offerings. The OSGi service platform benefits also include security, service collaboration, and multiple network support (OSGi Forum, 2004). In this work, we focus on the capability of OSGi to provide *multiple network support*. OSGi specifies a framework (similar in functionality to an application server) where it is possible to dynamically load and manage software components also known as *service bundles* (Marples & Kriens, 2001). These bundles can be instantiated by OSGi to implement specific services required.

Integration of Discovery Technologies in OSGi

In recent years, several architectures such as UPnP, Jini, and Salutation (Salutation Consortium, 2004) have emerged to provide plug and play capabilities requiring little planning and minimal human intervention. A fundamental component common to all of these architectures is the *service discovery concept* exploited by each. Other technologies that provide service discovery include service location protocol (SLP) (Guttman, Perkins, Veizades, & Day, 1999) and Bluetooth (Bluetooth SIG, 2004). The device access specification (DAS) of OSGi allows multiple devices to be discovered and their services advertised thereby making these services available to other devices, services, and applications. Integration of discovery technologies with OSGi is based on an import/export model. Briefly, registered OSGi devices and services are exported out of the OSGi framework. For instance, an OSGi printing service can be exported to a Jini network to appear as a Jini printer. Similarly, devices and services found by native discovery techniques can also be imported into the OSGi framework to appear as valid OSGi entities and accessible to other OSGi entities. It is this importing/exporting feature that allows cross-technology discovery and promotes interoperability among multiple device types (Dobrev et al., 2002).

Our main goals in this chapter are threefold:

1. First, we demonstrate how the implemented residential gateway provides remote access to an Internet user.
2. Second, we also illustrate, by design and implementation interoperability between Jini and UPnP devices by exploiting OSGi capabilities. To achieve this, we exploit APIs of OSGi, which provide access from the OSGi framework to UPnP or Jini devices and services in the network. The APIs also make OSGi services available to members of UPnP or Jini networks. Consequently, the APIs provide bidirectional service discovery between UPnP or Jini devices and OSGi services: UPnP-OSGi or Jini-OSGi (*importing* UPnP or Jini device services into OSGi) and OSGi-UPnP or OSGi-Jini (*exporting* OSGi services to UPnP or Jini networks) (Dobrev et al., 2002). The software that we have designed and implemented to achieve these functionalities is called a driver bundle: the driver bundle responsible for interacting with the UPnP network will be henceforth referred as the *UPnP driver bundle* or *UPnP base driver*. The driver responsible for interacting with the Jini network will be henceforth referred to as the *Jini driver bundle* or *Jini base driver*.
3. Third, we describe the security features we have incorporated in our residential gateway design to provide secure access to the OSGi services offered by the different device technologies that constitute the HAN.

Internet Access to HAN Devices Residing on the UPnP and Jini Networks

By enabling the hypertext transfer protocol (HTTP) service (as shown in Figure 2) in the OSGi framework of the residential gateway, a remote user can use a username/password combination to gain access and perform operations on the bundles and services from anywhere on the Internet. This access allows users to remotely retrieve information from, and send control to, services supported by the residential OSGi-based gateway using a standard Web browser. Communication to and from the residential gateway is done using encryption through Secured Sockets Layer (SSL) to provide security and privacy to the user. The information from the browser is coded by using an encryption algorithm and at the residential gateway the information is decoded by using the corresponding decryption algorithm. We used *javax.crypto.** library to encrypt data using a secret key.

Bundle developers typically need to develop communication and user interface solutions using standard technologies such as HTTP, hypertext markup language, extensible markup language (XML), and servlets to enable users to access the OSGi resources via the HTTP service of the OSGi gateway. The HTTP service in the Java Embedded Server executes as a lightweight HTTP server. By exploiting the HTTP server, we can register OSGi services as HTTP services. In our gateway implementation, we exploit servlets to deliver OSGi services remotely via Web browsers to clients. A uniform resource identifier (URI) is used to remotely access the residential gateway.

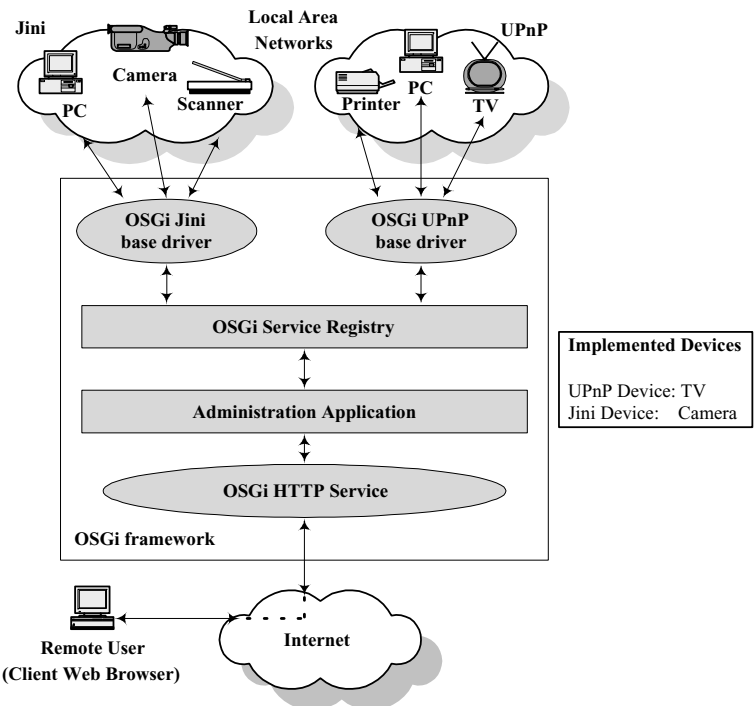

Figure 2: Design of OSGi-based residential gateway enabling Internet access to UPnP and Jini devices.

Once access is granted, OSGi services become available to the remote user. These services have been previously registered with the OSGi registry by using the `registerResources()` method of `HttpContext` object.

UPnP Device as an OSGi Service

The UPnP device architecture specification provides the protocols for a peer-to-peer network. It specifies how to join a network and how devices can be controlled using XML messages sent over HTTP. The UPnP specifications leverage Internet protocols (IP, TCP, HTTP, and XML).

This section describes our implementation of an OSGi bundle that interoperates with UPnP devices and UPnP control points. The implementation is based on the UPnP device architecture specification (UPnP, 2004) and the OSGi Service-Platform Release 3 (OSGi Forum, 2004). However, we had to make some changes where necessary to test it on a *Release 2* framework as implemented by Sun on the Java Embedded Server (JES2.0). Our implementation does not support exporting of OSGi services to a UPnP network.

To provide a comprehensive service for a UPnP device in an OSGi framework, we designed and implemented a UPnP base driver. This base driver enables the OSGi platform to offer UPnP services to its users by means of an interface registered with the service registry. This interface is made available through the implementation of the `org.osgi.service.upnp` service package that includes core components such as `UPnPDevice` (represents an imported UPnP device on a local network), `UPnPService` (representing services provided by the device), and `UPnPAction` (providing device controlling mechanisms).

There were some software development kits (SDKs) available to implement UPnP devices and control points in Java, but most of them were not open source, making

it difficult to incorporate into the OSGi framework. The only open source SDK available (and which we chose in our implementation) is from CyberLink for Java (Konno, 2004). The implemented base driver listens on the UPnP network for device announcements. As soon as the UPnP base driver detects a new device, it extracts the information about that device according to the UPnP specification for further processing. Using this extracted (advertised) information, the UPnP base driver creates a `UPnPDevice` object and registers it in the OSGi Service Registry with a property of `DEVICE-CATEGORY="UPnP,"` along with other properties, such as a unique device name called UDN, similar to a unique resource locator (URL) for device matching purposes. This `UPnPDevice` object is an instance of a class that represents an interface in the package `"org.osgi.service.upnp."` This package has been implemented according to the OSGi's specifications and provides an interface for a UPnP device in an OSGi framework. The UPnP device interface exposed by this package contains the `UPnPDevice` Java interface and other Java interfaces, which together with the UPnP base driver, constitute a UPnP Device Service in an OSGi framework.

Any bundle (`ServiceListener`) listening at the OSGi's service registry for a service with a `DEVICE-CATEGORY="UPnP,"` will be informed about the UPnP device. The listener bundle can query the interface about the properties offered by this `UPnPDevice` service and if interested can accept the service (control the device) according to the OSGi's UPnP device service specification. However, in most cases, a "refined" service is easier to use, if provided by the vendor. This refined service can provide a direct access to the functionalities of the registered devices, instead of dynamically finding the services and functionalities of a UPnP device. For UPnP devices in OSGi, a refined service is an OSGi service that knows about a specific device and its functionalities in

detail. Such a service provides targeted functionalities of the device it is serving, through its interface in the OSGi service registry. This refined service does not communicate directly to a UPnP device on a UPnP network; instead it utilizes already registered generic `UPnPDevice` (as mentioned previously). The difference between a generic `UPnPDevice` Service and a refined service is that a generic device service exposes the device's functionalities dynamically and a user does not know a priori these functionalities, whereas a refined service is static and the consumer knows in advance the functionalities available. For example, a `UPnPDevice` service interface provides a service for getting and invoking an action name, its arguments, and possible values associated with a state variable of the UPnP device on the network. Thus, to utilize a generic `UPnPDevice` service, a user input using menu options and their description for achieving particular goals becomes necessary. However, in the case of a refined service for the same device, the exposed functionalities such as `setPower` on or off or `getPowerStatus` to know whether TV is on or off, may be offered.

The unique device name (UDN) for this device is `edu.wayne.upnp.tv001` (in our implementation). As mentioned earlier, this UDN is a unique URL. However, the given format is our choice and is not specified by the UPnP forum. The UPnP base driver in the OSGi's framework detects this device, communicates with it, and after some information exchange, the base driver finally registers a `UPnPDevice` service in the OSGi's service registry. Based on the device matching criteria using properties such as UDN registered with the device service, or exposed by registered service interface, a refined service named `edu.wayne.upnp.tv001` (can be provided by some device vendor but in this case is our implementation) associates itself to this `UPnPDevice`. This refined service exports its interface so that other bundles in the OSGi framework know the functionalities this service offers. Some of the functionalities we have implemented include operations such as turning on and turning off the TV, or getting the current status of the TV.

Some functionality of a TV may involve video playback from some video source. This video stream may be provided by a Jini camera service in the OSGi framework. Our OSGi implementation can be further extended to monitor activities of these services. For instance, based on some stored correlation of functionalities in a database, an automated control command may be sent to the other device if one device starts an activity. For example, if a correlation is set such that whenever a camera playback is turned on, its video stream output is used as an input video stream for playback by the TV after the TV is switched on. As soon as the camera status changes to stop or record, a signal is sent to turn the TV off. Monitoring the two services and then invoking appropriate interface methods based on correlation stored in a database achieve the interoperability.

Security in UPnP

UPnP Security has defined a combination device and control point called the security console (SC). The SC takes security ownership of devices and authorizes control points (or other security consoles) to have access to devices over

which the SC has control. An SC can own a device, meaning that it has the right to edit that device's access control list, or it can be given some subset of rights to the device and have the privilege to grant all or some of those rights to another SC or CP (by way of an authorization certificate). The SC also defines the names of individual or groups of control points.

Vulnerabilities in UPnP Security

UPnP was originally designed for the relatively benign security environment of a typical home—specifically, one that was not continuously connected to the global Internet. UPnP is susceptible to various security threats. Several countermeasures may be employed to address security threats, including encryption, authentication (requiring users or devices to prove who they are), access control and authorization (granting permission to only particular users to do certain operations), digital signatures (which ensure a message was actually sent by whoever claims to have sent it), message integrity checking (ensuring a message is not altered in transit), and others.

UPnP does not directly implement these countermeasures. Instead, it assumes that measures such as network isolation (gateways, firewalls, and proxies), MAC layer encryption (provided by the network adapters), and physical access control will be employed to protect not only UPnP traffic, but also the rest of the HAN. Some security concerns associated with UPnP include the following:

- Allowing the use of UPnP-enabled equipment in public facilities, such as printer kiosks in airports, protecting the service providers from fraudulent use, and protecting sensitive information on the UPnP equipment.
- Preventing unauthorized users from using home wireless power line or telephone networks to discover devices present in an HAN and misusing these devices.
- Enabling homeowners to remotely access, control, and monitor their home equipment securely over the Internet.
- Enabling service providers such as electric utilities to securely access, control, and configure equipment, such as power meters, in the home over the Internet.
- Allowing UPnP-enabled equipment, such as digital cameras, from the home to be taken to the office and used with computers there, without interfering with enterprise security or becoming visible to others on the network.

The eEye Digital Security advisory (eEye, 2001) identified a few vulnerabilities within Microsoft's UPnP implementation: a *remotely exploitable buffer overflow* to gain system-level access to any default installation of Windows XP and *Denial of Service (DoS)/Distributed Denial of Service (DDoS)* attacks (Lough, 2001).

The system remote exploit: This vulnerability within the Microsoft's implementation of the UPnP protocol can result in an attacker gaining remote system-level access (highest level of access) to any default installation of Windows XP. During testing of the UPnP service, it was discovered that by sending malformed advertisements at various speeds one could cause access violations on the target

machine. Most of these violations were because of pointers being overwritten. Authors found instances of stack and heap overflows, both of which were exploitable. In the case of the heap overflow authors discovered pointers being overwritten for both buffers and functions. The Simple Service Discovery Protocol (SSDP) service also listens on multicast and broadcast addresses. Therefore gaining system access to an entire network of Windows XP-based machines is possible with only one anonymous UDP SSDP attack session.

DoS and DDoS: When a UPnP-enabled device is installed on a UPnP-based network, the device sends out an advertisement to notify control points of its existence. On a default Windows XP installation, no support is added for device control because the installation of UPnP would take place from the “Network Services” configuration. Microsoft added default support for an “Internet gateway device” to enable leading hardware manufacturers to make UPnP-enabled “gateway devices.” However, if an application is set up to “sniff” a network with Windows XP, then Windows XP can be observed searching for this device as Windows XP loads. By sending a malicious spoofed UDP packet containing an SSDP advertisement, an attacker can force a Windows XP client to connect back to a specified IP address and passes on a specified HTTP/HTTPS request. When the XP machine receives this request, it will interpret the URL following the location header entity. Without any checking, the URL is passed to the Windows Internet services API functions and a new session is created. A malicious attacker could specify a service on a remote machine causing the Windows XP client to connect and get caught in a tight read/malloc loop. This loop will throw the machine into an unstable state with maximum CPU utilization, and memory is allocated to the point where it is totally exhausted. As a result, the remote Windows XP system becomes completely unusable and requires a physical power-off shutdown. Attackers could also use this exploit to control other Windows XP-based machines, forcing such machines to perform unicode attacks, double decode, or random CGI exploiting. Because of the insecure nature of UDP, an attacker can also exploit security holes on a Web server using UPnP with almost total anonymity. A more serious problem arises when such attack becomes a DDoS attack, because a SSDP announcement can be sent to broadcast addresses and multicast. It is therefore possible to send one UDP packet causing all Windows XP machines on the target network to be navigated to the URL of choice,

performing an attack of choice. Moreover, because parts of the UPnP service are implemented using UDP, this makes these attacks completely untraceable.

Jini Device as an OSGi Service

Jini (Sun Microsystems 2004) is a framework based on the idea of federating groups of users and the resources required by those users. The focus of the framework is to make the network a more dynamic entity that better reflects the dynamic nature of the workgroup by enabling the ability to add and delete services flexibly. Jini systems provide mechanisms for service construction, lookup, communication, and use in a distributed system. Jini technology uses a *lookup service* with which devices and services register. When a device joins a Jini network, it goes through a phase called discovery and join-in. The device first locates the *lookup service* (discovery) and then uploads an object that implements all of its services' interfaces (join in). To use a service, a user or a program locates it using the *lookup service*. The service's object is copied from the *lookup service* to the requesting device where it will be used. Integrating Jini Services with OSGi would mean registering the services in the OSGi framework as OSGi services. This will make the registered Jini services accessible to any service or bundle in OSGi.

The OSGi specification works with various device access standards and is compatible with and can enhance a Jini environment. As mentioned previously, an OSGi implementation can also provide bridging capability between the Jini environment and non-Jini devices, such as UPnP, HAVi, and others.

Registering Jini Services as OSGi Services

To register Jini services in the OSGi framework, we designed and implemented a Jini base driver in the OSGi environment. The Jini driver is a bundle in the OSGi framework that imports Jini services into OSGi services. To import services, the Jini driver service transforms any Jini services discovered on the network to OSGi services thereby defining a bridge between a Jini network and an OSGi service platform. The importing of Jini services enables applications in the OSGi framework to interact with Jini services. Thus, OSGi bundles need not include extra components to use Jini Services and furthermore they do not even have to be aware of the fact that the service platform is Jini enabled. Figure 3 illustrates the steps

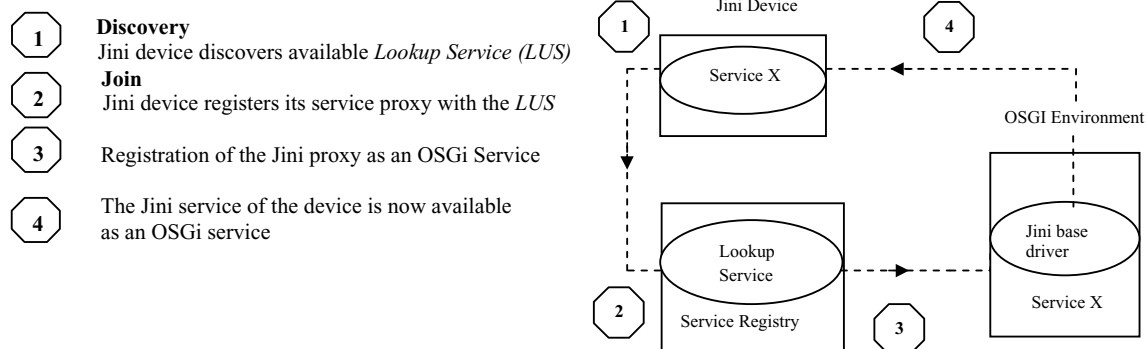

Figure 3: A device joins a Jini network and registers its services with OSGi.

involved when a device is introduced into the Jini network and registering its services as OSGi services in the OSGi platform.

After the Jini base driver (bundle) has been started in the OSGi framework, it waits for a Jini device to join the network. When the *JiniCamera* (a Jini device) is introduced into the network, the Jini base driver detects that a Jini device has joined the network and imports all the information needed to register that service as an OSGi service. The registration of the discovered Jini services is only possible if the interfaces under which they are registered are available to the OSGi framework. When the *JiniCamera service* is registered as an OSGi service using a `BundleContext` objects that provides a reference to a `ServiceRegistration` object. If the registration is successful, the following properties are set:

- **DEVICECATEGORY**: The property that must be used to participate in the OSGi device access mechanisms. The Jini base driver sets the value of this property to Jini when it imports a Jini service.
- **SERVICEID**: A unique Jini service identifier. Each service is required to have a unique service identifier. The Jini base driver sets this property to the identifier of the service in the service registry.

After registration, any application that is running on the OSGi framework can access and use the Jini services that are registered as the OSGi services. Applications that use these services do not and need not be aware that these are Jini and not OSGi devices.

When a Jini device (in this case the *JiniCamera*) is started, it registers its services with the LUS. The implemented *JiniCamera* service allows the following operations: `start`, `stop`, `record`, and `playback`.

The *JiniCamera* service provides an importable service that can be used by any other applications in the Jini network. The *JiniDriver*, a bundle in OSGi, gets access to this service and registers a proxy of this importable Jini service with the OSGi service registry.

Security in Jini

The design of the security model for Jini is built on the notions of a *principal* and an *access control list*. Jini services are accessed on behalf of some entity—the principal—which generally traces back to a particular user of the system. Services themselves may request access to other services based on the identity of the object that implements the service. Whether access to a service is allowed depends on the contents of an access control list associated with the object. The central difference between Jini and the other service location protocols such as Salutation, service location protocol, and UPnP is protocol independence. That is, Jini does not mandate any specific communication protocol between the clients and the services (except for bootstrapping the system), but relies on dynamic Java class loading instead (Eronen & Nikander, 2001). Because the proxies are written in Java, the system also claims operating system independence; this is in contrast with the other service location protocols that usually use nonportable device drivers. The protocol independence of Jini presents new security challenges.

The Jini architecture does not include any security other than the normal Java security facilities (for protecting the client Java virtual machine (VM) from malicious proxy code), and (jvm) the security aspects of remote method invocation, which by themselves do not provide adequate security. Because all communication goes through downloaded proxy objects, security methods used in environments with fixed protocols cannot usually be used without some adaptation. Haselmeyer, Kehr, and Vob (2000) and Eronen and Nikander (2001) have identified the following security requirements for Jini:

- *Principal authentication*: The Jini client should be able to verify that it is communicating to the right service and through the right proxy. Likewise, the service should be able to verify the identity of the requester of the service. It is important to note that authentication is impossible several situations. For example, in a pure ad hoc network there may be no prior information about the communicating peers.
- *Secure principal attributes*: In many circumstances, human readable and recognizable names are required for authentication. Services might also have other attributes such as security level (for example, a printer for printing classified documents) or the “owner” of the service. Users might have other attributes such as memberships in groups or roles. Not all clients or services necessarily have names with any uniqueness beyond one client or server.
- *Service access control*: Based on the result of principal authentication and/or capabilities presented by the client and/or other circumstances, the service should allow some operations and deny others.
- *Protection from applications*: The client JVM may run multiple applications, some of which are not fully trusted, such as applets and games. Untrusted applications should not be able to access services with the user’s privileges.
- *Protection from proxies*: The downloaded proxy code needs some special permissions (for example, to make network connections) while running inside the client JVM. Some proxies may need more permissions than others and these proxies need to be controlled. Although Java does provide some security facilities, they are inadequate for many applications.
- *Mobile code security issues*: One of the main differences between the Jini architecture and the “traditional” client/server systems such as CORBA or the World Wide Web is that in all these systems the client permanently contains the code for communicating with a server. The protocol code is part of the client and therefore part of the client’s trusted computing base. If a client needs some form of security (e.g., authentication or integrity), it can use any protocol that provides the required security properties (e.g., SSL). In contrast, the Jini approach is fundamentally different. Jini clients do not implement any network protocol. Instead, the clients rely on the service’s proxy object to perform the communication with the server. Proxy objects usually originate from some (usually untrusted) source on the network. This includes the downloading and execution of code from that source. A Jini client does not and cannot

know what a proxy object does with the supplied data. A security approach that is different from those of traditional client/server systems is therefore required. Because the proxy is supplied by its associated service it should know the appropriate level of security for its application domain. This approach relies on trusting the proxy to enforce the required security constraints. To establish trust in a proxy object, we need to ensure its integrity. The proxy object should not be changed on its way from the service (via the lookup service) to the Jini client. Digitally signing the object's code as well as the use of encrypted connections between the lookup service and the Jini clients are required to provide secure in-transit service descriptions.

- *Lookup service interaction:* Even with encrypted communication and authenticated objects, we still need Jini clients to trust the lookup service they are communicating with. This trust can be achieved by requiring the lookup service to authenticate itself to the Jini clients.

Integrating UPnP and Jini Services in OSGi

One of the main goals of this chapter is to demonstrate, by design and implementation, the seamless interoperability between Jini and UPnP devices and services by exploiting the OSGi framework. To achieve this we implemented an integration bundle we called the *UPnP-Jini bundle*. The UPnP-Jini bundle obtains a reference to both the *JiniCamera* and the *UPnP-TV* by searching the service registry using `DEVICECATEGORY` as the search keyword and the value Jini or UPnP device. Once objects to *JiniCamera* and *UPnP-TV* are obtained, the UPnP-Jini bundle uses methods for both devices to pass information and images between the *JiniCamera* and *UPnP-TV*. Thus in our implementation, the UPnP-Jini bundle acts as a bridge for the Jini and UPnP devices. In this way, both the *JiniCamera* and *UPnP-TV* have access to the services offered by each other and seamlessly interoperable and communicate with each other via OSGi as depicted in Figure 4.

The major task in our design was the implementation of the base drivers, which conforms to OSGi

specifications, and handles the registration of UPnP or Jini services in the OSGi's registry. To test the driver and service implemented, a UPnP and Jini device were implemented. In our prototype implementation, we have the UPnP device (simulating a TV) and the Jini (simulating a camera) each executing separately on a workstation. The OSGi bundles (UPnP, Jini, UPnP-Jini bundles) were all executed on a third workstation running JES 2.0. All workstations resided on a 100 Mbps Ethernet local area network. The implementation was tested as follows: the *JiniCamera* was used to pass images to the *UPnP-TV*, which then displayed them on its screen. When the "record" of the *JiniCamera* was activated, the camera sent a series of JPEG images to the residential gateway (OSGi framework), which passed the images to the *UPnP-TV* (another workstation in our prototype). The UPnP device captured the images and displayed them on the screen. In this way, our design and implementation demonstrate how an event in one device (for instance, switching on the "record" function on the *JiniCamera*) triggers an event in another device (display images on the *UPnP-TV*), thereby enabling devices in two different networks (Jini and UPnP) to interoperate through OSGi.

OSGi Security Implementation Issues for Secure Internet Access to the HAN

Security is an essential requirement for residential gateways and often involves many different aspects. Security in the OSGi framework is based on the Java 2 security architecture (Gong, 2001). Many methods defined by the OSGi API require the caller to have certain permissions. *Permission* is the authority to access some resource or to perform some operation. The bearer of certain permission is allowed to access a resource or to perform an operation specified in the permission, and the lack of it denies the caller an access or operation. For any service gateway, such as the residential gateway we have designed and implemented, the issue of security is of paramount importance because the gateway will be accessed by service providers and homeowners. In our residential gateway design, we address, by implementation, the following

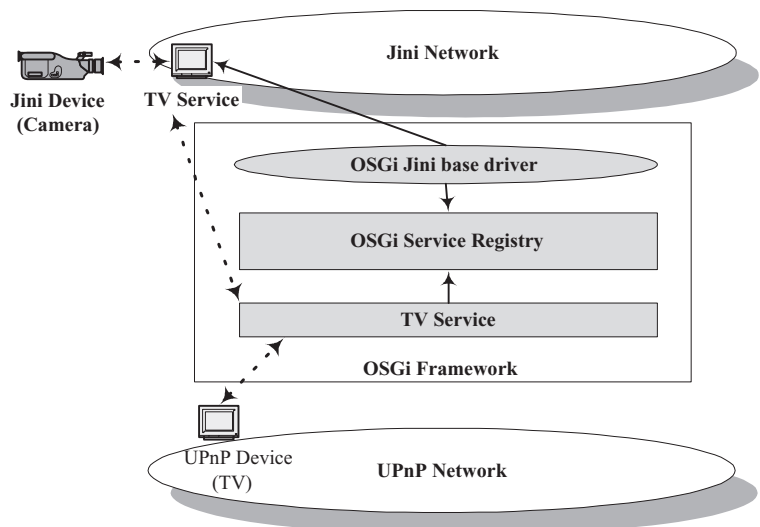

Figure 4: Integrating Jini and UPnP services through OSGi.

security issues during remote access to OSGi-based services:

- **Dispatch the right service to the right person:** When enabling Internet access to an HAN, security and authentication become an important concern. A basic authentication that is used to verify a user identity can also be used as a means to identify the services to which the user is authorized. An encrypted username/password is used to map to the services to which the user has access rights. Our implementation exploits OSGi-based HTTP authentication. The Java Embedded Server's HTTPService provides the necessary operations (via the `handleSecurity` method) to implement any HTTP-related authentication schemes. The `handleSecurity` method uses the `BasicSchemeHandler` (service of the JES framework), which performs the necessary authentication by checking the user's username/password combination.
- **Maintain the integrity of the services:** The integrity of the services is guaranteed by exploiting the three-level security model of the OSGi framework: service (level 1)-, package (level 2)-, and admin (level 3)- level privileges defined by the `ServicePermission`, `PackagePermission`, `AdminPermission` classes of OSGi (subclasses of `java.security.BasicPermission`), respectively. The service privilege is the very first or basic protection as it permits authentication on a per service level. This privilege permits a user to "register" a service or to "get" a service from the service registry. The package privilege represents a permission to import or to export a package. A package name and an action must be specified. This kind of permission grants a user access to all the resources that are contained in that package whether it is a service or a bundle. Similarly, a user can also export a package. The admin privilege is the highest permission level and users with this kind of privilege can perform administrative operations in the OSGi-based residential gateway. However, the admin privilege can be subject to abuse in that a bundle with such privilege has full control over the OSGi service platform.
We have implemented all the three types of permissions mentioned previously. In our implementation, we exploit the `java.security.Policy` to grant permission to classes loaded using the Java security manager, which enforces the permissions that have been granted. It does so by examining the set of permissions owned by a calling class against the required permission. If a class has the needed permission then the execution proceeds; otherwise, access is denied.
- **Protect the services from intruders:** The services and their implementation details are protected from malicious attacks by means of secure sockets and authentication. Even if a user has access to the service it is not possible to modify the service implementation (i.e., code) because package- or admin-level privileges will still be required.

By implementing the three-level security permission in the OSGi framework we have protected the service and bundles that reside in the OSGi-based residential gateway. Security and authentication for remote access is provided

by the HTTP basic authentication scheme. By combining these security features, we are able to provide secure, Internet access to the HAN via the OSGi-based residential gateway.

CONCLUSION

In this chapter, we describe the design and implementation of an OSGi-based residential gateway that provides seamless communication and interoperability between heterogeneous Jini and UPnP devices. We achieve this by designing and implementing Jini and UPnP base drivers. Our proposed solution enables the capability to bridge disparate discovery technologies and allows a richer device interaction and service delivery. In addition, our OSGi-based gateway also provides secure, remote access to the HAN devices and services. We are currently working on automation of device actions based on a one-time initialization by the user. This feature will make it possible to trigger several devices automatically to achieve the desired actions of several devices that the user may want to activate based on certain set criteria or home user preferences.

Although tremendous progress has been made within the home networking industry in recent years, several challenges remain. Particularly, making such a system secure from an end-to-end perspective is a critical area that needs greater investigation. For instance, one may have a scenario where Jini is used to discover available services within a community, following which an OSGi bundle is installed within the residential gateway and HAVi is used to actually deliver the service itself. In such a case, the interworkings of different technologies require greater investigation into the security implications.

GLOSSARY

Access Control List A set of data that informs a computer's operating system which permissions, or access rights, that each user or group has to a specific system object, such as a directory or file.

Advanced Encryption Standard A symmetric 128-bit block data encryption technique.

Certification Authority A certificate authority (CA) is an authority in a network that issues and manages security credentials and public keys for message encryption.

Data Encryption Standard Data Encryption Standard (DES) is a widely used method of data encryption using a private (secret) key.

Denial of Service Denial of service (DoS) attack is an incident in which a user or organization is deprived of the services of a resource they would normally expect to have.

Home Area Network Home area networks (HANs) facilitate communication among appliances, home systems, entertainment products, and information devices in a home so that they can work cooperatively and share information.

Home Audio/Video Interoperability A standard, developed by several leading electronics and computer manufacturers, that allows a number of different home

- entertainment and communication devices to operate from a single controller device such as your TV set.
- HyperText Markup Language** The authoring language used to create World Wide Web documents.
- HyperText Transfer Protocol** The underlying protocol used by the World Wide Web. HTTP defines how messages are formatted and transmitted and what actions Web servers and browsers should take in response to various commands.
- Jini** Software from Sun Microsystems that seeks to simplify the connection and sharing of devices, such as printers and disk drives, on a network.
- Mobile Information Device Profile** A set of Java 2 Micro Edition (J2ME) APIs that define how software applications interface with cellular phones and two-way pagers.
- Network Address Translator** An IETF standard that enables a local area network to use one set of IP addresses for internal traffic and a second set of addresses for external traffic.
- Open Services Gateway Initiative** An industry plan for a standard way to connect devices such as home appliances and security systems to the Internet.
- Public Key Infrastructure** A system of digital certificates, certificate authorities, and other registration authorities that verify and authenticate the validity of each party involved in an Internet transaction.
- Realm Specific Internet Protocol** An IP address translation technique that is an alternative to NAT.
- Remote Method Invocation** A set of protocols being developed by Sun's JavaSoft division that enables Java objects to communicate remotely with other Java objects.
- Service Location Protocol** A protocol or method of organizing and locating the resources (such as printers, disk drives, databases, e-mail directories, and schedulers) in a network.
- Session Initiation Protocol** An Internet Engineering Task Force (IETF) standard protocol for initiating an interactive user session that involves multimedia elements such as video, voice, chat, gaming, and virtual reality.
- Simple Service Discovery Protocol** The service discovery protocol provides a mechanism for client applications to discover the existence of services provided by server applications as well as the attributes of those services.
- Transmission Control Protocol** A set of rules (protocol) used along with the Internet protocol (IP) to send data in the form of message units between computers over the Internet.
- Universal Plug and Play** A standard that uses Internet and Web protocols to enable devices such as PCs, peripherals, intelligent appliances, and wireless devices to be plugged into a network and automatically know about each other.
- Wide Area Network** A network that spans over large distances; usually connects many other networks together.
- Wired Equivalent Privacy** A security protocol for wireless local area networks defined by the IEEE 802.11b standard.

Wireless Application Protocol A specification that allows users to access information instantly via handheld wireless devices such as mobile phones, pagers, two-way radios, smart phones, and communicators.

Wireless Markup Language An XML language used to specify content and user interface for WAP devices.

Extensible Hypertext Markup Language Hybrid between HTML and XML specifically designed for networked device displays.

Extensible Markup Language A specification (designed especially for Web documents) developed by the World Wide Web Consortium (W3C).

Extensible Stylesheet Language Transformation The language used in XSL style sheets to transform XML documents into other XML documents.

ACKNOWLEDGMENTS

We thank Aruna Banda for her security contributions and ideas on Jini and UPnP, and Mohammad Saklay for his help on a home area networking survey. We express our gratitude to all the anonymous reviewers who made excellent suggestions and comments that led to improvements of the chapter. We also thank Hossein Bidgoli and his excellent editorial board team for their kind encouragements and support during the preparation of this chapter. We are grateful to Farhan Siddiqui for her remarks, which helped to improve the presentation of this chapter. This work was supported by grants from Sun Microsystems (Palo Alto), Microsoft Corporation (Seattle), OPNET (Maryland), and Ixia Corporation (Calabasas).

INTRODUCTION

Networks for the transfer of data between computers, both public and private, are ubiquitous in today's business world. A public network is one that is publicly available to subscribers (Stallings, 2001). It provides service to multiple subscribers and is built and maintained by a public network provider. Internationally, the term *public network* is often applied to networks that are under government control or are a national monopoly. However, a network can also be a privately owned network whose services are sold to the public. Whether the network is under government control or is a privately owned network whose services are sold to the public, businesses access the network by installing an access device at each site and using an access line to the nearest point of presence (POP) of the public network provider (Panko, 2001).

This chapter gives an overview of the secure use of public networks. It begins by describing public network concepts and services and the structure of the public switched telephone network (PSTN) system. The technologies used both for access to a public network and within the public network itself, issues related to choosing a public or a private network, the secure use of public networks, and public networks in the Internet and e-commerce environments are covered.

OVERVIEW OF PUBLIC NETWORK CONCEPTS, SERVICES, AND STRUCTURE

Traditionally, companies desiring to connect business computers in different geographic locations have used private networks. That is, they have used point-to-point leased lines between business sites to create their own

circuit-switching or packet-switching networks for their data communication requirements (Panko, 2001). Unlike telephone calls, which set up the required capacity as needed, leased lines provide dedicated transmission capacity between sites. These networks are called private networks (Stallings, 2001). By using leased lines, companies have a dedicated, guaranteed network capacity. In many cases, volume discounts are offered for the bandwidth available on the leased line. An example of a private network is shown in Figure 1.

There are several disadvantages to private networks. Private networks require higher initial costs. The leased line connections must be planned and installed. The switching devices must be provided. In addition, once a network is operational there are ongoing management and maintenance costs of the networks (Panko, 2001). A public network is an alternative to a private network.

A public network provides connectivity to other locations as a service. There are advantages to using a public network. A public network requires no complex network of leased lines and switching devices that the business must plan and install. There is commonly one access line installed per site. Even if a leased line is used to connect to the nearest POP, there are usually fewer leased lines required. For example, if there are 10 sites using the public network, then there are 10 leased lines. Compare this to a fully meshed private network that requires 45 leased lines. For N locations, $N(N - 1)/2$ leased lines are required for a connection to and from each site. Even if not every site is connected to every other site in the private network, but sites are connected through intermediate sites, the number of leased lines for a public versus a private network is generally smaller. Finally, because of competitive pricing, public networks are less expensive than private networks (Stallings, 2001). Figure 2 illustrates an example of a public network.

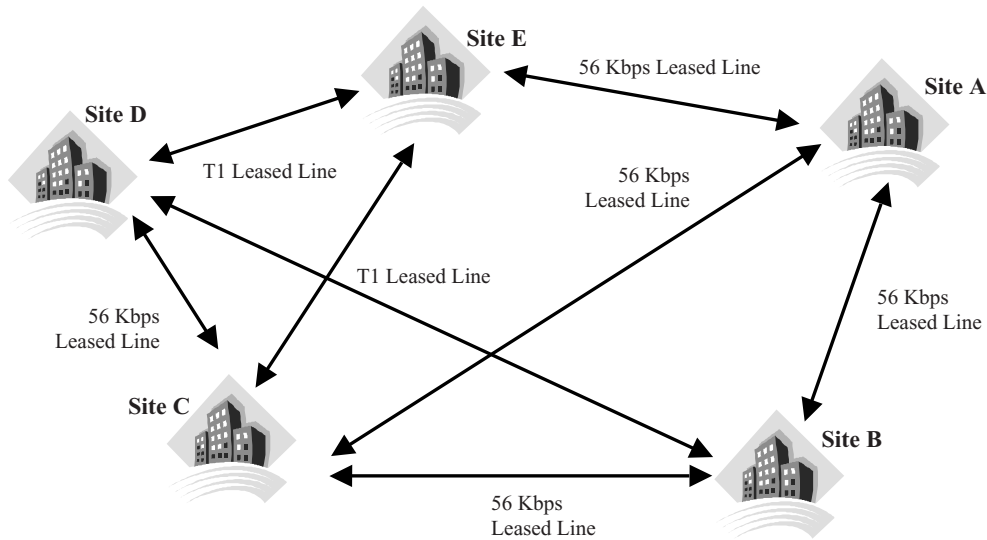

Figure 1: A private switched data network.

The global Internet is a network that is publicly accessible worldwide. The Internet is not one single network but is composed of several networks connected together and communicating with standard Internet technologies (Moody, 2001). Access to the Internet is achieved via an Internet service provider (ISP). The Internet allows a business to have a worldwide presence, and purchases can be made automatically using e-commerce software.

A network that transfers data and information only within a single business is called an intranet (Moody, 2001). Intranets are used to carry corporate information that can range from being routine, such as e-mail, manuals, and directories, to sensitive information such as that of project management and internal purchasing. Intranets use the same technologies as the Internet but access is restricted to employees. A private network that uses Internet technologies is naturally an intranet. A public network can be used by a business as an intranet by asking that the data

be restricted to go only to other locations of the same business. Of course, the bandwidth is still shared with other businesses that use the same public network.

An extranet is a hybrid between the public Internet and the private intranet (Moody, 2001). A portion of the intranet is extended to business partners in a controlled and restricted way. The extranet can be used for project management of projects between partners. Another common and practical use of the extranet is to allow partners access to stock levels and shipping status, for example direct online purchasing of supplies and other applications are made possible through the use of an extranet. A public network provider has a value-added network if it owns the packet-switching nodes and leases transmission capacity from an interexchange carrier such as AT&T (Stallings, 2001). It is called a value-added network because the leased lines add value to the packet switching nodes. A network provider that provides a value-added network is

Figure 2: A public switched data network.

sometimes called a value-added carrier. In many cases, a public network provider will partner with companies that provide services that require network connectivity such as Web hosting and give discounts to them for using their network. A business that bundles a service with a particular public network provider is called a value-added reseller.

Public network providers often offer services such as Web hosting to subscribers in addition to connectivity between sites. These additional services are called value-added services. These services include asset management, configuration control, fault management, monitoring, Web-based reporting, Web hosting, e-mail services, and content delivery networks.

Asset management is keeping inventory of devices that are connected to the network. As devices are added or taken off the network, the asset management system will keep an up-to-date log of the assets. Configuration control is about maintaining and keeping records of the configuration of networked devices. The network provider typically maintains the configuration of the packet switching node that connects each of the subscriber locations to the network. A provider will also monitor devices to detect faults and either fix them or notify the appropriate on-site personnel. This is called fault management. A provider can invest in large network operation centers for monitoring their subscribers' network devices. This includes maintaining a firewall to prevent unwanted users into the network and intrusion detection systems for detecting activity that is consistent with common hacker techniques. With Web-based reporting, the provider gives the subscriber reports about the status of their network and a history of its downtime and performance.

One of the most popular value-added services is Web hosting. The provider maintains one or more servers and allocates space on them for the subscriber's Web site. The provider maintains the server and performs backups. Subscribers are given access to their portions of the server to post their Web sites and control their content. An advantage to using this value-added service is that it is likely that the subscriber has other sites that are connected to the same public network. If the server is connected to the same public network, it provides faster response times to the end users.

Medium to large users who have high volumes of content serving a distributed set of users may consider a value-added service called a content delivery network (CDN). A CDN intelligently distributes the content to multiple locations and closer to the end user. By moving the customized content closer to the end user, faster response times are achieved (Allen, 2001). Queries to the main server or group of servers are routed to the location that can best respond to the query. Content is cached at each of the locations and future requests are serviced more quickly because the information traverses fewer links in the network. There are three main advantages to a CDN. First, end users receive faster response times. Second, it relieves congestion on the original server that maintains the master copy of the content. Finally, it reduces the amount of data transmission capacity required on the network because the content is distributed to multiple locations and does not have to come from

the original server. Some of the popular CDN providers are Akamai (<http://www.akamai.com>) and Mirror Image (<http://www.mirror-image.com>).

Structure of the Public Switched Telephone Network System

The PSTN system is often used to provide the technology that a business uses to access a public network or is the technology of the public or private lines. The structure of the PSTN in the United States has evolved from one that was almost entirely controlled by a single company to one that allows competition in a free market. Before January 1, 1984, AT&T (also known as the Bell System) controlled 80% of the PSTN in the U.S. (Bellamy, 2000). A Justice Department antitrust suit filed in 1974 and a private antitrust case by MCI resulted in a breakup of AT&T (Noam, 2001). The suit argued that AT&T used its control of the local operation as an unfair advantage against competing long-distance carriers.

On January 1, 1984, AT&T was divided into smaller companies. The breakup involved the divestiture of seven Bell operating companies (BOCs) from AT&T. The seven regional BOCs, known as "baby Bells" or regional BOCs (RBOCs), initially carried only regional telephone and mobile service. The network was partitioned into two levels (Bellamy, 2000), and the remaining part of AT&T retained the transport of long-distance telephone service.

The United States was divided into local access and transport areas (LATAs), which are controlled by local exchange carriers (LECs). LECs can transport telephone calls within a LATA (called intra-LATA traffic) but are not permitted to transport traffic between different LATAs (called inter-LATA traffic), even though the same BOC may control both LATAs. The inter-LATA traffic is transported by interexchange carriers (IXCs), commonly known as long-distance carriers. Each IXC interfaces at a single point in the LATA called a point of presence. At divestiture, AT&T became an IXC and it opened the door to competition for other companies' long-distance service. The major IXCs in the United States include AT&T, MCI-WorldCom, and Sprint.

The divestiture decree was supervised by District Judge Harold Greene and known as the modified final judgment (Noam, 2001). LECs had to grant equal access to all IXCs. The service offered by the LECs to the IXCs had to be equal in type, quality, and price (Bellamy, 2000). In addition, users could specify their "primary" IXC to transport their long-distance and international calls (Noam, 2001). Alternatively, users could use other IXCs on a call-by-call basis by dialing a prefix.

Another major change in the U.S. PSTN occurred with the 1996 Telecommunications Act that amended the Communications Act of 1934 (Noam, 2001). RBOCs had to comply with a list of tasks before they were permitted to provide long-distance service within their regions. The list permitted competition in the RBOCs regions. It was argued that it was necessary to induce competition in these local markets. RBOCs were required to provide interconnection to new market competitors, unbundle their network, permit competitors to resell their service, and provide users with number portability.

The new local service providers became known as competitive local exchange companies (CLECs) (pronounced “see-lecks”) (Noam, 2001). The incumbent LECs became known as ILECs. For a CLEC to be competitive with the ILEC requires that it is able to interconnect with the users cost-effectively. Therefore, there came a great struggle between CLECs and ILECs on the issue of collocation because the ILEC had a significant advantage with the existing network. In *physical collocation* a CLEC places its cables and equipment inside the ILEC’s central office (CO) to hand off traffic. In another arrangement called *virtual collocation* the physical handoff of the traffic occurs inside or outside the CO, but uses ILEC-owned equipment and must be the economic equivalent of physical collocation.

It may appear from the previous discussion that the breaking up of the U.S. PSTN is relevant only to the United States but the trend is happening in other parts of the world as well (Noam, 2001). Japan opened its markets to competition. In addition, the Europeans have privatized their service. Noam argues that at first a network is not feasible unless supported by outside sources such as governments. As the network grows the average costs decline initially and then rise as a few high-cost users are added. Without regulation, the network would not grow beyond a certain point because of the high cost of adding these high-cost users. From a political and societal point of view the network becomes a necessity instead of a convenience and should be offered to everyone. Therefore, the monopolistic breakdown of the network is caused by its own success.

Data Public Networks and the Internet Protocol

The volume of *data* traffic carried by networks exceeded the volume of *voice* traffic in the late 1990s and continues to grow at a rate of about 100% per year (Autorité de Régulation des Télécommunications, 2003). Also, many businesses are now carrying their long-distance and international voice traffic that was previously carried over circuit-switched voice networks over packet-switched data networks. Unlike the circuit-switched networks that carry voice traffic, packet-switched data traffic is divided into pieces called packets that vary in size from 100 to 1000 bytes (Panko, 2001). Each packet has a header that contains the source address and destination address to route the data to the correct destination. The most widely used protocol for carrying data in packets is the Internet protocol (IP) used in the Internet. An IP address is like a telephone number for a packet-switched network and uniquely identifies a computer.

PUBLIC NETWORK TECHNOLOGIES

To use a public network for data services, a user must access the public network through some network service from the user’s computing equipment to the nearest public network node. Factors in selecting a particular service include the cost of the service that is provided and the features, including the transmission speed, that are provided by the technology. Generally, the higher the transmission speed that a technology can support, the more costly the service becomes. Transmission speeds for networks are

described in bits per second. Unlike when memory size is described, 1 Kbps is exactly equal to 10^3 bits per second, 1 Mbps is exactly equal to 10^6 bits per second, and 1 Gbps is exactly equal to 10^9 bits per second.

Many technologies are available for access to a public network and for use within the public network. The most inexpensive network access is through a voice-grade modem. A modem is used to convert a digital computer signal to an analog signal that can be sent across ordinary telephone lines. Voice-grade modems can receive data at up to 56 Kbps. In contrast, digital lines that are used to access the network range in transmission speed from 56 Kbps to 10 Gbps. Within the public network a few technologies, including X.25, frame relay, asynchronous transfer mode (ATM), and synchronous optical network (SONET), have become the most commonly used technologies. Table 1 lists the most common technologies along with a comment about usage. Table 1 also compares the transmission speed and the time to download a 10-Mb (1.2 Megabyte) file.

Voice-Grade Modems

A modem is the most inexpensive and easiest to use access technology. The use of modems for data transmission will be substantial for many years to come (Stallings, 2001). Voice-grade modems use a 4-kHz bandwidth on an ordinary telephone line, the same bandwidth that is used for voice signals. Modems can be packaged inside an information product, such as a personal computer. Companies often have modem banks that allow employees to dial in directly to the company intranet or to access a large computer system.

On March 1, 1993, the International Telecommunications Union (ITU) Telecommunications Standardization Sector (ITU-T) was created as a permanent organ of the ITU, an agency of the United Nations. The charter of the ITU-T is to standardize techniques and operations in telecommunications. Several standard specifications for voice-grade modems have been designated by the ITU-T. Two of the most significant modem specifications are V.32, which is a dial-up modem that transmits at 9600 bps, and V.90, also a dial-up modem. V.90 sends at 33.6 Kbps and receives at 56 Kbps, the highest rates available for voice-grade modems (Stallings, 2001).

Digital Subscriber Lines

A faster service than voice-grade modems that is being offered by telephone companies is the digital subscriber line (DSL). A widely publicized version of this is asymmetric digital subscriber line (ADSL). ADSL offers high-speed downstream access to the customer site and a lower speed upstream access from the customer. The ITU-T has developed a standard for low-speed ADSL called G.992.2, or G.Lite. G.Lite specifies downstream speeds of 1.5 Mbps, but sometimes lower downstream speeds are used. Most users find asymmetric speeds to be acceptable, because upstream traffic frequently consists of keystrokes or the transmission of short e-mail messages, whereas downstream traffic may include Web pages or large amounts of data. In addition to data speed, an advantage of DSL over voice-grade modems is that DSL modems allow voice

Table 1 Common Network Technologies

Service	Usage Comments	Transmission Speed	Download
Voice-Grade Modem	Modems are inexpensive, telephone rates reasonable for modest connect times	Upload: up to 33.6 Kbps Download: up to 56 Kbps	3 min or more
Digital Subscriber Line	More expensive than voice-grade modems, downlink rates higher than uplink	Upload: from 16 to 640 Kbps Download: from 786 Kbps to 9 Mbps	1.1–13 s
Cable Modems	Download rates depend on the number of simultaneous customers and configuration	Upload: from 64 to 256 Kbps Download: from 10 Mbps to 30 Mbps	0.3–1 s
Satellite	A cost-effective choice in remote locations	Upload: from 56 to 256 Kbps Download: from 150 Kbps to 1 Mbps	10–67 s
Fixed Wireless WiFi	Rates depend on distance from access point and on the number of customers	Upload: from 1 to 11 Mbps Download: from 1 to 11 Mbps	1–10 s
Integrated Services Digital Network	Charges generally based on duration of call	Basic rate: 128 Kbps, higher rates available	1.3 min
Digital leased lines: 56 Kbps (DS0), T1 (DS1), T3 (DS3), ...	Most common leased line for high-traffic voice and data; fixed price for a specific capacity	DS0: 56 Kbps T1, DS1: 1.54 Mbps T3, DS3: 44.7 Mbps	56 Kbps: 3 min T1: 6.5 s T3: 0.22 s
SONET	Specification for optical links, highest speed	From 155.52 Mbps to 2.488 Gbps leased	0.004–0.06 s
X.25	Older technology, still in use in public networks	56 Kbps, but can be slower or faster	3 min or more
Frame Relay	Fixed price per month for a specific capacity, widely installed and used	From 16 Kbps to 44.736 Mbps	0.22–625 s
ATM	Universal technology for wide area networking	From 1.544 Mbps to 2.488 Gbps for access	0.004–6.5 s
Ethernet Passive Optical Network	Future passive technology based on Ethernet	From 100 Mbps to 10 Gbps	0.001–0.1 s

traffic to be multiplexed onto the telephone wires coming into the customer site. A customer can talk on the telephone at the same time that data are being transferred.

The telephone company does not have to install any special equipment to use voice-grade modems. However, when the telephone company offers DSL service it has to install digital subscriber line access multiplexers at the end offices. Because special equipment has to be installed, DSL service is not available in all areas. One factor that determines the availability of ADSL is the distance to the central office. In general, if the distance is greater than 18,000 feet ADSL service is not available. Also, the prices are fluctuating as DSL becomes available in more and more areas.

Cable Modems

Cable modems are a service offered by cable television companies. Often, the cable television company or the

telephone company operate as both a transmission carrier and a network provider. As with ADSL, the downstream speed of cable modem is much faster than the upstream speed. The upstream speeds are similar to ADSL, but the downstream speeds can be several times faster. However, multiple customers on the same cable line share the capacity. When many customers are accessing the network at the same time the real downstream transmission speed can be much lower. If network traffic is bursty, though, the chances are unlikely that all customers are downloading at exactly the same moment so that sharing does not become an issue until about 100 customers share the same cable service (Panko, 2001).

Satellite

An often cost-effective alternative for network access is the use of satellite technology. This may be particularly true in areas where other wire-based technologies are not

yet available. For example, many rural areas do not have the density of potential users that can justify the cost of installation of wire-based technologies such as DSL or cable modems.

Satellites are characterized by the type of orbit they use. The most common type of satellite is the geostationary satellite. These satellites orbit the Earth at about 22,300 miles directly above the equator at exactly the same speed as the Earth's rotation. Because of this, the satellite always appears to be in the same position in the sky and tracking of the satellite by stations on Earth is simplified (Stallings, 2001). The disadvantage of this type of satellite is that the propagation time it takes for the signal to be sent from a transmission station on the Earth to the satellite, and then to be received back on the Earth is about 0.24 s. For large data downloads this is not noticeable because the time overlaps with the time to receive the entire message. However, for interactive computer use or for applications such as telephone calls the time is noticeable and can be annoying. In addition, geostationary satellite signals are not received well in very far northern or southern regions of the Earth.

Two other types of orbits include low and medium Earth-orbiting satellites. This technology is being proposed for use with mobile terminals and remote locations that need stronger signals and less propagation time. Successful businesses that use this technology are rare. One company currently operating under bankruptcy regulations, Iridium, provides global, mobile satellite voice and data solutions with complete coverage of the Earth through a constellation of 66 low Earth-orbiting satellites (Iridium Satellite, 2002).

At least one company offers packages with two-way, always-on, high-speed Internet access via satellite that is specifically designed to meet the needs of small businesses (StarBand Communications, 2002). StarBand uses a 24 × 36 inch dish and a special modem at the customer's site to connect the user's site to the network. StarBand also serves as a network provider. Fees include an initial equipment fee and a monthly fee for access. Value-added services such as domain registration and networking support for setting up small office networks can be a part of the package.

Fixed Wireless

Fixed wireless access to public networks is available in some public places such as airports and coffee shops, called hotspots, to provide Internet access for customers. It is also popular for private individuals and businesses to provide access to the wired public Internet. The preferred wireless access technology is known as Wireless Fidelity (WiFi) and is defined in the IEEE 802.11b standard (Henry & Luo, 2002). The IEEE 802.11 is a family of specifications for wireless technology (Webopedia, 802.11, 2003). The 802.11b specification provides up to 11-Mbps transmission in the 2.4-GHz band, the 802.11g specification provides 20+ Mbps in the 2.4-GHz band, and the 802.11a specification provides 54 Mbps in the 5-GHz band.

Wired equivalent privacy (WEP) is the standard for securing WiFi networks, but it is often not enabled because of its complexity (Henry & Luo, 2002). When WEP is not

enabled, a hacker can sit in a car in the parking lot outside of a business and read the network traffic, which may include information such as credit card numbers. Even if WEP is enabled, the encryption key can be recovered with a small amount of effort to read the traffic. The best way to provide secure access over WiFi is to run a virtual private network (VPN) with encryption such as IPSec to provide a secure end-to-end channel. But this is also a complex configuration to support.

Although the IEEE 802.11 standards such as WiFi are very popular, they have performance limitations when supporting more than just a few users. A new standard is being developed to provide broadband wireless access for longer distances and broader coverage called IEEE 802.16 (Geier, 2003). The IEEE 802.16 standard was published in April 2002 and is meant to provide network access to homes, small businesses, and commercial buildings. The IEEE 802.16 standard supports point-to-multipoint connections, with data rates as high as 120 Mbps in the 2 to 66 GHz band. At these frequencies only line-of-sight transmission is possible. A version called IEEE 802.16a, published in January 2003, operates between 2 and 11 GHz to provide non-line-of-sight access.

Integrated Services Digital Network

Many telephone companies offer integrated services digital network (ISDN), a digital service that runs over ordinary telephone lines. As with voice-grade modems the ITU-T has set standards for ISDN. ISDN can be used as an access technology and within a public network. Basic ISDN service includes two "B" channels, each at 64 Kbps, and a "D" channel that is used for signaling. It is possible to use one "B" channel for voice and one for data, but most service providers bond the two "B" channels together to provide a 128 Kbps data rate. Standards for higher rates also exist. Like ADSL, ISDN requires that the telephone company install special equipment at the end office before an ISDN service can be offered. A special ISDN "modem" is used at the customer site.

ISDN is the result of efforts in the early 1980s by the world's telephone companies to design and build a fully digital, circuit-switched telephone system (Tanenbaum, 1996). Because ISDN is circuit-switched, there is never any congestion on the line from the customer to the network service provider. However, because data traffic is generally bursty, the user pays for bandwidth that may not be used. ISDN is expensive compared to the modest gain in transmission speed. The customer generally has to pay for the ISDN line to the telephone company and then has to pay an additional fee to a network service provider. The use of ISDN is likely to decline as other technologies that have higher speed and are more economical become available.

Digital Leased Lines

In terms of number of circuits, the most common leased lines are 56 Kbps (Panko, 2001). The transmission capacity of a 56 Kbps is actually 64 Kbps but 1 bit of 8 is used for signaling, leaving the user with 56 Kbps. A 56 Kbps line is the same as digital signal zero (DS0). The next higher transmission speed is a T1 (DS1), which provides

1.544 Mbps. Although a 56-Kbps leased line is relatively inexpensive, the difference in cost and performance between a 56 Kbps and a T1 line is large. Therefore, fractional T1's are also available at 128 Kbps, 256 Kbps, 384 Kbps, and so on. In Europe and other parts of the world a different digital hierarchy of transmission capacities is used. The standards are defined in the Council of European Postal and Telecommunications authorities (CEPT). The E1 standard operates at 2.048 Mbps and is analogous to the T1 standard. The next step is a T3 (DS3) at 44.7 Mbps and the corresponding CEPT E3 standard operating at 34.4 Mbps. Higher transmission capacities are available using synchronous optical network (SONET) and the synchronous digital hierarchy (SDH) and range from 155.52 Mbps to 10 Gbps.

Digital leased lines can be used to build a company's leased line private network, as shown in Figure 1, or can be used in combination with a public network, as shown in Figure 2. When leased lines are used to access a public network the traffic between several sites must be multiplexed over the single access line. Therefore, it is important to be sure that the leased line is fast enough to support this traffic. For example, if a site has fifteen 56 Kbps leased lines connected point-to-point with other sites and wants to convert this to a single access line to a public network, then the access line would require at least 840 Kbps of capacity. From Table 1, this would require a T1 line (Panko, 2001).

Synchronous Optical Network

SONET defines a hierarchy of standardized digital data rates. A compatible synchronous digital hierarchy version has been published by the ITU-T. SONET is intended to provide a specification for high-speed digital transmission over optical fiber.

SONET, or SDH, is the highest speed and most costly digital leased lines. SONET/SDH operates in multiples of 51.84 Mbps. Standards are specified as OCx for SONET and STMx for the SDH specification. A common SONET/SDH speed is OC3/STM1 at 156 Mbps. Other common rates include 622 Mbps, 2.5 Gbps, and 10 Gbps. SONET technology can be used for access both to the public network and within the public network. It is installed in a ring for a fault tolerant network (Dunsmore, Skandier, Martin, McKelvey, & Woods, 2003).

X.25

X.25 was developed during the 1970s for use in public packet-switching networks, and this standard was later ratified by the ITU-T (Tanenbaum, 1996). X.25 is very slow, often running at only 9600 bps, but it is fast enough for the text-based transmissions of early networks. Its use is declining, but it is still popular in the United States for low-speed applications such as a department store's point-of-sale transaction network. Also, there are many X.25 legacy connections, particularly in Europe and in countries where the telecommunications infrastructure is lagging. X.25 is one of a few standards that have been set by the ITU-T for public switched data networks. Other standards set by the ITU-T for public networks include ISDN, frame relay, and ATM.

Frame Relay

Frame relay is the most popular technology choice within public switched data networks today (Panko, 2001). Its speed range matches the needs of the greatest corporate demand, and it has very competitive pricing. Frame relay can also be used instead of leased lines as an access technology or to connect company private networks. Its low overhead even makes it suitable for interconnecting LANs and high-speed stand-alone systems (Stallings, 2001). Current commercial offerings of frame relay include MCI-WorldCom, which offers frame relay service access speeds from 28.8 Kbps to 45 Mbps (MCI-WorldCom, 2002), and Qwest, which offers frame relay service access speeds from 64 Kbps to 45 Mbps (Qwest, 2002).

Typically, a company accesses a public frame relay network through a leased line. Several frame relay virtual circuits are multiplexed over a single access line to the public network. A virtual circuit is a connection from source to destination and represents an end-to-end path that all packets from the same source to the same destination go through. Virtual circuits simplify forwarding decisions and make the costs of the switches cheaper. A permanent virtual circuit (PVC) is one that is set up manually when a company first subscribes to a public network and changes only when the site changes. For a large company network, a PVC is established for every pair of sites that would get a leased line in a private leased line network as seen in Figure 3.

The frame relay protocol includes functions for detection of transmission errors and congestion control functions. The frame relay protocol allows users to negotiate a committed information rate (CIR) when a connection is set up. The CIR is the network's commitment to deliver data in the absence of errors and represents the user's estimate of its "normal" traffic during a busy period. Any traffic sent above the CIR is not guaranteed to arrive but may arrive if the network has the capacity to deliver it. In addition, a maximum allowable rate is defined, and all traffic above this level is discarded (Frame Relay Forum, 2002).

Figure 3: Permanent virtual circuits.

Pricing for frame relay is usually divided into several different components. First, the company needs a frame relay access device. This is a router that has been modified to allow it to communicate with the frame relay's first switch. Second, the company must lease an access line to the nearest POP of the public network. If the POP is a long distance away, then the customer must use expensive, long-distance access lines. The leased line must be fast enough to handle the available bit rate on the line.

At the POP, the leased access line connects to a port on the frame relay switch of the public network. The fee for the port is usually the largest single element in frame relay pricing. To prevent wasting port capacity, the speed of the leased line should be at least as fast as the port speed. There is usually a monthly fee for each PVC and this fee depends on the speed of the PVC. Finally, some vendors build in other fees, such as per-bit traffic charges or fees to set up and tear down switched virtual circuits that are established on a call-by-call basis. Frequently there are substantial initial charges to install the access device, leased line, port connection, and PVC.

Asynchronous Transfer Mode

Asynchronous transfer mode is sometimes viewed to be the universal technology for networking and may replace many other current offerings (Stallings, 2001). ATM is not as popular as when it was first introduced but still is used in many networks. Just as frame relay allows messages to be divided into many frames that can be sent across a switched network, ATM uses cell relay. Like frame relay, ATM multiplexes many logical connections over the same physical interface, sending information in fixed size 53-byte cells. ATM can support data, video, voice, and Internet traffic on a single access line.

The use of cells in ATM allows many important features to be defined for a virtual channel. For example, users can negotiate the ratio of cells lost to cells transmitted, cell delay variation and parameters such as the average rate, peak rate, burstiness, and peak duration for a virtual channel (ATM Forum, 2002). The ATM service can use permanent virtual channels for static connections. ATM also allows switched virtual channels to be set up dynamically on a call-by-call basis.

Four classes of ATM service have been defined as follows (Stallings, 2001):

1. **Constant bit rate:** The network provider ensures that this rate is available, and the customer is monitored to be sure the rate is not exceeded.
2. **Variable bit rate (VBR):** A sustained rate for normal use is defined, and a faster burst rate for occasional use is also defined. The faster rate is guaranteed, but not continuously. The ATM Forum divides VBR into real-time VBR (rt-VBR) and non-real-time VBR (nrt-VBR) (ATM Forum, 2002). With rt-VBR the application has tight constraints on delay and delay variation, but the rate is allowed to vary according to parameters specified by the user. The nrt-VBR is for applications that are bursty but do not have tight constraints on delay and delay variation.

3. **Available bit rate (ABR):** The user has a guaranteed minimum capacity. When additional capacity is available on the network, the user may burst above this without risk of cell loss.
4. **Unspecified bit rate (UBR):** Cells are delivered with best effort, meaning that any cell may be lost. The main difference between UBR and ABR is that ABR provides feedback to the user so that the user can control the amount of data being sent and reduce the risk of loss.

ATM is a high-performance service and is expensive. In the range of speeds where ATM speeds overlap with frame relay, frame relay is more attractive because it is cheaper. However, as customer needs increase, ATM becomes a more attractive option. ATM is widely used within high-speed public networks and by companies that need higher speed private networks. Most ATM public switched data network providers currently offer speeds from 1 to 156 Mbps, with higher speeds on the way. These public networks require access lines ranging from T1 to a SONET OC-3 line. MCI-WorldCom offers ATM access speeds from 1.544 to 622 Mbps (MCI-WorldCom, 2002). Qwest offers ATM access speeds from 1.544 to 155 Mbps (Qwest, 2002).

Passive Optical Networks

The telecommunication backbone networks capacity has grown much faster than the access networks (Kramer & Pesavento, 2002). The access network, sometimes called the *last mile*, between the backbone networks and business local area networks is still the bottleneck. Today, cable modems and digital subscriber lines are the most widely deployed solutions. The capacity that they provide will be too small for future applications and they require placing electronic devices near the users that are too far away from the CO. One of the highest costs is providing and maintaining electrical power for these devices (Kramer, 2002). Fiber optical cables can provide the needed capacity. One configuration for the last mile problem is to run a separate fiber optical cable from the CO to every business and home, but the expense of multiple point-to-point links is too great. Another possible solution is for multiple users to share a fiber optical cable as in passive optical networks (PON). A PON uses a point-to-multipoint architecture as seen in Figure 4, where the internal components are passive optical components such as splitters that require no power (Kramer, 2002).

Figure 4: Passive optical network.

Originally, it was assumed that a PON would use ATM as its data link layer protocol (Kramer, 2002). The use of ATM is described in the ITU-T standard G.983.1 (Effenberger, 2001). But ATM has not kept up with the popularity of Ethernet in the LAN (Kramer, 2002). Ethernet is widely available and an accepted standard so may be the protocol of choice for a PON and is sometimes called an Ethernet PON (EPON). In the downstream direction from the CO to the user, Ethernet packets pass through a passive optical splitter and are delivered to 4 to 64 users. The users extract only the packets that are directed to their media access control (MAC) address. In the upstream direction from the user to the CO, Ethernet packets reach only the CO, not other users. However, the packets may interfere with each other because they share the link from the splitter to the CO. Because packets destined for a single user are broadcast to multiple users encryption should be used to provide privacy (Kramer, 2002).

Choosing a Private Network or a Public Network Provider

There are several categories to consider when one decides whether to use a private network or a public network. If a public network is chosen, then these same categories can help in choosing a network provider. A survey of ISPs conducted in 2001 found that the top three areas that differentiated the best ISPs from the rest were reliability, performance, and low cost (Greenfield, 2001). Subscribers to ISPs in the survey also considered support to be important. In addition, network control is a factor in deciding, whether to choose a private network or a public network. Other factors mentioned in the survey include breadth of service, security, installation, repairs, and remote access.

Reliability is defined as the amount of time the network service is available. Reliability can be difficult to evaluate because several different things can cause downtime. For example, if a user is trying to transfer data from a server that is down then from the user's point of view the network is down. When a packet switching node or dedicated leased line in a large complex network does fail it affects a large amount of transmission capacity and therefore a large number of users. For example, MCI-WorldCom's frame relay outage in August 1999 lasted 8 days and affected 30% of MCI's frame relay customers, perhaps as many as 70,000 users (Orenstein & Ohlson, 1999).

An advantage to using a private network is that the redundancy of the network can be designed according to the business requirements. The major disadvantage is that it requires investment in redundant packet switching nodes and leased lines for fault tolerance, personnel training, disaster recover planning, and testing. These expenses are often overlooked or have less priority when a private network is designed (Snow, 2001). Or, once the private network is operational, these expenses are considered low priority. Therefore, when there is an outage the business is not prepared for it, and its effects are worse than if a disaster recovery plan had been written.

The reliability of a public network has advantages and disadvantages. The advantage of using a public network is that because the cost is spread out over several subscribers

added investment in reliability can be cost-effective. The disadvantage is that a subscriber is completely dependent on the provider for reliable service. Service level agreements have to be negotiated with clear and strict penalties if the provider does not meet the negotiated reliability. If reliability is of high importance to a business, then they may subscribe to two or more public network providers for added reliability.

The choice between a public and private network includes determining the trade-offs between the cost and performance of the network. The performance of the network is defined by throughput and delay. The throughput is the actual data speed seen by the user in bits per second. The delay is the maximum end-to-end delay that a packet will incur in the network.

The costs of the network may vary depending on the type and volume of traffic that the network will carry. The type of traffic on a network is classified as either stream or bursty (Stallings, 2001). Stream traffic is long and relatively constant and therefore more predictable than bursty traffic. An example of stream traffic would be voice traffic or uncompressed video. Bursty traffic is short and sporadic such as computer-to-computer communication in the Internet. Although sporadic, bursty traffic often requires a large transmission capacity for brief periods of time. Many Internet applications such as the Web and e-mail create such bursty traffic. If there are several bursty traffic sources that share a communications link and the volume of the combined traffic is high then the aggregate traffic on the link may be considered stream traffic.

Bursty traffic requires a different type of network than stream traffic. For example, if one file is required to be transferred from an office to a central site once a day, then a dial-up connection may be the most feasible. Conversely, if there is bursty traffic to be transferred among a small number of sites and the aggregate of the bursty sources has a high volume, then a private packet-switching network would be more efficient. Leased lines are not dependent on volume but have a constant fixed rate for a given transmission capacity and distance. If the percentage of use of the leased line is high enough then the volume discount given by the constant fixed rate can be cost-effective. For example, large nationwide contracts can negotiate T1 access lines for \$200 a month, whereas users in metropolitan areas can get T1 access for approximately \$900 per month (The Yankee Group, 2001). Compare this to \$50 per phone times 24 channels; this is \$1,200 per month for an equivalent amount of bandwidth.

If there is a moderate volume of bursty traffic to be transferred among a medium to large number of sites, then a public network may be a better choice. Because the public network provider has several subscribers, the aggregate volume of traffic is great enough to have high use and therefore is cost-effective for the provider. These savings are passed on to subscribers who do not have enough volume of traffic to justify a private network.

The costs for some network technologies can be negotiated with the expected performance in mind. For example, with frame relay, the user chooses the committed information rate in bits per second and committed burst size (Frame Relay Forum, 2002). A frame relay network provider will also specify a maximum end-to-end

delay for a frame in their network. These parameters are a part of the pricing for frame relay service.

The price of a network is usually divided into a fixed cost and a variable cost. The fixed access cost depends on the type of access technology that a user connects to the POP with and the distance the user is from the POP. There may not be a variable cost, but if there is, the price is dependent on the volume of traffic. A user may subscribe to a certain data rate from the network for a fixed cost and if the user exceeds the limit, the user is charged for the additional usage.

Support is defined as the quality of a provider's technical and logistical help. In one survey the complaint most cited was the lack of support (Greenfield, 2001). Networks do break and fail. A good network provider should be fast to respond and correct problems. A business should consider where the nearest technician would be coming from to service their sites. Service-level agreements will define minor and major problems and the type of responses that the network provider will provide.

An organization relies on its network to operate its business (Stallings, 2001). Management requires control of the network to provide efficient and effective service to the organization. There are trade-offs between a private and public network when considering control. Three areas of control need to be considered, including strategic control, growth control, and day-to-day operations.

Strategic control of a network is designing and implementing a network to satisfy the organization's unique requirements. If the organization operates its own private network then it can determine the configuration of the network. But, if the organization uses a public network the organization does not have strategic control over the configuration of the network. The public network provider designs the network for the average subscriber.

Growth control of the network is the ability to expand and make modifications to meet the changing requirements of the organization. It includes adding switching nodes and leased lines, modifying the capacities of the leased lines, and changing the network technology. A private network provides the maximum flexibility for growth control because the organization has complete control over the network. If an organization is a subscriber to a public network it has almost no growth control. All requirements are constrained by the capabilities of the public network.

The other type of control is the day-to-day operation of the network. This includes the ability to handle traffic during peak times, to diagnose problems, and to repair problems quickly. In a private network the organization sets the priorities of the day-to-day operation to fit their business. But, with a private network, they also have to hire or develop in-house expertise to maintain the often complex network. In addition, the organization has to address the reliability of the network by determining where to install redundant packet-switching nodes and dedicated leased lines. If an organization is a subscriber to a public network then it is dependent on the public network provider. There are peak traffic times and the public network provider may focus its efforts on the overall health of the network and not on an individual user. Conversely, the provider can afford more redundancy and hire

or develop more in-house expertise because these costs are spread out over several subscribers.

Other factors that are important in choosing a network solution include breadth of service, installation, repairs, and remote access. Many network providers offer a wide breadth of value-added services, as previously described. A provider that can provide value-added services such as Web hosting bundled with its network service can have a big advantage. If the server is on the same network that other customers are connected to then performance is better.

The installation and repairs category includes the timeliness and quality of an installation. Networks are complex and often require coordination among multiple organizations. For example, in the United States if a leased line crosses two different LATAs, then at least one local provider and at least one IXC will be required. Also, realistic time schedules are important because a rushed installation usually results in a poor-quality installation and long-term problems.

For many businesses remote access is important to be competitive. Remote access permits users in a business to communicate often with e-mail and to access corporate data. Remote access is dependent on the number and location of the network provider's in-dial modem pools. If this is an important part of the business model, then a business should look for a provider that has multiple access points in the areas that their employees travel.

PUBLIC NETWORK SECURITY

When data from multiple sources is shared on the same public network, such as the Internet, there are several security concerns about the data. For example, it is possible that the data can arrive at a destination that did not originate from the expected location. Authentication is a mechanism for ensuring that a message was sent by the user identified as the sender in the message and that the original message content has not been modified. A second security concern is that the data may have been maliciously altered. Verifying that the data has not been modified is called maintaining integrity. In addition, the data may be monitored by a third party. Confidentiality prevents users other than the two communicating users from reading the exchanged messages by scrambling the content of the message in such a way that only the receiving user can unscramble the message. Protecting the confidentiality of the data may be important.

The global Internet can be used to provide an intranet or an extranet by creating a virtual private network (VPN). A VPN is a private network that is deployed over public facilities but provides the additional levels of security, confidentiality, quality of service, and manageability over public networks (Cisco, 2001). A VPN can be created when all sites are already connected to the Internet. With a VPN, hosts at different sites communicate across the Internet using either a tunnel mode between local networks or by using a direct transport communication.

Security issues still exist with VPNs because the company no longer has control over the entire data network. One problem is the confidentiality of the data, because the Internet was not designed to support confidential

transmission. This problem can be solved using encryption and by using tunnel mode for communication. A second problem is congestion on the Internet. Congestion is a security issue as well as a performance issue. Congestion can cause data to be lost or delayed. Additionally, a malicious user or group of users can perform a denial-of-service attack. In a denial-of-service attack, the network is flooded with malicious data and useful data is prevented from using the network.

Security can be implemented in the individual applications. For example, electronic mail can use S/MIME or PGP to secure the message or the Web can use SET to secure credit card transactions (Stallings, 2003). Authentication services such as Kerberos or X.509 restrict access to authorized users and authenticate requests for service. Security can be implemented between the application layer and the transport layer that transfers information between hosts as in SSL or TLS. One of the most successful security protocols SSL is typically integrated into Web browsers but can be used by other applications. Finally, security can be implemented at the network layer securing all information that is transmitted on the public network even though the application may not be aware of it as in IPsec. This provides security for all applications, including those that have no inherent security built in. At a minimum, a firewall should be installed to protect internal applications and hosts from being accessed by external unauthorized users. Many times these security mechanisms are applied at the application, transport, and network layers providing multiple layers of security.

Authentication Services

An authentication service is one that verifies the identity of the party who sent the data and the integrity of the data. A principal is the party whose identity is verified, and the verifier is the party who demands assurance of the principal's identity. Data integrity is the assurance that the data that is received is the same as the data that was sent. An authentication service verifies a principal on behalf of a third party that is the target of the communication. Two of the most commonly used authentication services are X.509 and Kerberos.

X.509 and several secure network protocols, including S/MIME, IPsec, SSL/TLS, and SET, use public key cryptography in some manner (Stallings, 2003). With public key cryptography there are two keys, a private key that is only known to the owner of the private key and a public key. The private key/public key pair can be used to encrypt and decrypt messages. For example, if Alice wants to send an encrypted message to Bob, Alice can encrypt the message, called plaintext, using Bob's public key and send the encrypted message, called ciphertext, to Bob. After receiving the ciphertext, Bob can use his private key to decrypt the message. The idea behind this encryption is that, given the public key, the amount of computing time that it would take to calculate the private key (and then to decrypt the message) is much longer than the usefulness of the encrypted message.

Public key encryption also works using the keys in the other direction. Alice can use her private key to encrypt the message and send the encrypted message to Bob. Once

Bob receives the message, he can decrypt the message using Alice's public key. A message that is encrypted by a sending party using the sender's private key is said to have a digital signature. A receiver can decrypt the message with the sender's public key and be assured that only the sender could have sent it. To be secure, however, a user must be assured that the public key is in fact the public key of the identified user and not an imposter. If authentication and confidentiality is required, Alice can sign the message using her private key and then encrypt the result with Bob's public key.

The X.509 authentication service maintains a repository of public keys that are signed by a certificate authority. A certificate is a public key of a user that is signed (i.e., encrypted) with the private key of a trusted certificate authority (CA). The certificate is stored in a directory server so that other users can obtain a copy. Any user that has a copy of the certificate authority's public key can then verify a registered user's certificate by obtaining a copy of the certificate and then checking the digital signature of the certificate. The process to communicate securely using the X.509 authentication service is as follows. First, Bob registers his public key with the CA. The CA signs Bob's public key with the CA's private key. Alice wants to communicate with Bob and has a trusted copy of the CA's public key but does not have Bob's public key. Alice requests a certificate for Bob, which is Bob's public key signed by the CA's private key. Alice verifies the signature by decrypting the CA's encrypted copy of Bob's public key using the CA's public key and comparing it to the copy provided by Bob. If the two keys are the same, then Alice is sure that it is Bob's public key and then uses it to securely communicate with Bob.

An alternative to public key cryptography is secret key cryptography. With secret key cryptography there is a single key that is shared between parties that want to exchange messages. If Alice wants to send an encrypted message to Bob she encrypts the message with the shared secret key and sends the ciphertext to Bob. Bob uses the same secret key to decrypt the message. Secret key cryptography is preferred to public key cryptography because the time to encrypt and decrypt, for the same length key, is much faster. In addition, secret key cryptography is considered more secure than public key cryptography because none of the key information is made public. With public key cryptography there is a very small probability, depending on the length of the key, that the private key could be calculated quickly enough to be able to decrypt the message while it is still useful. However, the difficulty with secret-key cryptography is how to exchange the shared secret key between a client and a server without a third party discovering it.

Secret key cryptography is faster than public key cryptography, but requires exchange of a shared secret key. A hybrid system that solves the key distribution problem, but is faster, uses both secret key and public key cryptography. Public key cryptography is used to exchange a secret session key. This session key is used as input into a secret key algorithm for encrypting and decrypting messages during a session. The session key could be used for a single session or may last for a limited amount of time.

Kerberos is a distributed authentication service that allows a process (a client) running on behalf of a principal (a user) to prove its identity to a verifier (an application server, or just server) without sending any shared secret key across the network (Neuman & Ts'o, 1994). Kerberos uses secret key cryptography to create a new shared secret key and exchange it between two parties who want to have a secure communication. Because a shared secret key can be regenerated at any time, Kerberos uses a timeout to cause the shared secret key to expire in a time period that is much shorter than the computing time that it would take an attacker to calculate the shared key by seeing only the ciphertext.

With Kerberos the client and the application server do not initially share a secret key. The basic Kerberos authentication protocol allows the client to obtain a shared secret key, called a session key, with the application server. In the basic protocol, the client shares a secret key (i.e., a password) with a special authentication server. Similarly, each application server shares a secret key with special server called a ticket-granting server. When the client contacts the authentication server, the authentication server generates a special key, called a Kerberos ticket, which authenticates the client to the ticket-granting server. The Kerberos ticket is encrypted using the client's secret key, along with a timestamp, and sent back to the client. The client then uses the client secret key to decrypt the message and retrieve the Kerberos ticket, and timestamp. With this technique no passwords are ever sent over the network. The client then uses the Kerberos ticket in a series of messages with the ticket-granting server to obtain the shared secret session key with the application server.

Kerberos is not effective against password attacks. If a user selects a poor password then an attacker can impersonate the user. Also, if the computer in which the password is being entered has been compromised then the password may be able to be obtained by an attacker. To be useful, Kerberos must be integrated with all parts of the system so that all application servers require the Kerberos protocol to be observed (i.e., the servers must be "Kerberized") before granting access to a client. Since it was first developed in the mid-1980s, Kerberos has gone through several enhancements to improve the level of security that it provides. A free implementation of the Kerberos protocol is available from the Massachusetts Institute of Technology and in several commercial products (Kerberos, 2003).

Application-Layer Security

PGP (Pretty Good Privacy) is a general-purpose application providing confidentiality and authentication service (PGP, 2003). The first version of PGP was released in 1991 and was one of the first widely available packages to offer confidentiality and authentication service to the public. PGP packages several algorithms for public key encryption and symmetric key encryption into an easy to use package that runs on many platforms such as Windows, UNIX, and Macintosh. It is used for providing secure and authenticated communication, e-mail, and file storage. It was not developed by the government, nor does the government control it. A freeware version is available

for individual, noncommercial use. PGP is popular and OpenPGP is on the standards track for the Internet community (RFC 3156, 2001).

S/MIME (Secure/Multipurpose Internet Mail Extension) is a standard way to provide confidentiality and authentication service for the MIME Internet e-mail format originally developed by RSA Data Security, Inc. (Internet Mail Consortium, 2003). It is defined in several RFCs and an overview can be found in (Internet Mail Consortium, 2003). It is an industry standard for commercial and organizational use. S/MIME uses public key certificates in the X.509 version 3 format. S/MIME and PGP/MIME are the two proposed methods for providing secure e-mail and provide the same type of services to users, but the formats are very different.

SET (Secure Electronic Transactions) is an open technical standard developed by Visa and MasterCard for secure payment card transactions over the Internet (Webopedia, "SET," 2003). SET uses digital signatures for authentication to allow merchants to verify that buyers are who they claim to be. In addition, SET provides a mechanism for a buyer to transfer a credit card number directly to the credit card issuer for billing and verification without requiring that the merchant have access to the credit card number (Webopedia, SET, 2003). SET operates by using a hierarchy of Certificate Authorities and a method of entity authentication called trust chaining. The trust chain begins with the card holder and then moves up to the merchant CA and on to a Payment Gateway CA and up the hierarchy to the CA at the top of the hierarchy, which is referred to as SET Root CA. Each CA is validated by the CA above it in the hierarchy. SET Root CA is owned and operated by SET Secure Electronic Transaction LLC and is the only CA that can issue digital certificates to a Brand or a financial institution that has its own distinct logo and issues and accepts payment cards or accounts. Current SET Brands are Maestro, MasterCard International, PBS International A/S/Dankort, and Visa International (SET Brands, 2003).

PayPal enables online transactions between buyers and sellers who do not have the resources to process credit cards (PayPal, 2004). Sellers establish accounts with PayPal. Then, buyers go to PayPal's Web site and pay by credit card or bank account. PayPal pays the seller minus a fee based on the amount and a static transaction fee. The service is free for the buyer. PayPal is not an escrow service. Escrow services take money from potential buyers and hold the funds until the buyer receives and inspects the merchandise. There are escrow services such as escrow.com available.

Socket-Layer Security

The secure socket layer (SSL) was originally developed by Netscape and came bundled with their Web browser to secure credit card transactions across the Internet (Stallings, 2003). It prevents an adversary from intercepting an online order with the credit card number. It also authenticates the server to the client so that an adversary cannot set up a Web site that appears to be a legitimate business, but just gathers credit card numbers and makes fraudulent charges. It is an interface between

an application layer protocol and the TCP transport layer. The original and most common use of SSL is by the application layer protocol hypertext transfer protocol (HTTP) for Web transactions. SSL is embedded in specific applications such as Netscape and Microsoft Internet Explorer. The use of SSL over HTTP is set by using “https” instead of “http” in the Uniform Resource Locator. SSL can also be used for other application layer protocols. Transport layer security (TLS) is based on SSL and is defined in RFC 2246 (RFC 2246, 1999). There are two differences between TLS and SSL. First, TLS uses the HMAC authentication method described in RFC 2104 (RFC 2104, 1997), which is slightly different than the one defined for SSL. Second, the authentication covers more fields in TLS than in SSL.

At the beginning of a SSL session the client and server negotiate an encryption algorithm, the session keys, and authenticate the server to the client. As an option, the client can be authenticated to the server although this is not common. After setup, SSL encrypts all the data using the session key providing a secure channel for exchange of information such as credit card numbers, online banking, and stock trading. At the sender, SSL/TLS receives the data from the application such as HTTP, encrypts it, and then sends it over the transport layer protocol TCP. At the receiver, TCP hands the data to SSL/TLS, which decrypts it and passes on to the application.

Network-Layer Security

Security implemented at the network layer secures all information that is received or transmitted over a public network. This provides security for all applications, including those that have no inherent security built in. A business that connects to a public network such as the Internet should have a firewall that restricts and controls access to internal information resources from external users. This provides one level of security for applications and operating systems that have no inherent security or have security vulnerabilities. In addition, the Internet has developed an architecture for the Internet protocol that operates at the network level and is called IP security or, more commonly, IPSec for securing received and transmitted information (RFC 2401, 1998). IPSec defines an architecture for providing security at the network layer in which there are several options. The individual components of IPSec are defined in several RFCs and a list of these RFCs are listed in RFC 2411 (RFC 2411, 1998). A high-level overview of IPSec is presented in (Stallings, 2003).

It is essential for businesses to have Internet connectivity. However, the connection to this public network permits the outside world to have access to the assets of the business. Because it is impractical to secure all systems in many businesses, a firewall is placed between the private network and the public Internet to protect the business from external attacks on their internal systems (Stallings, 2003). All traffic between the private and public network is directed to the firewall providing a single choke point to enforce defined security policies. The firewall is configured to only pass authorized traffic. A single choke point simplifies management and gives the business an ability to monitor and audit events. It also provides a platform for IPSec.

There are several ways to configure and operate a firewall. A packet-filtering firewall filters traffic based on IP addresses and TCP port numbers. Systems are addressed by IP addresses on the Internet and individual applications on a system are referenced by TCP port numbers. E-mail and web server applications operate on particular TCP port numbers. Therefore, a packet-filtering firewall restricts services by restricting the access to certain hosts based on the IP address and restricts access to services based on TCP port numbers. Stateful inspection firewalls create a directory of output TCP connections and matches their profiles with incoming connections to control access. Application-level firewalls have a proxy server that relays application-level traffic. If the application-level firewall does not support an application, then no communication is possible between the private and public networks. In addition, certain specific features of an application can be restricted. This can be more secure than the other types of firewalls, but requires a system that can support the processing needs of all users. In other words, it does not scale well to a large community of users.

IPSec is used for secure office connectivity over public networks, secure remote access, extranet and intranet connectivity, and to enhance electronic commerce (Stallings, 2003). A remote office can use IPSec to connect to the main office network over a public or private network to provide connectivity and make it appear that the remote office is directly connected to the main network. IPSec can also be used by mobile users such as salesmen to provide a secure remote access to the main office network. The user can connect to a local ISP and with IPSec software connect to the main office network. It can also be used to provide secure communications to a partner in an extranet, providing limited access to internal resources. Finally, it can be used to secure electronic commerce for financial transactions.

Two protocols are used to provide security in IPSec. The authentication protocol adds an authentication header (AH) to the packet to authenticate the data. The second protocol combines encryption and authentication to provide confidentiality and authentication by adding an encapsulating security payload (ESP) header. ESP can be used with or without authentication.

There are two modes of operation in IPSec: transport mode and tunnel mode. In transport mode the data being transferred is kept confidential and/or authenticated, but the source and destination addresses are known. Therefore, an adversary can determine the two parties that are communicating and could infer something from it. For example, a large amount of traffic between an individual and a bank is most likely financial transactions. This is called traffic analysis in the security community. Transport mode is used for remote, host-to-host, or host-to-intermediate connectivity.

Tunnel mode is commonly used to create an intranet over a public network. The data being transferred and the source and destination addresses are kept confidential and/or authenticated. This information is carried in a packet that has a new source and destination address. These new addresses are the addresses of an intermediate device, often a firewall, which connects between the internal business network and the public network.

Figure 5: IPsec tunnel mode.

Figure 5 shows using tunnel mode in IPsec. Using tunnel mode hides the original source and final destination addresses preventing traffic analysis.

To provide authentication and confidentiality in IPsec requires that secret keys be exchanged between the communicating parties. IPsec supports either manual or automated exchange of secret keys. In manual mode an administrator manually configures the devices with the secret keys. This is practical only for relatively small networks. For automated exchange of keys, IPsec has defined a protocol called the Internet Security Association and Key Management Protocol (ISAKMP). ISAKMP provides a framework to negotiate a specific key exchange algorithm, but specifies no specific algorithm. The default specific key exchange algorithm is the Oakley key determination protocol.

Remote users that need access to a corporate network can establish an encrypted virtual private network (VPN) connection (Poptop, 2004). A popular protocol called point-to-point tunneling protocol (PPTP) uses a client/server model for establishing VPN connections. It was developed by a consortium, including Microsoft. Server software called Poptop is available to connect PPTP clients to Linux servers.

PUBLIC NETWORKS IN THE INTERNET AND E-COMMERCE ENVIRONMENTS

Public networks provide a cost-effective solution for small businesses to connect to the Internet and participate in e-commerce because they provide connections to the public Internet through one or more locations. Access to the Internet is restructuring the marketing, sales, management, production, accounting, and personnel management in businesses (Moody, 2001). The Internet provides online up-to-the-minute reports for marketing. Marketing can easily monitor their competitors by accessing the online information and competitors can easily monitor a business. The Internet has had two effects on sales. First, a business can have a worldwide presence. Second, customers are demanding the correct information for deciding which business to buy from. The online purchase is now being handled automatically by software (e-commerce). Members of the sales department can access corporate information over the network while on the road. Management can now have access to more of

the organization. They can access information from marketing, sales, production, accounting, and personnel, including previous years' sales and regional performance of a product. They can have online meetings and stay in contact with e-mail. Production can receive quicker feedback from the field and have feedback from suppliers about their stock levels. Accounting can pay online and receive up-to-the-minute information. Personnel information such as directories can be provided online and manuals and training material can be placed online.

CONCLUSIONS

Public networks are an increasingly popular solution for businesses to link multiple sites together to exchange information and to connect to the Internet. Public networks offer several advantages over private networks composed of leased lines, including lower cost for a given performance, value-added services, and fewer requirements of maintaining in-house expertise for network maintenance, support, and similar administrative and management tasks. Public networks do have some disadvantages, including potential variation in performance because of congestion on the public network, lack of control over day-to-day operations, upgrades, and long-range planning for capacity changes and concerns for security. However, public networks that combine connectivity with extra services for secure communication are a good choice for many businesses.

Security concerns about public networks can be addressed with a variety of services and protocols, including the installation of VPNs, firewalls, authentication services and enhancements to the application, socket, and network layers. In the future, only organizations with special requirements in the areas of performance, control, and security will continue to maintain and install private networks. Even organizations that continue to have private networks will have at least one connection to the one global public network called the Internet to participate in activities such as e-mail and e-commerce.

GLOSSARY

Asynchronous Digital Subscriber Line A digital service that uses ordinary telephone lines to connect a customer to a public network. Asynchronous DSL has download speeds that are much faster than the upload speeds.

Asynchronous Transfer Mode A network technology characterized by sending data in fixed-size 53-byte cells and offering various levels of service.

Authentication Verifying the identity of the party; that is, being assured that that party is who he says he is.

Authorization Verifying that an authenticated party has permission to access a service or data.

Certificate A public key of a user that is signed (i.e., encrypted) with the private key of a trusted certificate authority (CA).

Certificate Authority A trusted service that maintains a database of public keys. The certificate authority guarantees that the keys in the database are legitimate by signing (i.e., encrypting) them with its own private key.

Ciphertext In cryptography, this is the result of encoding a plaintext message.

Confidentiality Ensuring that the data is only viewed by authorized parties.

Content Delivery Network (CDN) A value-added service that distributes the content to multiple locations and closer to the end user. By sophisticated caching schemes a CDN reduces response times.

Data Integrity The assurance that the data that was received is the same as the data that was sent.

Digital Signature The encryption of a document with a user's private key.

Firewall A gateway router, often between an internal business network and the public network, that has special functionality to filter out unwanted traffic or to redirect traffic to addresses that are hidden from the outside world.

Frame Relay The most popular technology choice within public switched data networks. Data are divided into frames that are sent on switched networks.

Interexchange Carrier A long-distance carrier in the public switched telephone network system.

Internet Service Provider An organization that provides access to the Internet by providing an Internet address and support of Internet protocols to the subscriber.

Leased Line A digital line that provides dedicated transmission capacity between sites.

Local Exchange Carrier A carrier that controls traffic within a single local access and transport area.

Plaintext In cryptography, this is the original message before it has been encoded.

Private Key One of the pair of keys used in public key encryption.

Private Network A business network composed of point-to-point leased lines between sites.

Public Key One of the pair of keys used in public key encryption.

Public Key Cryptography An encryption technique that uses two different keys, a public key and a private key.

Public Network A network that is publicly available to subscribers. A public network can be under government control, operate as a national monopoly, or can be a privately owned network whose services are sold to the public.

Public Switched Telephone Network The network that makes up the public telephone system.

Secret Key The key that is shared between two parties in secret key encryption.

Secret Key Cryptography An encryption technique that uses a single key for both encryption and decryption.

Secure Channel A communication channel or network that connects authenticated senders and receivers and provides encryption to maintain the confidentiality of the data.

Session Key A secret key that is valid only during a session, that is, between the time that a user logs in and the user logs out, or until a certain time period has elapsed.

Value-Added Carrier A network provider that provides a value-added network.

Value-Added Network A network constructed by a network provider that owns the packet-switching nodes and leases transmission capacity to add value to the network.

Value-Added Reseller A business that provides a service (e.g., Web hosting) that requires network connectivity and sells it for use with a particular public network provider. The network provider often gives discounts to the business for using the network.

Virtual Private Network A network that uses a collection of technologies applied to the public network to provide the same levels of privacy, security, quality of service, and manageability as private networks.

INTRODUCTION

The name of an information system often describes the utility it provides. The functionality of a transaction processing system, a decision support system, and an executive information system are self-evident. However, client/server computing is broadly defined; rather than describing system utility, client/server describes the system's architectural configuration. As a result, a client/server system may incorporate a broad range of technologies and address a variety of business situations.

Client/server computing is a form of cooperative processing. Specifically, a client/server system includes at least two software processes working together to provide application functionality. At the most basic level, a client software process requests services from a server software process. In turn, the server process supplies services to the client process. The service request may provide access to an organizational resource, such as a database, a printer, or e-mail.

Client/server computing involves the coordination of assorted computing/networking devices and the coordination of various software processes. The client/server *system* architecture describes the physical configuration of the computing and networking devices and the client/server *software* architecture describes the partitioning of an application into software processes.

The system architecture focuses on the physical architecture of the system. In this context, clients and servers are seen as computers rather than software processes. Simple client/server system architectures include a client (e.g., a personal computer) that links to a server (e.g., a mid-range computer) using a network (e.g., a local area network). Each computer provides processing and memory resources to the client/server application. The system architectural perspective views a client/server application as a network of computers sharing resources to solve a problem.

The client/server *software* architecture describes the partitioning of an application into software processes. In this context, clients and servers are seen as software

processes rather than computers. These processes may reside on the same computer or they may be distributed across a network of computers. The software architectural perspective views a client/server application as a set of programming modules sharing resources to solve a problem. This chapter focuses on the client/server *software* architectural perspective; consequently, a client shall refer to a software process that requests services from other software processes and a server shall refer to a software process that provides services to other software processes.

The resulting architectural complexity and physical separations within a client/server application introduce many security weaknesses. A typical client/server application consists of a set of software processes spread across several computers using exposed interprocess communications over a network. Beyond managing the overall configuration and increase exposure, each individual component (e.g., process, computer, and network) has its own set of security threats.

An effective security analysis consists of several activities, including an examination of the attractiveness of an attack to an adversary, a detailed list of security vulnerabilities, the likelihood and potential damage of each violation, and a list of existing and potential countermeasures (CCPS, 2002). The attractiveness of an attack to an adversary is influenced by many factors such as disgruntled employees, contractors, and trading partners; symbolism of the system assets, the system itself, and the organization; the number of and fundamentalism of activists; interests from foreign governments and terrorists; industry competitiveness; intellectual challenge; potential for adversary notoriety; potential adversary benefits; and the degree of impact to the organization, local/regional/national governments, and the community. Because the threat environment is constantly evolving, vulnerability analysis is exceedingly difficult. Within this chapter, we will identify several of the hardware, software, and data security vulnerabilities associated with client/server systems.

The damage from an information security violation may include a loss of system integrity, availability, and/or

confidentiality. Integrity strives to maintain data and process precision, accuracy, consistency, and usability. An available system provides authorized parties making an appropriate request with timely, complete responses. Confidentiality encompasses both privacy and access control. Privacy maintains the secrecy of data and user identities. For instance, an online shopper does not want others to learn his or her identity, credit card information, contact information, or buying behaviors. Access controls inhibit nonauthorized people from using a system and from knowing what system assets exist. Access controls may target systems, applications, particular functions, and/or specific data elements. Password protections are commonly used to control access.

This chapter begins with a review of three common client/server classification methodologies. The first methodology classifies a client/server application based on the computational role of the constituent processes. In particular, how an application distributes its presentation, application processing, and data services determines how the application is classified. The second methodology classifies an application based on the number of constituent processes; this is known as the tier-based classification. Finally, a server-based classification methodology is presented; it describes a client/server application in terms of the server process utility.

The subsequent section describes three broad categories of enabling technologies. The first set of enabling technologies, middleware, provides a client/server application the ability to integrate client processes with server processes. The second set of enabling technologies, component software, provides self-contained, self-describing software modules that may be combined to form applications. The third set of enabling technologies, networking technologies, bridges the gap among the computing and networking devices.

The final part of this chapter reviews intranets, extranets, and the Internet, three popular client/server implementations.

CLIENT/SERVER CLASSIFICATION

A client/server classification provides information about the particular system architectural configuration. Three client/server classifications are reviewed below. The first classification employs the PAD architecture, which describes the computational role of the client process. The second classification describes the number of separate processes in a client/server application, otherwise known as the number of tiers. The final classification describes the functional role of the server process.

Presentation/Application/Data Architecture

Client/server computing divides an application into two or more separate processes. The PAD architecture describes the computational role of both the client and server processes. In particular, the PAD architecture defines the computational requirements of an application in terms of presentation services, application services, and data services. The presentation services layer details the interaction between the user and the application. The application

services layer includes the embedded programming and business logic. The data services layer describes the connectivity to organizational resources such as data, printers, and e-mail (Goldman, Rawles, & Mariga, 1999).

Presentation Services

Presentation services represent the interactions an application has with the external environment. At the most basic level, these interactions involve user input and application output. User input represents the portion of the user's knowledge submitted to an application. Input provides application boundaries, operating parameters, and/or data. Application output strives to provide the user/process/application with new knowledge. Output includes printed reports, audio signals, screen displays, and data. In many cases, a client/server application receives input from and provides output to multiple sources, such as users, other software processes, and/or other applications.

Presentation services can also influence the degree to which a person will use an application. A complex, synergistic relationship exists among the user, the business problem/context, and the application (Dix, Finlay, Abowd, & Beale, 1998). Several areas of study explore how people and technology interact, such as cybernetics, human-computer interaction, ergonomics, human factors analysis, technology acceptance, and industrial engineering.

Security vulnerabilities for presentation services include impersonation, interception, modification, and interruption. Impersonation describes when a person or program disguises itself as someone or something else. Interception is when a person or program intentionally receives a message addressed for another party. Modification attacks involve altering the content of a message. A presentation service interruption would involve an intentional blockage of communications.

Application Services

Application services describe how input is transformed into output. The application services layer represents the procedural knowledge (i.e., business logic) embedded in the application. These services include statistical, mathematical, graphical, and/or data transformations.

Application services suffer from malicious code attacks and inadvertent programming errors. Malicious code attacks include viruses, worms, Trojan horses, and information leaks. A virus is malicious software that alters and propagates itself to other files. A worm is similar to a virus; however, a worm propagates itself throughout a network. A Trojan horse is a program that disguises itself as another program, satisfies the functions of the original software, and performs additional malicious acts. An information leak describes a process that secretly collects and transmits sensitive information to others.

Although malicious code receives most of the media attention, inadvertent programming errors cause much more damage (Pfleeger & Pfleeger, 2003). Inadvertent programming errors result from insufficient software debugging, sloppy coding practices, misinterpretation of requirements, and/or unforeseen application longevity/utility. Commonly exploited errors include validation errors, buffer overflows, inadequate authentication, and serialization errors. Exposed interprocess

Table 1 PAD Architectural Classification of Client/Server Applications

Computational Service	Distributed Presentation	Local Presentation	Distributed Application Logic	Local Application Logic	Distributed Data
Data services	Server	Server	Server	Server	<i>Shared</i>
Application services	Server	Server	<i>Shared</i>	Client	Client
Presentation services	<i>Shared</i>	Client	Client	Client	Client

communications make application services vulnerable to receiving intentionally altered messages. Unfortunately, because data validation is typically handled by the presentation services, application services often neglect to further validate requests. A buffer overflow describes when a process writes data into an area of memory that is owned by another process or the operating system. Overwriting data can have potentially crippling effects on a system. Inadequate authentication procedures provide an opportunity for an adversary to assume another's identity. Serialization errors result in the delay experienced in sequencing requests and responses. Serialization errors might allow an individual to execute commands as a different user by exploiting the time between authorization and request transmission.

Data Services

Data services provide access to organizational resources including information-based resources (e.g., databases), hardware-based resources (e.g., printers), and communication-based resources (e.g., e-mail). The data services layer provides utility to the application services layer and/or the presentation services layer.

Organizational resources are often difficult to access as a result of security, budgetary, and/or technical constraints. Security rules restrict access to sensitive data such as payroll information. Budgetary constraints restrict accessibility to consumable resources such as printers. Additionally, technology-based resources, such as databases, often require special and/or proprietary interfaces. As a result, data services often attempt to hide the implementation difficulties associated with accessing and using organizational resources.

Security vulnerabilities include data theft, physical damage, data value integrity, data structure integrity, availability, auditability, accessibility, authentication, and confidentiality. Data theft includes eavesdropping, unauthorized replication, and unauthorized removal of resources. Data value integrity is compromised when data are maliciously or inadvertently altered, deleted, inserted, or moved. Data structure integrity involves the validity, consistency, and accuracy of the relationships shared among the data elements. Data structures allow data to be located, retrieved, combined, and understood. As a result, the data structures are as important as the data values themselves. Availability means that appropriate and timely responses are provided to authorized parties during prescribed operating hours. Auditability allows administrators to track and retrace the actions of users and processes. Accessibility defines which parties have access to which system resources at what times and under what

circumstances. Although controlling direct accessibility is relatively straightforward, adversaries may access non-sensitive data in several ways to indirectly infer or derive sensitive data. Controlling indirect data access is particularly challenging. Authentication ensures that each party is specifically and accurately identified for accessibility and audit purposes. Confidentiality describes when the content of a message and identities of the parties are kept private.

PAD Architecture-Based Client/Server Classification

The PAD architecture classifies client/server applications based on the distribution of computational services between the client process and the server process. As seen in Table 1, the PAD architectural framework includes five client/server classification levels. Each level is defined by the client-side PAD functionality.

In the first level, *distributed presentation*, the client shares the presentation processing with the server and the server handles all application and data services. In the second level, *local presentation*, the client handles the presentation services and the server handles the application and data services. In the third level, *distributed application logic*, the client addresses the presentation services and a portion of the application services; the server handles the data services and shares the application services with the client. In the fourth level, *local application logic*, the client handles the presentation and application services and the server handles the data services. In the last level, *distributed data services*, the client handles all presentation and application services and the data services are shared by the client and the server.

Tier-Based Client/Server Classification

Client/server computing partitions an application into two or more separate processes. The tier-based classification methodology views each software process as a computational component/layer/tier within the overall application.

A two-tier system is the simplest and oldest client/server architecture. In a two-tier system a client communicates with a server directly. This architecture often strives to provide reusable, robust links to organizational resources, such as printers and data.

In a three-tier system, a client communicates to a server through an intermediary process. This intermediary process provides functionality as well as connectivity. Middle-tier functionality may include message queuing, application execution, and database staging. The middle tier also provides encapsulation for the data source and abstraction for the presentation services. As a result, changes to

the data structure and/or user interface are less disruptive and more transparent. Furthermore, data encapsulation improves connectivity with legacy and/or mainframe systems. A three-tier system may support a large number of concurrent users and is able to handle very complex processing (Carnegie Mellon Software Engineering Institute, 1997e).

The n -tier client/server architecture is a natural extension of the three-tier architecture. An n -tier system has an undetermined number of intermediary processes and server processes. A client process might call upon a middle-tier process, which in turn might call upon another middle-tier process. In combining narrowly focused processes together, the n -tier architecture strives to provide application flexibility and software reusability.

Server Functionality Client/Server Classification

Many client/server applications strive to reuse server process functionality. Because a server process often embeds and hides complicated implementation details, reusing a process significantly reduces system development time and effort. Furthermore, reusing successful, robust server processes improves overall system reliability (Weiss, 2001).

To promote reusability and clarity, the functional role of a server process often describes the server. The following list describes a few server types. Table 2 provides a summary of the servers listed below.

Web Server

A Web server creates a standardized way for objects to communicate with each other over the Internet. A Web server provides session connectivity to clients running Web browsers. Early Web servers fetched files for clients without processing or interpreting the content. However, technologies such as common gateway interface (CGI), active server pages (ASP), JavaServer Pages (JSP), Java Applets, ColdFusion, extensible markup language (XML), and Web services have dramatically expanded the processing and interactivity capabilities of Web servers.

Application Server

Application servers provide interactivity and processing functionality to clients. An application server may execute programming logic, store and process information, and/or manage user interactivity. Centrally storing programming logic allows developers to reuse existing, proven application functionality as well as simplifying software version control and software deployment.

Wireless Server

A wireless server provides network and Internet connectivity for wireless devices. Two popular wireless servers are *wireless enablers* and *wireless gateways*. A wireless enabling server stores information specifically designed for wireless devices, such as wireless markup language (WML). WML is a wireless-friendly version of hypertext markup language (HTML). A wireless client accessing a wireless enabling server would be provided with a WML file rather than an HTML file. Unlike a wireless enabler, a wireless gateway typically does not store content. It accepts requests from wireless and traditional devices and routes each request to an appropriate server based on the request and device type. Some wireless gateway servers also translate wireless and traditionally formatted messages to/from WML and HTML. These translations allow wireless devices to access both traditional and wireless content.

Transaction Processing Monitoring Server

A transaction processing (TP) monitoring server introduces performance efficiencies when serving a large number of users. These servers accept client requests, merge requests together by type, and then transmit the resulting consolidated messages to appropriate servers. In addition, a TP monitor might monitor, prioritize, schedule, process, balance, and/or rollback service requests.

Message Server

A message server accepts and routes messages. A message is a service request that is packaged with destination information. An e-mail request is a message; it has embedded intelligence regarding the specific message destination. As a result, an e-mail server is a message server.

Table 2 Functional Descriptions for Several Server Types

Server Type	Functional Description
Web server	Connectivity and interactivity to clients running Web browsers
Application server	Interactivity and processing functionality
Wireless server	Wireless content locating services and/or wireless-friendly content
Transaction processing (TP) server	User responsiveness, processing prioritization, scheduling, and balancing
Message server	Message routing and delivery
E-mail server	Electronic-mail storage, routing, and delivery
Fax server	Fax storage, routing, and delivery
Proxy server	Intermediary content and processing functionality
Firewall	Access restriction based on a predetermined set of security criteria
Dynamic host configuration protocol (DHCP) server	Dynamic reuse of network addresses
File transfer protocol (FTP) server	File transfer capabilities

E-mail Server

An e-mail server accepts, routes, stores, and delivers electronic mail (e-mail) messages; it handles incoming and outgoing e-mail messages. Several e-mail standards exist, such as messaging application programming interface (MAPI), X.400, and the Internet e-mail standard. Any compliant software product, regardless of the authoring product, may read standardized messages.

Fax Server

A fax server is similar to an e-mail server. It accepts, routes, stores, and delivers faxes; it handles incoming and outgoing faxes. Most fax servers provide additional features such as a direct-to-print option (i.e., allowing a fax to be sent to a printer rather than an electronic inbox).

Proxy Server

A proxy server is an intermediary process. It intercepts client requests and attempts to satisfy each request itself. If a request cannot be satisfied, the proxy server routes the request to an appropriate server.

A proxy server may control and manage Internet usage. Because all client requests go through the proxy server, an organization is able to monitor and/or limit Internet usage. A proxy server that filters Internet requests and/or logs Internet usage is acting as a firewall.

Firewall

A firewall reduces the risks associated with unauthorized access to a network and inappropriate use of networking resources. All requests entering or leaving a network must pass through a firewall. The firewall rejects those requests failing to satisfy the predetermined security criteria. A firewall might also record request and network activities. Firewalls are highly configurable based on organizational security and auditing concerns.

Dynamic Host Configuration Protocol Server

Like a postal address for a brick-and-mortar building, each computer on a network must possess a unique address. Traditionally, these addresses were fixed, meaning (1) each computer required individual configuration, (2) potential conflicts were inevitable, and (3) organizations were required to manage large blocks of addresses.

A dynamic host configuration protocol (DHCP) server dynamically assigns Internet addresses to computers on the network. This permits an organization to standardize computer configurations, to reduce network address contention, and to continually recycle a smaller number of network addresses.

File Transfer Protocol Server

A file transfer protocol (FTP) server transfers files from one computer to another using a network. An FTP server accepts file uploads (i.e., copying files to a server) and file downloads (i.e., copying files from a server). Although many FTP servers provide unrestricted access, others provide access to authorized users only.

Targeted Malicious Code

The reusable nature and global availability of server functionality provides many benefits; however, these circumstances also provide adversaries with fixed targets. Although generic and script-based malicious code indiscriminately infects any system (e.g., viruses and worms), targeted malicious code infects only specific types of applications. Examples of targeted malicious code include SQL injection attacks, trapdoors, covert channels, and salami attacks. SQL is a standardized, simple to use, powerful, and very popular language used to interact with databases. An SQL injection attack describes when an adversary uses the exposed interprocess communications to alter the SQL code being sent to the server. Successful SQL injection attacks can allow adversaries to read, insert, delete, and/or alter organizational data. A trapdoor is undocumented access point into a system; they are often intentionally created to provide support and/or future enhancements. A covert channel surreptitiously sends data to others in plain sight. A covert channel will encode a message in a standard report or in a seemingly benign message. A salami attack introduces subtle modifications to data. Consider an adversary who shaves 10 cents off of every \$1000.00 transaction. Even if this inaccuracy is noticed, the organization might tolerate it as within acceptable margins of error. Furthermore, the organization may feel it would be too costly to fix such a seemingly insignificant error. However, over time or with large enough transactions an adversary may be able to redirect large sums of money.

ENABLING TECHNOLOGIES

Enabling technologies allow heterogeneous software processes, computing devices, and networking devices to interoperate. Enabling technologies include technological standards, organizing frameworks, and product implementations. Three enabling technologies are discussed: middleware, component software, and networking technologies.

Middleware

Middleware is a primary enabler of client/server computing. Middleware acts like glue holding together the separate software processes. Middleware products simplify the design, development, and implementation of complex applications by hiding server location issues, networking protocol details, and operating system differences (Carnegie Mellon Software Engineering Institute, 1997a). Middleware is broadly defined; it may be a type of program-to-program interface, a set of standards, or a product. Table 3 provides a summary of the middleware categories listed below.

Transactional Middleware

Transactional middleware supports transaction-processing functionality; it strives to provide responsiveness and data integrity while supporting a large number of users. It often includes load balancing, replication, and/or two-phase commits. The Customer Information Control System (CICS) from IBM is a transactional

Table 3 Middleware Categories and Implementation Examples

Middleware Category	Implementation Examples
Transactional middleware	CICS—IBM DTP—Open Group BEA Tuxedo—BEA Systems
Procedural middleware	ONC RPC—IETF DCE RPC—Open Group
Message-oriented middleware	WebSphere MQ—IBM JMQ—Sun Microsystems

middleware product. CICS is common on IBM mainframes and on several other IBM platforms, including OS/2, AS/400, and RS/6000. The distribute transaction processing (DTP) protocol from the Open Group is another transactional middleware standard. Many relational and object-oriented database management systems support DTP. BEA Tuxedo, from BEA Systems, is another popular transactional middleware product.

Message-Oriented Middleware

Message-oriented middleware (MOM) supports client/server processes using asynchronous, peer-to-peer messages. A MOM does not require continuous, active communication between the client and the server. A client sends a message and does not wait for a response. If a server is busy or unavailable, received messages wait in a queue until they are satisfied. MOM solutions are well suited for event-driven and object-oriented applications. However, many MOM implementations are proprietary. As a result, they tend to be inflexible, difficult to maintain, and lack interoperability and portability (Carnegie Mellon Software Engineering Institute, 1997b). MOM middleware products include WebSphere MQ (formerly MQSeries) from IBM and Java Message Queue (JMQ) from Sun Microsystems. WebSphere MQ is a mature product supporting over 35 platforms (<http://www.ibm.com>). JMQ is based on Java Message Service (JMS), which is a Java application programming interface (API) included in the Java 2 Platform, Enterprise Edition (J2EE). JMS is one of the many standards included in J2EE, which is a platform for developing distributed applications using the Java programming language. J2EE, using the CORBA/IIOP communications infrastructure, specifies many services including asynchronous communications using JMS, naming services using Java Naming, Directory Interface (JNDI), transaction services using Java Transaction API (JTA), and database access services using Java Database Connectivity (JDBC). J2EE implementations are developed and provided by a variety of vendors (Sun, J2EE, n.d.a; Alur, Crupi, & Malks, 2001).

Procedural Middleware

A remote procedure call (RPC) supports synchronous, call/wait process-to-process communications. When

using an RPC, a client requests a service then waits for a response. As a result, an RPC requires continuous, active participation from the client and the server. Each RPC request is a synchronous interaction between exactly one client and one server (Carnegie Mellon Software Engineering Institute, 1997d). Open Network Computing Remote Procedure Call (ONC RPC), developed by Sun Microsystems and now supported by the Internet Engineering Task Force (IETF), was one of the first RPC protocols and is widely deployed to a variety of platforms (IETF, n.d.). The Distributed Computing Environment (DCE), developed and maintained by the Open Group (formerly known as the Open Systems Foundation), is a set of integrated services supporting the development of distributed computing environments. DCE provides distributed services and data-sharing services, including RPC, directory services (i.e., the ability to identify and locate system resources), time services, security services, and thread services (i.e., the ability to build concurrent applications). DCE data-sharing services include diskless support and distributed file system services (Open Group, 1996). DCE RPC is the protocol used by several object and component middleware solutions, such as Microsoft's Distributed COM (DCOM) and COM+ and it is also an optional protocol in the Object Management Group's Common Object Request Broker Architecture (CORBA).

Component Software

Component software strives to improve software development productivity through the reuse of self-describing, self-contained software modules called components. Each component provides specific functionality. An application calls upon components at run time.

Component software exists within a component model, which defines the way components are constructed and the environment in which a component will run. The component model consists of an interface definition language, a component environment, services, utilities, and specifications. An interface definition language (IDL) defines how a component interacts with other components to form applications. The components exist within a component environment. A component environment is a computing environment providing the ability to locate and communicate with components. Popular component models include Microsoft's Component Object Model (COM), the Object Management Group's CORBA, Sun Microsystems's Enterprise Java Beans (EJB), and Web services.

Component Object Model (COM)

Microsoft's COM is a way for multivendor software components to communicate with each other. It provides a software architecture that allows applications to be built from binary components supplied by different software vendors. COM provides the foundation for many technologies, including object linking and embedding (OLE), ActiveX, and Microsoft transaction server (MTS). Distributed COM extends COM by allowing remote component interactions. COM+ further expands the COM by encapsulating DCOM, MTS, and a host of other services, including a dynamic load-balancing service, an

in-memory database, a publish-and-subscribe events service, and a queued-components service. COM components require the COM application server, available on the Windows operating system platforms (Microsoft COM Technologies, 1998).

Common Object Request Broker Architecture

CORBA is an open, vendor-independent architecture describing object-oriented process interactions over a network. CORBA, supported by the Object Management Group (OMG), utilizes a standard communication protocol IIOP (Internet inter-ORB protocol). IIOP allows a CORBA process running on one computer to interact with a CORBA process running on another computer without regard to network, vendor, programming language, or platform heterogeneity. CORBA supports a variety of services, including asynchronous and synchronous, stateless and persistent, and flat and nested transactions (OMG, n.d.).

Enterprise Java Beans

Similar to CORBA, Sun Microsystems's EJB is a specification. An EJB must be programmed using Java and must be hosted on a J2EE application server. EJBs interact with each other using Java remote method invocation (RMI). An RMI is a set of APIs used to create distributed applications using Java; it is also an implementation that operates in a homogeneous environment using Java virtual machine (JVM). RMI allows Java objects to communicate remotely with other Java objects. Alternatively, an EJB built with EJB 2.0 specification, or higher, may communicate using the message-oriented-middleware, JMS (Marinescu & Roman, 2002).

An EJB system consists of three parts, the EJB component, the EJB container, and the EJB object. An EJB component exists within an EJB container running on an EJB server. The EJB object provides access to the EJB components. An EJB component is a software module that provides specific functionality; it may be discovered and manipulated dynamically at run time. The EJB container provides the execution environment for the EJB components; it handles the communication and interface details. An EJB container may support more than one EJB component. Although an EJB component runs on a server, an EJB object runs on a client. An EJB object remotely controls the EJB component (Sun, n.d.c).

Web Services

Web services are an extremely promising set of technologies; they may represent the first successful cross-platform component architecture. A Web service is a self-contained program providing a specific function that is packaged in such a way that it may be called upon remotely. A Web service is a platform-independent module that utilizes existing Internet standards, primarily XML, to provide, validate, and interpret data; hypertext transfer protocol (HTTP) to provide synchronous communications; and simple mail transfer protocol (SMTP) to provide asynchronous communications.

Web services provide Internet-accessible, building block functionality to developers; they allow for incremental development and deployment. Web services support

new application development and promise to provide access to existing applications. By wrapping traditional processes in Web service protocols, an existing computing infrastructure can improve interoperability and utilization without having to reprogram existing applications. Furthermore, an existing application may enhance functionality by integrating with new Web services.

Web services are distinctive in several ways. Although a traditional server process is designed to provide function to a particular client, a Web service strives to provide global access to a very specific function. A Web service is not duplicated or moved; it is simply called upon as required at run time by applications. Furthermore, unlike other distributed application environments, such as CORBA, J2EE, and COM+, Web services do not dictate the underlying communications framework (Singh et al., 2002).

Open, standardized interfaces are the heart of Web services. Standards define how a Web service communicates, how it exchanges data, and how it is located. Simple object access protocol (SOAP) is an XML-based protocol for exchanging information in a distributed environment. SOAP is platform independent; it consists of an envelope, a set of encoding rules, and a convention describing procedure calls. A SOAP envelope describes what is inside the message and how the message should be processed. The encoding rules describe the application-specific data types. The conventions describe remote procedure calls and responses. Other standards include the Web services description language (WSDL), which defines the Web service interfaces, and the universal description, discovery, and integration (UDDI), which allows developers to list/post new Web services and to locate existing Web services (Ewald, 2002).

Networking

The Internet consists of host computers, client computers, routers, applications, protocols, and other hardware and software. As an organizing framework, these technologies may be categorized using three broadly defined functional areas, namely network access, network core, and network edge.

As seen in Table 4, network access describes how devices connect to the Internet. The network core describes the intercommunications among the computing

Table 4 Internet Networking Categories and Components

Internet Networking Category	Components
Network access	Internet access providers Internet connectivity: Dial-up, ISDN, ADSL, HFC, wireless, T1/T3
Network core	Routers and bridges Data routing: circuit-switching, packet-switching
Network edge	Computers, users, applications Internet protocol stack

Table 5 Comparison of the OSI Model and the Internet Protocol Stack

OSI Model	Internet Protocol Stack	Layer Description	Protocols
Application Presentation Session	Application	Specifies how applications and processes will communicate with each other	HTTP, SMTP, MIME, DNS, NFS. Middleware products: RPC, MOM, CORBA/IIOP, CICS, DTP
Transport	Transport	Specifies how information is transmitted	TCP, UDP
Network	Network	Specifies host and application addressing	IP
Link Physical	Link Physical	Specifies how the media are shared Specifies the physical characteristics of the media	PPP, SLIP, ATM, Ethernet 100BaseT, IEEE802.5, IEEE802.11, Token Passing, TCS, PDM

and networking devices. The network edge describes those objects using the Internet such as clients, servers, and applications (Kurose & Ross, 2001; Peterson & Davie, 1999).

Network Access

An Internet access provider (IAP) provides Internet access. The structure of an IAP is roughly hierarchical. At the lowest level, a local Internet service provider (ISP) provides connectivity for residential customers and small businesses. The local ISP connects to a regional ISP. The regional ISP connects to a national/international backbone provider (NBP). The various NBPs interconnect using private connections and/or public network access points (NAP) to form the backbone of the Internet.

To communicate with an IAP, a connection must be established and maintained. Several connection alternatives exist, including dial-up, integrated services digital network (ISDN), asymmetric digital subscriber line (ADSL), hybrid fiber coax (HFC, via a cable modem), radio wireless, cellular wireless, satellite wireless, microwave wireless, T1, and T3.

The Network Core

The network core describes how networking devices interconnect with each other. The backbone of the Internet is an extremely large mesh. Data are sent through this mesh using either circuit-switching or packet-switching channels. A circuit-switching network establishes and maintains a circuit (i.e., a specific network path) for the entire duration of an interaction. A circuit-switching network knows where to look for messages and the data are received in the order in which they are sent. A packet-switching network divides each transmission into a series of individually addressed packets. Because each packet is addressed, the network path need not be determined and packets may be sent using whatever bandwidth exists at the time the message is transmitted. As a result, each packet might take a different network path. The receiver of the message is responsible for unpackaging and sequencing the packets.

The Network Edge

The network edge consists of those objects using the Internet such as clients, servers, and applications.

To communicate, objects must adhere to the same networking protocol. A protocol is an agreed-on set of rules governing a data transmission. The Internet supports a variety of protocols. Some protocols are competing, meaning they serve the same purpose; others are complementary, meaning they serve different purposes.

Internet Protocol Stack

A protocol stack is a framework used to organize and describe networking protocols. Each layer in a protocol stack serves a particular networking need. Furthermore, the lower layers of the stack provide a foundation for the upper layers (Kurose & Ross, 2001; Peterson & Davie, 1999). As seen in Table 5, the Internet protocol stack is a variation of the widely accepted OSI model. The OSI model has the following seven layers: physical, link, network, transport, session, presentation, and application. The Internet protocol stack has the following five layers: physical, link, network, transport, and application. The application layer on the Internet protocol stack envelops the application, presentation, and session layers of the OSI model. A description of each layer of the Internet protocol stack follows.

Physical Layer. The physical layer of the Internet protocol stack describes the physical characteristics of the networking media. Media can be broadly categorized as guided or unguided. Guided media includes copper and fiber optics. Unguided media include radio, microwave, and satellite. The media type influences bandwidth, security, interference, expandability, contention, and costs. Examples of physical layer protocols include 10BaseT, 100BaseT, Gbit Ethernet, IEEE802.5 Token Passing, IEEE802.11 Wireless, transmission convergence sublayer (TCS) and physical medium dependent (PMD) for asynchronous transfer mode (ATM), and transmission frame structures T1/T3.

Link Layer. The link layer of the Internet protocol stack describes how devices share the physical media. These protocols define host/host connections, host/router connections, and router/router connections. The primary role of link layer protocols is to define flow control (i.e., how to share the media), error detection, and error correction. Link layer protocols include point-to-point (PPP) and

serial line Internet protocol (SLIP), which allow clients to establish Internet connections with Web servers. Ethernet and ATM are also popular link layer protocols.

Network Layer. The network layer of the Internet protocol stack defines host and application addressing. The Internet protocol (IP) assigns a unique number, called the IP address, to devices connected to the Internet. The IP address uniquely identifies every computer connected to the Internet.

Transport Layer. The transport layer of the Internet protocol stack defines how information is shared among applications. The Internet transport protocols include transmission control protocol (TCP) and user datagram protocol (UDP). TCP is a connection-oriented protocol. A TCP-based application establishes and maintains a connection for the entire duration of each transaction. This connection provides reliability and congestion control. Applications using TCP include e-mail, file transfers, and Web browsing. UDP is a connectionless protocol. An UDP-based application communicates by sending individual datagram packets. Datagrams support applications requiring large bandwidth and those tolerating some degree of data loss. Applications using UDP include telephony, streaming video, and interactive games.

Application Layer. The application layer of the Internet protocol stack defines application/application communications. For example, the HTTP allows Web clients to locate, retrieve, and interpret HTML objects and other Web-based objects (e.g., VBScript, Java Applets, JPG files). SMTP sends and stores Internet e-mail messages. Multipurpose Internet mail extension (MIME) supports e-mail attachments. Post office protocol (POP3) and Internet mail access protocol (IMAP) allow clients to download e-mail messages from e-mail servers. FTP allows file transfers between computers. The domain name system (DNS) resolves IP addresses and universal resource locator (URL) names. Telnet allows for remote terminal access over the Internet. The network file system (NFS) protocol allows for remote storage of files.

Networking Security Vulnerabilities

Networks suffer from many security vulnerabilities including accessibility or altering of programs or data; intercepting, creating, or modifying data in transit; and blocking traffic. These attacks may involve social engineering, performing reconnaissance, launching denial of service attacks, impersonating users, or spoofing systems. A social engineering attack strives to manipulate or trick users and/or support staff into divulging sensitive information. These attacks may be direct such as asking for a password reset or they may be indirect whereby an adversary may infer or derive sensitive information from the responses of several “individually nonsensitive” questions. Reconnaissance is an information finding activity. Adversaries may engage in reconnaissance activities ranging from searching through physical and virtual recycle bins to analyzing design diagrams and configuration information. A port scan is a common reconnaissance activity. A port is a virtual communications channel used by specific applications. A port scan is a program that

systematically searches hosts to determine available ports and what applications are using the ports. A denial of service attack inundates a server with requests with the intent of overwhelming and significantly reducing the performance of the system. Impersonation describes when a party assumes the identity of another person or process. Spoofing occurs when an adversary acts on behalf of another party. Spoofing includes masquerading and session hijacking. Masquerading involves pretending to be someone else. Session hijacking involves intercepting a connection that has been established by another party.

CLIENT/SERVER IMPLEMENTATIONS

Internet

The Internet is a network of networks. Hundreds of millions of computers, users, and applications utilize the Internet. The Internet utilizes a variety of protocols, including TCP/IP, HTTP, and FTP. The Internet supports Web browsing, online chatting, multiuser gaming, e-mail delivery, fax delivery, and telephony.

The size, heterogeneity, complexity, globalization, and varied utility of the Internet make it extremely vulnerable to security attacks. Because the Internet supports hundreds of millions of client/server applications, it suffers from and is the breeding ground for practically every maliciously program designed to inflict harm on a client, a server, or a network. In addition, the World Wide Web (WWW) introduces several new threats, including Web site defacement, relative addressing issues, cookies, and Web bugs. Web site defacement describes when a Web page is vandalized with graffiti or unauthorized information. Because the WWW often passes parameters and data in an exposed, human readable form, adversaries can easily alter interprocess messages. Relative addressing attacks describe when the directory path and/or filename shown in a browser's address window are intentionally altered. A cookie is a data object copied to a user's computer that stores information about the user. The author of the cookie is able to use this information to specifically identify and recall prior transactions of a visitor. By retrieving or intercepting a cookie an adversary may be able to impersonate another user and/or gain accessible to sensitive information. Furthermore, because cookies are typically encrypted, a user is unable to read the information that a server is collecting and transmitting about himself/ herself. A Web bug is a hidden image placed on a Web site in an e-mail message. When a Web page or e-mail message is opened, the Web bug is automatically activated. This bug, in cooperation with cookies, might send information about you to someone on the Internet and/or it might copy an executable file to your hard disk. These executable files are able to secretly collect and transmit information from your personal documents. Furthermore, executable Web bugs are able to secretly send copies of your files to someone over the Internet.

Intranet

An intranet is a private network using the same technologies as the Internet. Because the foundation, protocols, and toolsets are the same, an intranet looks, feels,

and behaves like the Internet. The difference between an intranet and the Internet is scope. An intranet user is limited to visiting only those Web sites owned and maintained by the company hosting the intranet, whereas an Internet user may visit any publicly accessible Web site. Because intranets are private, individuals outside the organization are unable to access intranet resources. As a result, organizations may publish internal and/or confidential information such as organizational directories, company policies, promotion procedures, and benefits information. A firewall protects an intranet from the nonsecure, public Internet.

Extranet

An extranet is an intranet that provides limited connectivity with the Internet. Specifically, an extranet allows authorized Internet users to access a portion of the company's intranet. This access is granted through a firewall. An Internet visitor submits a username and password to the firewall. If authenticated, the visitor is permitted limited access to the company's internal intranet. Similarly, an extranet may provide authorized internal users limited access to the Internet.

Extranets often support field personnel and employees working from home. In addition, extranets are designed to interconnect suppliers, customers, and other business partners. The exposure of the extranet is based on the relationships a company has with its partners and the sensitivity of the content stored on the extranet. In the most relaxed scenario, individuals gain access to common business materials by completing a brief survey. In more restrictive scenarios, an organization may sign a contract detailing acceptable use of the extranet or consumers may be required to pay subscription fees.

CONCLUSION

Client/server computing is so broadly defined, that it says little about a particular system. A client/server application may provide national security services to a government or it may provide publicly available editorials and commentaries. Additionally, client/server computing encompasses several architectural interpretations. The client/server *system* architecture describes the physical configuration of the computing and networking devices. In this context, clients and servers are seen as computers. The client/server *software* architecture describes the configuration of the software processes. In this context, clients and servers are seen as software processes. Furthermore, client/server computing utilizes an enormous array of heterogeneous technologies, protocols, platforms, and development environments. Although some client/server applications are relatively simple, involving only a few technologies, others are extremely complex, involving a large variety of technologies.

Common to all client/server systems is the partitioning of an application into separate processes. Two general categories of processes exist, those that request services (i.e., clients) and those that provide services (i.e., servers). A client process works together with a server process to provide application functionality.

A client/server classification provides information that describes a particular system. A classification may describe the computational role of the processes, the physical partitioning of an application into tiers, or the functional role of the processes. Although these classification methodologies help describe systems, they also highlight the variety and complexity among client/server implementations. The computational and functional role of the processes varies from system to system. Furthermore, a client may interconnect with many servers and a server may interconnect with many clients.

Enabling technologies strive to provide seamless integration of hardware and software in complex environments. Specifically, middleware governs the interactions among the constituent software processes, component software provides the ability to create applications using existing, self-contained software modules, and networking technologies bridge the gap among the computing and networking devices.

Early distributed computing consisted of vendor- and platform-specific implementations. However, the trend in client/server computing is to provide standardized connectivity solutions. Web services represent one of the most promising new client/server developments. Web services strive to utilize the communication infrastructure of the Internet to deploy client/server applications. Although it is too early to know whether Web services will fulfill their potential, they promise to change the way application programs are developed and deployed. As the excitement and investments in such technologies continue to grow, the standardization and globalization of client/server computing will likely become a reality in the near future.

The ever-increasing flexibility, power, standardization, and globalization of client/server computing provide unprecedented capabilities; however, these same characteristics make the technology extremely vulnerable to undesirable, illegal, and malicious acts. Although the vast majority of people use client/server computing in productive and meaningful ways, there are underground communities that support, educate, and encourage malicious acts. Ironically, these communities exist within the environment in which they intend to damage and destroy. Even unsophisticated users (called script kiddies) can access these communities to download and execute malicious scripts capable of causing significant damage. A script kiddy may not even be aware of the damage he or she is causing.

Security is established and enforced through management practices rather than technological innovations (Panko, 2004). Security management involves defining, maintaining, and enacting security policies and security training programs. Security policies articulate the security rules (e.g., conduct a daily search for software patches), the violation reporting procedures, and the resulting sanctions (i.e., punishments). Enforcement is essential to a security policy; a security policy is only as strong as its enforcement. Furthermore, effective training is a prerequisite for just and impartial enforcement. Training programs engender awareness, appreciation, and understanding of the security policies for users, developers, and support personnel.

The security rules detail the countermeasures used to protect organizational assets from adversaries. Security countermeasures strive to prevent, detect, and respond to security violations. Prevention involves deterring, blocking, and isolating security abuses. Deterrence begins with well-publicized security policies, procedures, standards, and guidelines (Volonino & Robinson, 2004). Blocking entails firewalls, encrypting data and messages (e.g., AES, DES, and RSA), establishing secure communication channels (e.g., IPsec, SSL, S-HTTP, PPTP, and WTLS), disabling unused communication ports, and access controls. Isolation efforts include hardware, software, and data redundancy, physically separating sensitive and public data, providing a staging area for newly developed hardware/software solutions, and physical security. Detection includes monitoring, auditing, and verifying system and user activities. Monitoring products seek out malicious code and system malfunctions. Monitoring also involves continually searching for unauthorized user and host access, frequent reviews of audit logs, surveillance equipment, observation windows, and security personnel rounds. Auditing entails maintaining a detailed, time-oriented, permanent record of all system, user, and security activities. Verification procedures strive to validate system and user activities. Organizations should implement security countermeasures in a redundant manner, providing several layers of protection. In an adequately protected environment, several countermeasures must fail for a violation to occur.

Once a security violation is detected reaction measures strive to minimize the impacts and to recover the systems and/or data. Reaction measures include system and data recovery, disaster planning, emergency response planning, the ability to quarantine data and software, notification procedures, debugging, and cleansing. Finally, after the violation is contained and the recovery efforts are complete, a forensic analysis is employed to learn from the adversaries who successfully violated the system. Analyzing adversary practices goes beyond identifying exploited weaknesses, it provide insights into the strategies and motivations of adversaries. These insights help organizations anticipate and prepare for future attacks.

GLOSSARY

Client Process A software program that requests services from one or more server processes.

Client System A computer that supports a client process and requests services from one or more server systems.

Client/Server Software Architecture The logical and physical partitioning of an application into software processes.

Client/Server System Architecture The architectural configuration of computing and networking devices supporting a client/server application.

Client/Server Tier A well-defined, separate process representing a portion of a client/server application.

Component A self-contained, self-describing software module that provides specific functionality, where several can be combined to build larger applications.

Component Environment A computing environment providing the ability to locate and communicate with components.

Component Model The way components are constructed and the environment in which a component will run, consisting of an interface definition language, a component environment, services, utilities, and specifications.

Enabling Technology Provide a client/server application with the ability to locate, communicate with, and/or integrate the constituent processes.

Extranet An intranet that provides limited access to/from the Internet using firewall technology.

Interface Definition Language (IDL) Defines how a program may communicate with a component.

Internet Protocol Stack A subset of the OSI model, and a framework that organizes and describes Internet networking protocols.

Internet A global network of networks supporting hundreds of millions of computers, networking devices, applications, and users.

Intranet A private network based on Internet protocols and technologies.

Middleware The software governing the interaction among the client and server processes.

n-Tier System An application that is partitioned into an unspecified number of separate processes that work together to provide system functionality.

OSI Model A general framework that organizes and describes networking protocols.

PAD Architecture Defines an application in terms of the following three computational services: presentation services, application services, and data services.

Process An executing program.

Server Process A software program that provides services to one or more client processes.

Server System A computer that supports a server process and provides services to one or more client systems.

Three-Tier An application that is partitioned into three separate processes that work together to provide system functionality.

Two-Tier An application that is partitioned into two separate processes that work together to provide system functionality.

INTRODUCTION

Peer-to-peer systems (P2P) have grown in importance over the past 5 years as an attractive way to mobilize the resources of Internet users. As more and more users have powerful processors, large storage spaces, and fast network connections, more actors seek to coordinate these resources for common goals. Because of their unique decentralized nature, security in these systems is both critical and an interesting problem. How do you secure a dynamic system without central coordination? Good security on P2P systems must reflect the design goals of the system itself. In this chapter, we introduce some basic concepts for P2P systems and their security demands and then discuss several case studies to highlight issues of robustness, privacy, and trust. We analyze systems that offer secure distributed routing, privacy-enhancing and censorship-resistance publishing, shared storage, and decentralized collaborative work spaces. We conclude by examining how accountability and trust mechanisms must be built into a secure system.

ABOUT PEER-TO-PEER SYSTEMS

What Is Peer-to-Peer?

Peer-to-peer systems have two dominant features that distinguish them from a more standard client/server model of information distribution: they are overlay networks that have unique namespaces. P2P systems link different, possibly heterogeneous, systems as “peers” and allow them to interact on top of existing network configurations. It does this by defining relationships unique to that system, usually in the form of a topology by which systems are linked. Occasionally a system will piggyback atop an existing namespace, such as the IP/port labeling, but still treats these separately from the Internet-layer protocols. The combined effect of independent systems interacting through a unique namespace is *decentralization*. Not every system generally considered a P2P system is strictly decentralized in management—the infamous Napster actually ran through a centralized server—but the matter of decentralization brings out important concerns for system security.

Although they have won the most attention for their roles as (often illicit) file-swapping networks, peer-to-peer systems can serve many functions, and design considerations must reflect these. One proposed use of a P2P system was that of shared expertise. A Gnutella pioneer has suggested that the system could be used to propagate queries of any sort through a network until a peer felt that it could respond to the query, anything from a lexical lookup to a specialized calculation (Kan, 2000). In a network with varied resource availability, P2P systems have been used to distribute those resources to those who need or want them the most. The shared resources in question are usually computation or storage. This can create efficient resource usage, given a low marginal cost of using a resource not otherwise needed. Beyond sharing computation power for enormous tasks, P2P networks have been proposed as an escrow system for digital rights management, or for distributing searches across a wide range of other peers. A new class of business software systems known as groupware uses many P2P principles. Groupware networks are closed networks that support collaborative work, such as the Groove network discussed below. Finally, the decentralized nature of peer systems offers many positive features for publishing and distribution systems, not least of which is their resilience to legal and physical attacks and censorship. P2P architectures have many different functions, and different functions lead to different design conclusions with respect to overall system structure and specifically to security issues.

A Sample Architecture: Gnutella

Gnutella can illustrate the role of security in the design of a P2P system. Developed in 2000, this system was one of the first widely deployed truly decentralized P2P networks and was used largely for file swapping. Nodes keep a list of other nearby nodes in the network. When they have a query, a node will send the message to all neighbors, with a time-to-live counter measured in hops. Nodes will pass the query along until the counter runs to zero; any node that can positively respond to the query will contact the original node directly, using network location information embedded in the original query. Nodes discover each other through IP/port announcements, which

are unauthenticated, opening the way for flooding or denial of service attacks. Peers are not required to authenticate either the query or the response. An attacker can return an erroneous response, directing the querying node to download files from the target node: if enough seekers are duped, the target node cannot identify or defend itself against the denial of service attack. Moreover, because a node, its query, and its target are not secured with information-hiding techniques, information about all can be exposed. This has been exploited by vigilantes to publicly expose the machines of those who sought child pornography and by the recording industry to identify holders of illegally obtained music files. Concerns about security for P2P systems have very real ramifications.

Before we can examine security in a P2P system, it pays to have a brief look at the components of a P2P system for construction. Like all complex systems, designing peer-to-peer networks is a matter of trade-offs. Because they are defined by their heterogeneous environment, it is impossible to optimize for everything. Once distributed, implementing additional control structures is much more difficult, so the original design must at least consider the following issues. The system consists of clients running on hosts. Hosts must be made aware of each other and have a means to communicate, forming nodes in a network. Nodes that wish to communicate to other nodes without a direct connection need a routing mechanism to go through the network. A routing mechanism may or may not need special consideration for the return path. Routing is distinct from the default network-level routing used by the host and rides above that layer. Instead, the namespace of the P2P system is used to find appropriate peers. Routing for specific queries can take different forms, including a broadcast to all known nodes, a multicast through neighbors with a search horizon, or an interconnection through well-placed “superpeers” at key junctions in the network. If attention is not paid to how nodes are distributed throughout the network, there can be load-balancing issues resulting in traffic problems. If we assume a dynamic Internet, then nodes need to know how to enter the network and how to leave gracefully. The existing network must be able to integrate new nodes, and recover after a node failure. As more nodes join, the network must scale well to maintain functionality. Many standard design trade-offs, such as redundancy versus efficiency, are made all the more salient by the heterogeneous environment we assume in P2P.

Peer-to-Peer and Security

Security expert Bruce Schneier is often quoted as claiming that “security is a process.” As such, it matters very much whether security administration is centralized or decentralized. The basic model of the commercial Internet is the client/server relationship. As the network user base grew, less and less responsibility for administration was placed on the edges of the network and more was concentrated in smart “servers.” This model is most evident on the World Wide Web, but file servers, mail servers, and centralized security administration mechanisms such as virtual private networks have all grown apace. In a centralized system, security policy can be dictated from a single

location, and a “that which is not permitted is forbidden” policy can be enforced with firewalls, monitoring, and intervention.

Conversely, centralization offers a single point of failure. Both direct malicious attacks and lax or negligent administration at the heart of a centralized network can undermine security for an entire system. With a single breach, outgoing or incoming content can be corrupted or intercepted or the system can be rendered inoperable with a denial of service attack. Critical infrastructure systems such as the domain name system (DNS) have redundant implementation exactly because a single point of control is vulnerability in and of itself. In a decentralized P2P system, bad behavior has a locality impediment. Malicious attacks need to occur at or near every part of the system it wishes to affect.

P2P systems lack the tools available to a centralized administrator, so it can be much more difficult to implement security protections on a deployed P2P system. Moreover, the absence of a defensible border of a system means that it is hard to know friend from foe. Malicious users can actively play the role of insiders—that is, they can run peers themselves and often a great number of them. Douceur (2002) notes that this is incredibly hard for any open system to defend itself against this sort of attack, known as a Sybil attack (named after a famous Multiple-Personality Disorder case study). Several solutions are discussed below. As such, many systems are designed with strong security considerations in mind, depending on their function, from cover traffic to prevent monitoring of file transfer to a reputation system that can discourage single actors from controlling too many trusted nodes. As above, the wide range of security issues makes optimizing for all a nonfeasible option. This will become evident in our discussions of actual P2P systems below, but first we present some of the more common security demands.

One way to think about P2P is whether it applies at the network level, the application level, or the user level. At the network level, an adversary may try to break the routing system, block access to information by impeding queries, or partition the network. At the application level, an adversary can attempt to corrupt or delete data stored in the system or in transit. Finally, the users themselves can be the subject of attack if an adversary goes after anonymity and privacy protections.

Camp (2003) offers an operational definition of trust based on the risk that a system will fail to perform as specified. This is a broader view of security, but one that suits our purposes. In a P2P system, we are interested in not only how one aspect of the system behavior withstands attack but also how the entire system is defended. Because policy is not set dynamically, but is the sum of all behavior in the network, security also includes the expected behavior of other peers and what their incentives are. Layers of protection interact. These levels translate into more specific security goals for system to operate reliably.

In the examples that follow, we highlight security features of these systems, and the design choices made to offer optimal security for a given task. Discussions of cryptanalysis and other field-specific security issues employed by P2P systems are outside the scope of this chapter, as are more complete descriptions of these systems

and their performance. Instead, these descriptions are intended to illustrate security mechanisms rather than fully describe all nuances of any P2P system.

The case studies below highlight some of these goals. Secure distributed transport mechanisms such as Tarzan ensure that the identity of the user and the content of the message remain a secret, whereas secure overlay mechanisms are designed to ensure that the message gets through and gets there efficiently. Freenet and Free Haven ensure adequate file maintenance, so that users can reliably access any file they want or any file that has been published, respectively. Groove allows networks of peers to manage themselves. Distributed storage mechanisms can create conditions for cooperative behavior and coordinated dependencies. Finally, we discuss how accountability devices protect against free riding and nodes that are known to misbehave.

IMPLEMENTING SECURE PEER-TO-PEER SYSTEMS

Anonymous Transport: Tarzan

Peer-to-peer systems can serve disparate functions, and although many of them primarily act as applications or services, they can also serve as transport-layer anonymizers. The Tarzan system is a decentralized, distributed Chaumian mix system that enables client applications to seamlessly direct traffic through an anonymous network at the transport layer. Unlike a centralized server-based anonymous traffic system such as Anonymizer, Tarzan's P2P nature ensures that no one actor needs to be trusted for anonymous communication at the IP level. Users can direct their traffic into a tunnel through the network of peers, so the packets exiting the tunnel cannot be traced back to the original sender, even in the face of substantial networkwide traffic analysis.

Tarzan, as described by Freedman and Morris (2002), works as follows. Each node selects, from what it can see of the network, a set of peers to act as mimics. Initial node discovery and subsequent network maintenance is based on a gossip model, where nodes share their view of the network. Mimics are selected randomly from the available nodes for security and balance, in some verifiable manner. Each node exchanges a constant rate of cover traffic of fixed-size packets with its mimics using symmetric encryption. Symmetric keys are distributed using the relays' public keys. Actual data can now be interwoven into the cover traffic without an observer detecting where a message originates.

To build a path, the sending node randomly selects a given number of mimics and wraps the message in an "onion" of symmetric keys (Syverson, Goldschlag, & Reed, 1997) from each node on the path. The sender passes the packet—outwardly indistinguishable from cover traffic—to the first node in the chain, which removes the outermost wrapper with its private key, and then sends it along to the next node. With the exception of the last node, each node in the chain is aware of the node before and after it in the chain, but has no way of telling where it is in the chain itself. That is, the node cannot tell if it is the first hop or the penultimate hop. The final node in the chain of mimics

acts as the network address translator for the transport layer and sends the packet to its final destination through the Internet. This final node must know the content and destination but has no information about the sender.

Nodes store a record for the return path, so a reply from the Web host contacted can be received by the final node in the chain, rewrapped with its private key, and sent back to the penultimate hop. The message is then passed back through the chain, with each node adding another layer of encryption. The originating node can use the public keys of each node to unwrap the layers and read the message. Because it is the only node to know the public keys of each hop along the path, the content is secure.

The P2P nature of this system makes a network decentralized and thus highly scalable. The presence of cover traffic and the fact that all nodes are peers means that no actor inside or outside the system can readily identify the originator of the message. Unlike onion routing, the sender does not have to trust the first hop, and the list of available nodes can be dynamically maintained for participant flexibility. Moreover, the majority of cryptographic work is performed by the original sender, which must decrypt n public keys to read the reply through and n -node chain. Each node in the chain only performs one encryption or decryption, and implementation results have shown that the computational time is dominated by the expected latency of the underlying Internet.

Efficient Robust Routing: Secure Overlays

Like Tarzan, routing overlays also seek to provide a secure layer of communication, but they differ in their security objectives. Rather than protecting the anonymity and content of communications, routing overlays such as Chord, CAN, and Pastry try to provide mechanisms for nodes to access objects in a fashion resistant to malicious interference. Overlays use their namespace structure to build robust routing mechanisms so that an adversary with a significant number of nodes in the system could not cripple communication and access throughout the system. How the nodes and objects manifest themselves at the application layer is not directly relevant to the overlay design: these systems can be used for storage, publication, or even multicasting.

The salient feature of all routing overlay models is a large ID space, from which node identifiers and object keys are defined, forming a large, distributed hash table. Each object key is mapped through the overlay to a unique participating node, called the object's *root*. The protocol routes messages with a given object's key to the object's root. An object is replicated throughout the system to ensure greater robustness; each protocol uses a replica function to map an object's key to its replica's key, which can then be used to find the copy of the object stored at the replica's root. Like any hash tables, lookup can be very efficient, but distributed hash tables pose unique security questions.

Each overlay system is somewhat different, of course, but most follow a given structure. The generic system here is based on the discussion in Castro, Druschel, Ganesh, Rowstron, and Wallach (2002) and the Pastry system (Rowstron & Druschel, 2001). Nodes maintain two lists

of other nodes, a routing table of other nodes throughout the ID space and a list of “neighbors” or nodes that are in close proximity inside the number space. Each entry in the table consists of an identifier in the namespace and the IP address of the node belonging to that identifier. To route a message, a node consults these tables, and attempts to forward the message closer to the identifier keyed in the message. Routing tables are organized by key prefix, such that a host will try to find the node with an identifier closer in the namespace to the query key. Failing that, it will pass the message along to its neighbors in an attempt to find the proper location in the namespace. If the key is not found in the routing table or the neighborhood, the query is dropped.

This system is effective, but is not in and of itself secure, because there is no guarantee that an object will be placed on legitimate, trusted replica nodes. Nodes must regularly maintain their routing tables for arrivals and departures of other nodes. Such operations are difficult, especially in the face of high node churn, but are generally feasible in well-behaved networks. More importantly, malicious nodes or collections of nodes can seek to undermine routing efforts or even censor documents. For instance, an attacker could surround an object’s root with collaborating neighbors and pass on no message to that object’s root. To prevent this, secure overlay systems implement secure routing primitives.

First, node identifiers must be guaranteed to be randomly assigned to every node. If this is not the case, nodes under malicious control can simply choose their IDs to ensure that all the keys of a given object will point to hostile nodes. This randomization is not difficult if there is a centralized server solely responsible for handing out identifiers on joining the network; proof-of-work techniques or micropayments can be used to prevent Sybil attacks or pseudospoofing. Of course, P2P systems are often designed to explicitly avoid a centralized server of any sort, even one used only to assign names. Wallach (2002) acknowledges that, without a central authority, current means of assigning random identifiers can impose additional security risks. Routing table maintenance must also be secure against attack so that the chances of having a corrupt node in ones routing table will not be greater than the percentage of corrupt nodes in the system.

Secure overlay models can provide for message delivery to as many noncorrupt nodes as possible. Much of this is predicated on the fact that one’s ID space neighbors are very likely to be geographically disparate and thus less likely to be under the control of a single adversary. If we to sacrifice some performance by filling the routing table based on diversity rather than low latency, security increases. In Pastry, when less than 30% of nodes are not trustworthy, there is a 99.9% probability that at least one valid replica will receive the message (Castro et al., 2002). This particular defense may decline in utility if the attack is coordinated through a large set of geographically dispersed peers, such as an array of PCs under the control of Trojan horse malware.

One criticism of routing through the overlay model, rather than a higher application level, is that it is harder to eject a misbehaving node. Although nodes may recognize that other nodes are not behaving as they should,

proving systematic misbehavior is difficult at the routing layer. Apparently malicious behavior could be ascribed to the underlying network and vice versa. Thus, any accusation mechanism could be used to attack legitimate nodes and the system itself.

Secure overlay mechanisms and Tarzan both focus on message delivery but with different security objectives. Tarzan focuses on protecting the end parties, their identities, and the content of the message. A secure overlay such as Pastry is designed to protect the traffic flow itself. Both can be implemented in such a fashion to aid in the others goal. Tarzan, for instance, can add on control mechanisms to guarantee flow control, and Pastry can add layers of encryption and even use a multihop system to replicate a mix-net. Neither of these solutions, however, would be as secure in their objective as the other system. Security objectives of P2P systems need to be designed in from the beginning.

Censorship-Resistant Anonymous Publishing: Freenet and Free Haven

P2P systems can also be application specific. One of the more common applications of P2P systems is publication and storage of documents. Again, the security design of these systems is based largely on the purposes of the system and the security goals of the designers. Several systems have been designed for the express purpose of censorship-resistant publishing to make real the rhetoric of the freedom of ideas that the Internet was supposed to enable. However, a single server can be blocked for an entire nation (Zittrain & Edelman, 2003) and open documents can be identified and blocked. Secure P2P systems can be much harder to block, because they lack a single point of attack to block or destroy documents. We present, for comparison, two such systems, Freenet (Clarke, Sandberg, Wiley, & Hong, 2000) and Free Haven (Dingledine, Freedman, & Molnar, 2000b).

Freenet is designed to acknowledge that censorship can take the form of eliminating sought-after documents or punishing those who can be observed reading those documents. It consists of a network of peers that host encrypted documents. Peers use keys to request documents. Its two unique features are the structure of its storage space and the system of using keys to access content.

The storage mechanism of Freenet can be thought of as a nested caching structure in that data is stored as it is used. A peer request propagates through the network, with each node knowing only the node that passed the request along. A node that can positively respond to the request will pass the document back through the chain, one node at a time. Each node may keep a local copy of the document, in addition to sending it along toward its destination, so that it can respond to future requests itself, rather than passing the query to network neighbors again. This means that copies of the document will be duplicated as they are requested. It also prevents a single hosting node from being overwhelmed by requests for a popular file. Finally, this local caching policy causes a locality of resources, where documents tend to be hosted close to regions of the network where the document is heavily demanded. As nodes fill their storage space with documents

that they pass along to others, they will replace older and larger documents first. This leads to a more efficient use of network space, where peers host documents that are highly demanded and small enough not to be a burden on network resources, as well as creating an incentive to minimize file size of documents stored on the network.

As mentioned above, peers use keys to locate and access the encrypted documents on the network, and there are four key styles that can be used. Keys are used to identify the document sought and decrypt it once it is obtained. The simplest is just a key derived from a hash of the document itself. This insures that the key is unique and the document is tamperproof. However, they can be difficult to remember, and how does one obtain the key of a document one doesn't know about ahead of time? Moreover, the fact that the documents are tamperproof with respect to the key means that they cannot be edited (capabilities that allow you to trust the integrity of an editable document require an infrastructure like that of Groove, described below). For easier searching, Freenet allows keys to be derived from keyword strings. A one-way function is used to convert the keywords into a key, which is also used to access the document as above. This method has two flaws, however. First, popular key words can be vulnerable to dictionary attacks, where malicious nodes will attempt to use the client's transformation function to find the key value of specific search strings. With this, they can censor specific search strings while still appearing, to an outside observer, to be a fairly well-behaved node. Moreover, there is no guarantee that multiple separate documents will not be signed with the same keyword-generated keys. Imagine, for example, the number of distinct documents that could be "The Bible." These two flaws make false replies fairly simple.

To allow for document editing, Freenet offers signature verification keys, where document keys are generated along with a public/private key pair. This allows the author of the document to resign the key with every edit, enabling a persistent pseudonym in the form of a public key. Users can now better trust the authenticity of a document as associated with a specific online identity. Finally, redirects allow queries for specific key words to return the content hash key, rather than the document itself, and the hash key can obtain a verifiable copy of the original document.

All documents in the system are encrypted with some type of key, so the host node may not know what documents it is serving at any point. This also allows plausible deniability should any one legally or physically attack the owner of a node. The creators of Freenet acknowledge that if a document is notorious enough, its digital signature will be recognized, and hosts can purge it from their system and refuse to process requests. However, should some one wish to have it in the system, it is a simple matter to extract it, change a single bit to generate a completely new digital signature, and reinsert the document into the network. Actively trying to remove a document from inside the system is difficult.

Freenet's P2P structure ensures that documents spread in a "sticky" fashion to resist attempts to stamp out popular information while still protecting those who would either access or host that information.

Free Haven, like Freenet, is designed to be a censorship-resistant publishing network but places its design priorities on highly robust anonymity and document durability. Free Haven uses cryptographic techniques to protect the identity of the reader, the server, the author, the document, and the query, preventing any party other than that which is explicitly authorized to read or link information. Unlike some of the other P2P systems described in this chapter, its routing structure is relatively simple but uses very sophisticated techniques to protect anonymity and robust storage in a hostile environment.

As usual, content is kept on some number of machines in the network. The user, either a server in the network or an outside machine, broadcasts a request to as many servers as possible, who then reply directly to the querying machine. The initiator sends a request to a server that consists of the following: the initiator's public key (which can be temporary), a hash of the public key of the document sought, and a reply block. A reply block consists of an encrypted nested chain of addresses, so that a party can use it to pass a message to a destination through several intermediary parties that do know either the originator or destination of the message nor the content. If any recipient server has a document whose hash matches the hash of the given key, they encrypt that document with the requester's public key and send it back using the reply block. Thus, although the client must know of the existence of a server, it has no information about which server offered the document, nor does the server know anything of the client.

Free Haven's strength as a P2P publisher lies not just with its robust anonymity but also with its document management, which maintains the files in the system against strong attacks. Before inserting a document into the system, it is encrypted and broken up into a large number of shares, only some fraction of which are necessary to recreate the document. That is, a client can rebuild the document without finding every share. The parameters of the number of shares generated and the number required for regeneration are chosen to minimize not only the number of shares necessary for reassembly but also the size of each file that must be acquired. Each share has a duplicate "buddy" share, and the two contain location and storage information about each other for system robustness. Shares also have expiration dates, before which servers make an effort to keep shares alive.

Once on a server, the document shares do not necessarily rest on the same server but rather are traded between servers. Trading provides cover traffic to hide actual information queries, as well as allowing servers to find a home for their shares before exiting the system. The constant movement also makes it more difficult to locate and attack all the shares of a document. The buddy system creates some degree of accountability, as a share will notice if its buddy is no longer available from the server on which it was last residing. Each trade involves updating the buddies of the shares traded. Servers hosting machines with lost buddies can communicate to other servers their knowledge of the unreliability of the negligent (or malicious) nodes. We discuss how the system uses reputation to track good behavior below.

Free Haven was designed to be robust in the face of many different attacks. Reader and server anonymity are protected with the reply-block mechanism but can always be subverted with embedded malicious code in the documents or very extensive traffic analysis across the network. To attack the publishing system, an adversary would have to acquire many shares. Simply destroying servers will not help if the number of required shares for reassembly is small enough. Conversely, increasing the number of shares in the entire network minimizes the chances of deleting both a share and its buddy to attack the accountability mechanism.

Neither Freenet nor Free Haven can be said to be truly superior, or even more secure, because they have different design objectives and, thus, different security demands. The designers of Freenet did not worry about a networkwide traffic analysis attack, because they assumed any adversary with that many resources could mount a more direct legal or physical attack on users (Langley, 2000). The designers of Free Haven chose to take advantage of recent cryptographic developments to build a system that could stand up to a powerful cryptanalytic attack. At the same time, Free Haven was concerned with protecting *all* documents in the system, whereas Freenet was more concerned with guaranteeing access to those highly demanded at any given time. Dingledine et al. (2000b) suggest that their system might be used to protect a phone book from a war zone, whereas Freenet designers envisioned spreading a current issue of a dissident newspaper. P2P systems must be built for specific goals, and their security should reflect this.

Secure Groupware: Groove

Groupware is a designed forum and set of tools for sharing information and communication channels to enable collaborative work. Designing a secure P2P workspace is every bit as challenging as the systems described above for two reasons. First, a workspace has multiple internal applications, and the system must securely provide them all. Second, businesses that design workspaces must make them accessible to the average corporate computer user; user intervention as complex as assembling a reply block, or even verifying a digital signature, can be too complex for a product to be widely attractive. Ray Ozzie's Groove Network is a collaborative digital space that is built to be secure but designed to have as much security as possible completely transparent to the user (Groove Networks, 2003). At the same time, security mechanisms need to be self-organizing from the client level rather than dictated by a policy administrator. The proprietary system was built to be used in a business environment, which means addressing not only the potential presence of a highly motivated adversary but also the likelihood of a highly heterogeneous environment. Groove is designed to ensure a robust collaborative work environment even with some parties behind firewalls, others on low-bandwidth channels, and still more with intermittent connections. Moreover, everyone in the group may not expressly trust the other actors *inside* the system. Protection is offered at a finer level than that of the enterprise. The system employs

fairly established cryptographic techniques but uses them in innovative ways.

Groupware requires the negotiation of trust between appropriate parties while excluding those who do not belong. Each user in Groove has an account resident on each machine and one or more identities associated with each account. This enables users to use the same identity from multiple devices, as well as allowing a single user to have multiple identities in different contexts. A software engineer can use Groove to collaborate with his firm's research group, as well as work with several friends to develop a startup business without having to worry about information leaking between the two projects or even allowing either project to know about the other. Identities are manifested in shared spaces, which can allow for either mutual trust or mutual suspicion. In the former, users are presumed to trust each other's identities, so verifiability of authorship is relaxed in favor of efficiency. In a mutually suspicious space, Groove enables tools to verify authorship of statements. We describe how this works next.

Whoever decides to initiate a shared space decides whether to declare it a trusted or suspicious space and can specify several security parameters if desired. All data are encrypted, both on the wire and on disk. Messages are reliable, and even in a trusting mode, Groove can offer confidentiality and integrity of messages. Privileges can also be revoked.

All applications running on the Groove network use "delta" messages, or document updates, that communicate changes of state to other members of the network, whether in a collaborative file or in a chat session. Each delta is encrypted using the group's symmetric key for fast encryption and decryption. The group has a separate shared key for authentication, which is used to sign the digest to ensure message integrity; both keys are reestablished every time some one leaves the group. Local files log all changes initiated by any actor.

When users might have reason to be suspicious, however, shared keys are not sufficient to instill trust in the integrity of authorship. After the author signs the delta message with the group encryption key, he signs a separate hash of the message body using his private key and the public key of the recipient. As implemented, Groove actually precomputes distinct pairwise keys from the Diffie-Hellman public keys of each group member and the sender's private key, which results in a smaller key and a less expensive verification procedure. Thus, appended to each message there will be a signed hash for all recipients in the group, who can use their own pairwise key of the sender and their private key to verify authenticity. The sender can even sign the message with her own key to verify its integrity on another device.

Messages do not have to broadcast to all nodes but can use their local knowledge of the network structure to pass the delta messages to key central nodes. Moreover, messages are sequenced, so if a recipient misses a message for some reason, such as being offline, he or she can fetch another copy from the sender or from any other member of the group. Other members of the group leave the pairwise keys intact, allowing the node to be confident of the authenticity of the message and its sender.

Of course, all this depends on entry into the group-space, trusted or untrusted. Untrusted here does not mean a purely malicious actor, because all members of any group will have the ability to read messages sent through the group. Rather, it refers to a competitive situation, where users may need to know for certain who sent which message. If this is not the case, significant encryption overhead can be saved. Still, how does a user join a trusted group?

Suppose Alice wants to invite Bob into a Groove shared space. Bob must have a copy of the client software, of course. The most important aspect is for both Alice and Bob to trust that the identities “Alice” and “Bob” in the system match their belief of who the individuals actually are. This requires some out-of-band communication. That is, Bob must verify that the information being sent actually belongs to Alice and vice versa. This process can be as simple as a phone call, where both trust that the phone number leads to the other person and they can recognize the other’s voice. Using some trusted non-Groove channel, they can verify the authenticators supplied by Groove (a public key) are valid, and Bob can join the group. There is no need to change the existing group keys because Bob may need access to existing files. Should the existing group want to deny Bob access to certain information in the group, they must form a new shared space for Bob’s involvement that does not involve the protected documents.

Groove has a fairly rigid set of security policies, but the P2P nature of the system protects system security and increases system usability. Lacking a central point of failure, or a nexus where permissions can be negligently or maliciously opened, Groove’s decentralization improves robustness. Anyone can start a group, but little active administration is required: all encryption after the initial trust phase described above is transparent to the user. This openness means that the parties do not need to rely on a third party to negotiate trust among group members.

Secure Distributed Storage

Using a P2P system for simple storage, rather than interactive or static publishing, poses a different set of security requirements. The encryption used for document security and integrity does not have to be as complex, because only the original owner need access the document itself: a strong symmetric cipher is completely adequate. Storage is a problem of coordination. A user may seek to store files on a network to as a standard data backup measure or to hide a document for later retrieval. Keeping data on a range of nodes offers strong fault tolerance and survivability compared to the single point of failure in a solitary remote storage site. The security problem to be solved by a P2P storage system is instead a coordination problem.

It is obvious that the amount of storage consumed by a given node must be in proportion to the amount of storage space they will give the network. Otherwise, free riding will result in too much data for the storage space available. There are a number of fairly straightforward ways for a centralized administrator to coordinate storage. A third party can give each client a quota and refuse access to the system for any part breaking their quota. This

third party must be trusted and reliable, however. Some sort of currency can be used for storing clients to pay warehousing clients, but this requires a trusted currency and clearing mechanism. Alternatively, the trust can be placed in hardware, with a smart card containing a secure internal counter and an endorsement of the right to store information on the network. Of course, this removes only the need for centralization by one degree, because a trusted party must issue the cards, sign attestations about a right to store, and verify that storage has been reclaimed before certifying a new counter value.

Centralized authority is not necessary if storage is distributed symmetrically. For ephemeral resources, such as downloading a single file, a tit-for-tat mechanism works well. The BitTorrent file distribution system lets peers download segments of large files from other clients also trying to access the same file. Clients essentially swap the segments that they have not yet downloaded. Each client uploads to others based on how much they have downloaded from those clients. Thus, every client has an incentive to upload what it has to other machines, so it can continue to download. This works well but is not designed for long-term storage. A reduction in demand for a file will limit the number of BitTorrent clients that will swap segments to complete the download.

Long-term storage necessitates accountability. Of course, a symmetric configuration constrains how storage arrangements work out, if each actor must trace through a network of obligations before finding someone who is owed storage space. If we use a simple barter system for the entire network, where a given actor can simply claim they have a right to store data on any computer in the network based on their own local storage, some certification is still needed for that claim. A trusted group of quota managers can prevent free riding by verifying those claims, but there is no real incentive for these nodes to take responsibility for auditing an entire network.

The storage system presented here by Ngan, Wallach, and Druschel (2003) offers a mechanism for the publication and auditing of storage records for an entire network without relying on a single trusted party. Each node publishes a record of their storage activities, and a series of random, self-interested auditing is enough to encourage honesty.

Each node in the network advertises its total local storage capacity, the list of others’ files stored locally, and its own files stored remotely. The first list can be thought of as the “credits” to each node and the second as “debits” to the system. Each record in this usage file contains an identifier and size information for the file, as well as an identifier and location information for the node. When node A seeks to store a file on another machine, the potential host examines the balance sheet of the would-be storer. If A is not consuming more storage than its capacity, the remote machine accepts storage if it has room itself. Each agent that is storing a file for node A finds that it is in its self-interest to check on A to confirm that A does indeed have the hosted file in its debit file. Otherwise, the node in question can delete A’s stored file and free up disk space for others to acquire most system “capital.” As long as A does not know when any node will audit its published file, it will keep its debit file accurate for fear of losing stored

data. This auditing mechanism prevents a node from hiding its own use of the storage network to store more than its share. It is important to note that the auditing communication must be anonymous and randomly timed, so that A cannot detect which creditor is auditing it and coordinate its response accordingly.

This standard auditing does not prevent a greedy node from claiming that it is storing files it actually is not. That is, A could claim a huge capacity but then falsely assert that it is being used by some other node. Thus, A would not have to share capacity but could use the capacity of the network. Fully auditing all outgoing obligations would be very expensive. The file I claim I store should be on some node's debit list, but a chain of obligations could go on for some time. Eventually, there must be an "anchor" that claims it is storing a file that is on no node's debit list. Finding this anchor, however, involves searching through deep trees of dependency. If all nodes are honest, there is no effective way to bound this search. The system requires that all nodes occasionally pick a node at random and examines its outgoing list. Although this is not as effective as a full recursive audit, Ngan et al. show that it is much cheaper and shows that perpetrators can still be caught with high probability even in the face of infrequent audits. Moreover, because the usage file has been digitally signed, it provides hard evidence of malfeasance, and the node can be ejected.

This model of a P2P storage architecture focuses on security against node collusion to free-ride on the system. Nodes can encrypt data for storage to protect it, and knowledge of some identifying information about the other node is necessary to coordinate storage. Like other P2P systems, it could be further enhanced by a reputation mechanism. If nothing else, an incentive to acquire a good reputation serves as a disincentive to get thrown out of the system once a good reputation is obtained. This is further discussed in the next session. Distributed storage can be an effective way to securely backup data, but attention must be paid to a secure alignment of incentives.

REPUTATION AND ACCOUNTABILITY

Peer-to-peer systems require the effective cooperation of disparate parties. Unlike a centralized client/server model, where system satisfaction rests only with the successful performance of one party, many different peers must all work together within the confines of the system. Yet systems must reflect the fact that there may well be actors who are not eager to cooperate and who may seek to free ride on the resources of others or actively subvert the system. Fortunately, the initial solution is trivial—avoid interactions with nodes that do not behave. Unfortunately, this is much more complex in practice. A simple list of who not to trust requires good information collection and distribution and does not scale well. Use of reputation can make this easier.

A full discussion of reputation—or even an attempt at a formal definition—is outside the scope of this chapter. However, reputation presents several interesting security issues as a solution and a new problem. For our purposes, reputation can be thought of as information about an actor that can aid in the prediction of future behavior. It

serves two complementary purposes. First, the reputation of other actors can guide a decision maker's choice in selecting transaction partners. Second, it can act as an incentive for good behavior for those who fear acquiring bad reputations. A bad reputation often involves some sort of punishment or reduced privileges, so a good reputation can be a motivating factor for good behavior.

Reputation systems have been a popular topic in recent information technology literature, and they have blossomed in practice as well. The Search for Extraterrestrial Intelligence (SETI) is a P2P system that uses spare processing power on users' PCs to examine radio telescope data for patterns that might lead to the discovery of life beyond our solar system. It uses an advertised positive reputation system with group identities to encourage people to share computer resources. The desire to acquire a good reputation for social reasons grew so strong that people began to cheat, undermining the entire signal processing project. SETI was forced to implement an accountability mechanism that replicates all computations for quality control. This security control reduced the effectiveness of the system by half.

In general, reputation requires an enduring identifier of some sort and the ability to map information about past transactions to that user. If a user wishes to base his or her opinion on anything other than his or her own experiences, he or she can solicit reputation information from others but now must have some metric to trust the information of others. This need for credibility adds an additional layer of complexity to the system. There are several ways to apply reputation to a P2P system.

First, one can ignore reputation within the system and rely on users or applications to obtain and use the information they need. The P2P system can make this easier with good security. For instance, a Groove workspace offers no aid to a participant in evaluating the quality or trustworthiness of a document or fellow participant. Groove can, however, use cryptographic techniques to enable the user to know exactly who sent what information, so that an out-of-band reputation system based on external identities can be mapped into a Groove-supported work environment. It is also possible to imagine a reputation system layered on top of a P2P system, where users can define their own parameters of trust and simply rely on the underlying P2P layer to provide information, which is evaluated at the reputation layer. This information can then be passed back to the P2P layer for a decision about storage, transmission, or whatever function the P2P system provides. By layering them in this fashion, the reputation system can be adjusted independently of the P2P system, following good security procedures of separating functionality whenever possible.

Dingledine, Mathewson, and Syverson (2003) take the opposite approach, arguing that bolting security into an existing system is the incorrect solution. Their Free Haven system uses published reputations to encourage servers to keep shares they have promised other servers they will keep. Recall that documents are kept alive by servers trading them. Any server finding its trading contract broken can broadcast proof of malfeasance with the signed contract and certified proof of failure to deliver. Verifying disputed claims grow to be complex very quickly, however,

especially if the document in question was traded to another party. Free Haven uses credibility metrics to evaluate contested claims, which are in turn built from reputation records over time. The additional computation required for secure attestations places a fair bit of overhead on the system, without full incentives for any one node to follow through on the veracity of others' claims. The authors acknowledge that "designing the original system without a clear idea of the reputation and verifiability requirements made Free Haven's design complex and brittle."

The proprietary file-swapping software Kazaa also built in some degree of reputation to prevent free riding. If more than one user requests a given document from a server, the requesters are queued, and order in the queue is determined by reputation rather than order of arrival. Positive reputation is accrued by sharing files with others. This mechanism was designed with no security protections, however, so when the source code was reverse engineered, competing vendors distributed a client that could set its own reputation. Because all reputation information is kept locally by the client itself, there is no structural way to prevent this. Where the reputation mechanism is integral to the design of a P2P system, the reputation mechanism must itself be secure. Otherwise, it becomes the weakest link in a system that might otherwise be secure.

A final aspect of the reputation mechanism is the cost of acquiring a new identity. If a fresh reputation is easily acquired, then anyone with a bad reputation will handily jettison their bad name for a new one. This creates a world where bad reputations simply will not exist. Unfortunately, an actor choosing by reputation must now assume the strong possibility that anyone with a new (neutral) reputation is untrustworthy. This puts honest newcomers at a disadvantage. One way around this is to require some form of payment to obtain a new identity in the system. Of course, this also imposes a penalty on newcomers. Friedman and Resnick (2001) have shown that any identity-bound reputation system with nonpermanent identities must impose some cost on newcomers, either as an outright entry fee or with a below-neutral reputation.

A final way to enforce good behavior is through a transitive reputation tokens or a microcurrency. Rather than fixing reputation to an identity, microcurrency can be thought of as signaling information that can be passed from one person to another. There are many security issues with micropayment and electronic currency schemes that have been discussed elsewhere (see, e.g., Camp, 2000). One system that implemented a successful micropayment scheme is Mojo Nation, a P2P file-sharing system that used tokens known as "mojo" to encourage good behavior (Wilcox-O'Hearn, 2002). Every transaction required an exchange of mojo, so the more altruistic actor received something for giving up something of value. Thus, each actor had an incentive to offer files to the network in the form of the ability to barter for more files from others. Mojo Nation avoided some of the cryptographic hurdles of a distributed system by relying on a centralized token server for market clearing. However, the market was structured in such a way that trading could continue even if the token server was temporarily unavailable.

One definition of a secure system is one in which a user can have confidence of appropriate functionality. Peer-to-peer systems need security to defend proper operation of the underlying mechanism but may also need additional layers of security to encourage proper operation of other peers. Some of the systems described in this chapter, such as the secure overlay, are designed to require as little reputation information as possible. Others, such as the secure storage system, are predicated on their ability to overcome the free rider problem without a centralized coordinator. Reputation and accountability mechanisms can play a key role in the security and functionality of P2P systems, but they must be designed and implemented as an integral part of the system.

CONCLUSION

Peer-to-Peer systems are incredibly flexible and can be used for a wide range of functions, often more effectively than their client/server analogs. They can be used to anonymously or robustly route through a network of peers, protect content from censorship, enhance and protect collaborative processes, and coordinate use of diverse services. Security could be a concern to any of these functions and should be treated accordingly. In the systems discussed in this chapter, the security is always on: no administrator can accidentally or maliciously turn it off. This constant presence and absence of centralized support means that good security practices must be built into the protocols of the system. Each system has different design goals, and just as the security should reflect the purposes of the system, system design should reflect security exigencies.

GLOSSARY

Anonymity Not associated with a personal identifier. In the context of information networks, it is the ability to keep identifying information about the user from being known. There are different degrees of anonymity based on the set of possible identities and the strength of the attacker determined to ascertain a given identity.

Censorship Attack An attempt to keep the content from being accessible. It can manifest itself as an attempt to prevent content distribution, to prevent the content from being located, to pollute the content beyond use, or to expunge the content completely from the system.

Centralized Describes a system with a single point of control, with policy emanating from that one source. Such systems can be easier to directly administer, are useful for coordinating different tasks that need common information, such as sequential ID assignment, and can offer great economies of scale. However, the users must trust the centralized server; they are also particularly vulnerable to targeted attacks such as distributed denial of service attacks.

Decentralized Describes a system designed and implemented without a single administrative point of control. Decentralized systems can be more fault tolerant if properly designed, but it can be harder to coordinate behavior within the system.

Delta Message A message in groupware that contains only the changes to a given document. Delta messages often contain auditable information to create a history of the document and security information to maintain document integrity.

Distributed Hash Table (DHT) A hash lookup system that routes queries through nodes, where the local routing table of each node is used to forward the query to the node that is ultimately responsible for the key.

Groupware Software that enables shared, closed environments for an identified set of users, particularly for collaborative work. It can allow users in different environments to share common tools and documents.

Locality A node's place in the network topology, either in the overlay network or the underlying internet architecture. Systems can be designed to capitalize on locality, such as Freenet's ability to "push" content closest to where has been recently demanded, or ignore locality, such as a secure overlay's tendency to map close internet addresses to random parts of the namespace.

Namespace A context formed by a set of unique identifiers that allows each object referenced to have a mapping from identifier to object such that there is no ambiguity to which object a name points to. The domain naming system (DNS) is an example of a namespace where every internet object is referenced by at least one URL and every URL references at most one object.

Node A point on a network that is capable of sending or receiving information either for itself or to relay a message to or from others.

Onion Routing A system for anonymous network communication designed to be resistant to both eavesdropping and traffic analysis from threats inside and outside the system. Messages are passed wrapped in layers (like an onion) of encryption, each corresponding to the key of one of the routing nodes, so that only the destination node can decrypt the message or even determine the route of the message.

Out-of-Band A message that is not passed across the network in question but through some other channel. Out-of-band messages can be used to help secure the identity of a party where different channels can reinforce beliefs the end parties have about their respective identities. Out-of-band messages can be passed on the same physical network but using a secure overlay network, as with signaling the telephone network.

Overlay Network A communication network that functions above the transport layer. A virtual network that is built on top of the basic Internet architecture and that provides additional functionality such as searching, routing, encryption, and so on.

Peer-to-Peer (P2P) A style of network in which nodes communicate to other nodes via ordinary intermediate network nodes rather than a centralized server with full knowledge of the network so that each node performs client and server operations. Most P2P systems are overlay networks with unique namespaces.

Reply Block A list of anonymous remailers with the recipients address at the end, used to direct a message to the final account without disclosing the address to the sender or any intermediary. Reply blocks are used to allow anonymous communication between

two parties, where the sender might want to receive a reply from the recipient but not disclose his or her identity.

Reputation Information about a actor's past action that is believed to be is correlated future behavior.

Shared Space In a groupware environment, the shared space is the common namespace of specific set of nodes in a single zone of administrative control. Common tools and documents can be available to all users while the group space exists.

Signature Verification Key The public half of a public/private key pair; used to verify that a document was signed by the private key. In the Freenet P2P system, a signature verification keys allow a document to be tracked by a pseudonymous author's signature verification key rather than a key based on a hash of the document or specific key words.

Survivability The ability to survive while under attack by exhibiting gradual degradation rather than failing entirely. Characterized by graceful degradation rather than catastrophic failure.

Sybil Attack Also known as pseudospoofing, an attacker acquires multiple identifiers in the system to undermine some function of the system, such as attempting to control a large portion of the key space in a distributed hash table. These attacks have proven hard to defend against in open, anonymous systems and often inspire the use of reputation or cost-driven overlays.

INTRODUCTION

Security Middleware Architecture

Middleware refers to a broad range of software that enables communication or data exchange between network-based applications across networks. This type of software is often described as “glue” because it connects or integrates business-critical software applications to other applications. With today’s networked-based applications—especially enterprise resource planning (ERP), supply chain management (SCM), customer relationship management (CRM), and business-to-business (B2B) and business-to-consumer (B2C) electronic commerce (e-commerce)—business operations depend on secured data transfers between these applications. Figure 1 shows a generic security middleware infrastructure. This diagram shows security middleware acting as an integrator of applications and data and as a provider of secure connectivity and interoperability.

In a simplest description of how it functions, middleware sits between two or more applications to accept requests for access to information or network services and then responds to those requests. For example, when a user requests information from a Web site’s database, middleware provides the services and security necessary for that exchange. As such, it is also considered the “plumbing” or utility layer in networks. By promoting standardization and interoperability, middleware makes advanced network applications easier to use securely. Middleware provides security, identity, and the ability to access information regardless of location in addition to authentication, authorization, directories, and encryption.

Because it is a general term for any programming that serves to “glue together” or mediate between two separate and typically already-existing programs, middleware is used to refer to either software or infrastructure. As software, it is the layer between a network and the applications that use it. In addition, middleware is an infrastructure that manages security, access, and information exchange on behalf of applications to make it easier and more secure for people to communicate and collaborate.

It can be used to find people or objects (e.g., directory services) or to keep them confidential (e.g., security services).

Middleware programs are also used to provide messaging services so different applications can communicate. This systematic tying together of disparate applications is known as enterprise application integration (EAI). A common middleware application is to enable programs written for access to a specific database to access other databases.

For end users, middleware makes sharing of network resources transparent and much easier. Moreover, it increases security by protecting against unauthorized or inappropriate use. The problem of security in a distributed environment is too difficult to be solved properly by each individual application. Without middleware, applications would have to provide these services themselves, which could result in competing and incompatible standards—and increase the risk of unauthorized access. Therefore, having the middleware assume this responsibility leads to more robust and consistent solutions. This is done primarily through single sign-on (SSO) technologies. SSO makes it possible for a user to enter his or her credentials only once and remain authorized within the network until logging off. A widely used SSO technology is Kerberos. SSO and Kerberos are discussed in detail in the following sections.

For company networks or e-commerce operations, middleware plays a pivotal role in connecting enterprise information technology (IT) environments to the Internet. Secure connections are achieved using middleware to control access; that is, it allows only authenticated users, applications, or network end points to connect to an organization’s services, applications, and data.

The CIA Triad and Access Control

There are three main principles of information security, which are referred to as the *CIA triad*. These three principles are as follows:

1. Confidentiality: Sensitive information is protected against disclosure.

Figure 1: Generic architecture of security middleware operating between the supporting information technology (IT) infrastructure and corporate applications.

2. Integrity: Information and systems are protected against unauthorized modification.
3. Availability: Information and systems are protected against disruption.

To achieve these three goals, access to applications must be controlled. Without access control, there is no security. Access control means that only authorized (or intended) users can gain access to a network or application and that those users have only the level of access needed to accomplish authorized tasks. This concept is known as *least privilege*. Examples of tasks are reading data, writing data, or downloading files. The problematic part is that access controls must be incorporated in a layered approach; each layer needs to be understood, and the relationship of each layer with other layers needs to be understood (Harris, 2002). When implementing middleware to enforce access control, these technical issues must be addressed so that vulnerabilities are not overlooked and controls do not conflict with each other.

The essential access control services provided by security middleware include identity management (or identification), authentication, authorization, directory services (or directories), application program interfaces (API), and abstraction.

It is helpful to define the terms *subject*, *object*, *principal*, *access*, and *open* because they are used often when discussing access control:

- A *subject* is a person (user) or application that requests access to data, a service, application, and so on.
- An *object* is the data, service, or application that is being accessed by a subject.
- A *principal* refers to either a subject or object whose identity can be verified (e.g., a workstation user or a network server).
- *Access* refers to the tasks carried out on an object, such as read, write, modify, delete, and so on.
- *Open* means unprotected, such as an open network.

SECURITY MIDDLEWARE PROCESSES AND SERVICES

Before a subject can be authenticated, it has to be identified with an identifier. An identifier is a unique way of naming something. A social security number or personal e-mail address is an identifier because they uniquely name an individual—that is, unless two or more people share an account. In middleware, identifiers can name anything, including abstract concepts such as certain applications or a certain security clearance. The entity named by the identifier is known as its subject.

The key security middleware defense services providing access control are authentication, authorization, directories, application program interfaces (API), and abstraction.

Authentication

Authentication is the process of providing a private piece of information or physical token to establish whether a subject is who or what its identifier (e.g., username) claims it is. During authentication, a user or object proves it is the subject of an identifier. This service is generally performed by the middleware layer so that applications above it do not need to have their own authentication mechanism.

Identity is authenticated by the presentation of digital credentials. As explained previously, a user must present credentials to a network to gain access to it. In the case of people, the most common credentials used for confirming identity include the following:

- Something the subject knows, such as a password
- Something the subject has, such as a USB token, digital ID (certified public/private key), smartcards, or challenge-response mechanisms
- Something the subject is, such as photo identification, fingerprints, or biometrics

As such, authentication is the validation of a user's electronic identity based on proof provided by that user, typically a unique user id/password pair. If a user cannot be authenticated, then he or she would not be granted access to nonpublic network services.

Authentication is most frequently done by asking a user to enter a username and password. Although there are more secure approaches, passwords are often transmitted through open communication channels, which compromise security. The quality of the authentication depends on the guarantee that can be given that the authentication process was not fraudulent or compromised by a hacker attack, such as correctly guessing a password.

The primary issues to be considered about any authentication system pertain to how secure or strong the authentication process is. The security of any authentication process depends on several variables, primarily the number of factors used to authenticate a subject. Single-factor authentication such as using only a password is much less secure than using a USB token activated by a password, which would be a two-factor authentication.

Figure 2 illustrates and describes the steps involved in authentication in a distributed environment, such as secure Web pages. Several of the concepts illustrated in this figure (e.g., Kerberos) are described in subsequent sections.

Authorization and Directories

Once authentication has been performed, more credentials or attributes about a subject are needed before that subject can be given access permissions. Authorization is process of determining whether to allow a subject access to a specific resource or service or other subject. It is also the process of assigning authenticated subjects the rights to carry out specific operations.

Only having one valid identifier does not provide enough information about a subject. Although an authenticated identity may be sufficient for some purposes, it is often important to acquire more information, such as preferences, e-mail aliases, electronic credentials, and so on. Identifiers become far more powerful when they are combined with a technology known as directories. Along with its many other uses, a directory links an identifier with other attributes about a common subject.

A directory stores permissions and regulates permissions, such as viewing files. Directories are, in effect, databases composed of many sets of information with a similar format. A set of information is generally called an entry, and a piece of information within an entity is called an attribute. A primary function of a directory is to look up a given attribute from a given entry, such as a user's read or write privileges for a specific object (e.g., a payroll file). Because directories make information available, access to them must also be adequately protected. Access controls can be set to regulate who can read or update specific directory fields.

There is a one-to-many relationship between authentication and authorization. For example, once a subject has been authenticated during a session, then many authorizations for that subject can occur with a single cached authentication. During a Web browsing session, a user would need to authenticate only once to access many pages for which the user needs authorization. In this way, different applications can use the same authentication, but have different authorization permissions. Usually, authorization checks do not involve any input from the authenticated user because the system already knows that the user is authenticated and the permissions of that user. Of course, authentication may also be required for every new application, requiring multiple sign-ons in a single session. Single sign-on (SSO) is discussed under Application-Based Authentication.

The two major technical components of a middleware implementation are client software and enterprise middleware servers that provide authentication and directories. The client side does not require much work because most middleware functions can be performed by existing programs, such as Web browsers and e-mail clients. In contrast, the server side needs to perform many new services. The middleware system must provide an effective and secure layer for communication between client and server. The major client-side technological challenge

is establishing the authentication system. Although these systems can be built around passwords, public keys, smart cards, or other schemes, it must be available on every machine that a user will want to use to authenticate to the middleware server.

Application Programming Interfaces

APIs exist for (almost) all middleware products and establish the interface with which clients (applications) request services of the servers. In other words, APIs are part of all types of middleware, not a separate type. APIs provide for data sharing across different platforms. Specifically, an API is a set of standards and protocols by which a software application can be accessed by other software, or for communication between application programs. APIs enable the exchanging messages or data between two or more different software applications. The API must exist before a program can be called by an external program and before it can send a response to an external program.

There are several types of APIs that enable data sharing between different software applications on single or distributed platforms. Those APIs include the following:

- Remote procedure calls (RPCs): These are protocols that provide high-level communications. An RPC implements a logical client-to-server communications system specifically for network applications
- Standard query language (SQL): SQL is an ANSI standard computer language for accessing and manipulating databases
- File transfer: Transporting or sharing files between remote machines
- Message delivery: Reliable message delivery ensures that Web services architecture, protocols, and interfaces deliver secure, interoperable, transactional, and robust solutions (IBM, 2003)

Common Object Request Broker Architecture

Common object request broker architecture (CORBA) is an architecture and specification for creating, distributing, and managing distributed program objects in a client/server network. Distributed objects are also known as components or programs. CORBA enables programs at remote locations, which were developed by different vendors, to communicate in a network through an "interface broker." CORBA 3 is the latest version of this specification.

CORBA was developed by a consortium of vendors through the Object Management Group (OMG), consisting of over 500 member companies. Both International Organization for Standardization (ISO) and X/Open have sanctioned CORBA as the standard architecture for distributed objects. However, Microsoft has not adhered to CORBA and has its own distributed object architecture called the distributed component object model (DCOM). CORBA and Microsoft have agreed on a gateway approach so that a client object developed with the DCOM and CORBA servers can communicate with each other.

CORBA is based on the object request broker (ORB). ORB support in a multivendor client/server network

DISTRIBUTED AUTHENTICATION STEPS FOR SECURE WEB PAGES

STEPS:

1. User's browser requests the secure page from the local web server (Go to 2)
2. Local web server checks: Does user's browser have a cookie? (Go to either 2A or 2B)
 - A. **Yes** (Go to 2Ai)
 - i. Cookie is present. Local web server contacts AFS server (Go to 2Aii)
 - ii. Does the cookie content correlate with the AFS file? (Go to 2Aiaa or 2Aaib)
 - a. **Yes**
 - The cookie is valid
 - Local web server displays the secure page.
 - b. **No**
 - The cookie is invalid. Need a different cookie. (Go to 2Bii)
 - B. **No** (Go to 2Bi)
 - i. Cookie is not present (Go to 2Bii)
 - ii. Local web server passes the user's browser to the secure web server (Go to 2Biii)
 - iii. Secure web server requests login ID and Kerberos password (Go to 2Biv)
 - iv. Kerberos DB authentication server decides if login is valid (Go to 2Biva or 2Bivb)
 - a. **Yes**
 - Login is valid. Secure web server creates AFS file
 - Secure web server generates and sends cookie to browser, then redirects browser to local web server. (Go to 2)
 - Local web server displays the secure page.
 - b. **No**
 - Login is invalid. Try again. (Go to 2Biii)

Figure 2: Flowchart model of distributed authentication for secure Web pages.
 Source: <http://distauth.ucdavis.edu/docs/dachart.html>

means that any object (e.g., a client program) can request services from a server object without knowing the server's location is in a distributed network or its interface. To request or reply between ORBs, programs use the general inter-ORB protocol (GIOP); for the Internet, programs use the Internet inter-ORB protocol (IIOP). IIOP maps GIOP requests and replies to the Internet's transmission control protocol (TCP) layer in each computer.

APPLICATION-BASED AUTHENTICATION

As discussed, authentication is a method for confirming a user's identity to control access to enterprise information assets. IT departments need to manage user identities and system access across the enterprise and keep them simple and convenient to use. Users cannot be expected to securely remember multiple log-in (sign-on) routines. Authorized users cannot remember numerous usernames and passwords to be able to access enterprise information assets many times during the workday. So users tend to create simple passwords that are weak, which increases the risk of compromising the network and sensitive data.

To control access to enterprise information assets and services by authorized users (e.g., employees, customers, and partners), single sign-on technology is used.

Single Sign-On and Kerberos

Kerberos is a ticket-based authentication protocol based on symmetric-key cryptography. A Kerberos ticket is a certificate issued by an authentication server, encrypted using the server key. It allows principals communicating over networks to prove their identity to each other while preventing eavesdropping or replay attacks. The components used in Kerberos are as follows:

- Key distribution center (KDC): The KDC holds the user and service secret keys, provides authentication, and creates and distributes session keys
- Authentication service (AS): The AS is the component of the KDC that performs the authentication
- Ticket-granting service (TGS): The TGS is the component of the KDC that creates and distributes tickets to the principals (users, applications, resources, or services). Those tickets contain the session keys
- Ticket-granting ticket (TGT): The TGT is the initial ticket sent from the AS to the principal

The steps taken by Kerberos to authenticate users and other principals are necessary because the principals do not directly trust each other, but they do trust the KDC (Harris, 2002). Kerberos provides a means of verifying the identities of principals on an open network. This is accomplished without basing trust on host operating systems or addresses and without requiring physical security of all the hosts on the network. It is assumed that packets traveling along the network can be read, modified, and inserted without authorization or detection. Figure 3 illustrates the steps in the KDC ticket authentication process.

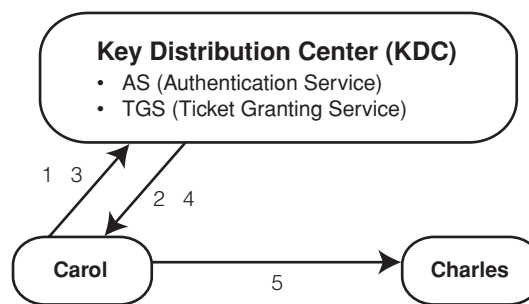

Figure 3: KDC ticket authentication process.

The process is accomplished as follows, using the names Carol and Charles as examples:

1. At login, Carol authenticates to the AS.
2. Carol receives an initial ticket, which is the TGT from the AS. Carol uses her password to retrieve a session key encrypted in the reply. The TGT allows Carol to obtain tickets from a TGS for other Kerberized services.
3. Carol requests to access Charles. For this request, Carol presents her TGT to the TGS to receive a service ticket.
4. The TGS creates a new service ticket with session keys for Carol.
5. Carol extracts one session key and sends the ticket to Charles. To authenticate to Charles, Carol constructs a timestamp (to prevent reply attacks), proving to Charles that she knows the session key inside of the service ticket.

The basic Kerberos authentication process proceeds as follows (Neuman, Yu, Harman, & Raeburn, 2004):

- A client sends a request to the authentication server (AS) requesting "credentials" for a given server
- The AS responds with these credentials, encrypted in the client's key. The credentials consist of a "ticket" for the server and a temporary encryption key (often called a "session key")
- The client transmits the ticket (which contains the client's identity and a copy of the session key, all encrypted in the server's key) to the server
- The session key (now shared by the client and server) is used to authenticate the client and may optionally be used to authenticate the server. It may also be used to encrypt further communication between the two parties or to exchange a separate subsession key to be used to encrypt further communication

Many applications use Kerberos's functions only at the initiation of a data stream network connection. Therefore, unless an application performs encryption or integrity protection for the data stream, the identity verification applies only to the initiation of the connection and does not guarantee that subsequent messages on the connection originate from the same principal.

Version 5 of the Kerberos protocol (released in 2004) has evolved from Version 4 based on new requirements

and desires for features not available in Version 4. The design of Version 5 of the Kerberos protocol was led by Clifford Neuman and John Kohl with contributions from the community. Reference implementations of both version 4 (V4) and version 5 (V5) of Kerberos are publicly available and commercial implementations have been developed and are widely used. Details on the differences between Kerberos Versions 4 and 5 can be found at <http://www.isi.edu/people/bcn/krb-revisions/krbclar/krbclar-draft-07.nroff>. Although V4 still runs at many sites, V5 is considered to be standard Kerberos.

Kerberos has significant limitations and needs to be integrated with other security measures. In particular, Kerberos is vulnerable to dictionary or password guessing attacks. If a user selects a weak password, then an attacker who has guessed that password can impersonate the user, in effect gaining all of the user's access privileges. Those privileges can be used to gain even greater unauthorized access to the network or databases.

Another limitation of Kerberos is that it requires a trusted path through which passwords are entered. If the user enters a password to a program that has already been compromised by an attacker or a Trojan horse, or if the path between the user and the initial authentication program is being sniffed or monitored, then an attacker may obtain sufficient information to impersonate the user. As such, Kerberos should be used with other access control defenses.

Secure Socket Layer

Secure Socket Layer (SSL) is a commonly used protocol for managing the security of a message transmission on the Internet. It transmits communications over the Internet in an encrypted form. SSL is used to ensure that the information is sent unchanged and only to the intended server. Most e-commerce and online shopping sites use SSL technology to safeguard transmission of credit card information.

SSL operates at the application/session layer. There are two strengths of SSL depending on the length of the session key generated by the encrypted transmission—40 and 128 bit. The 128 bit is exponentially more difficult to break than the 40 bit. Most browsers support 40-bit SSL sessions. Netscape Communicator 4.0 and higher allows 128-bit SSL sessions.

TLS (transport layer security) is replacing Netscape's earlier SSL protocol. The TLS layer resides between the transport and session layers of the TCP/IP stack. Many protocols use TLS to establish secure connections, including HTTP, IMAP, POP3, and SMTP. As with SSL, all of these protocols protect communications privacy over a public network with cryptography. It should be noted that HTTP, POP3, and so on are clear-text protocols by design. That is why they have to use other things such as SSL for confidentiality. They allow client/server applications to communicate in a way that is designed to prevent eavesdropping, tampering, or message forgery. From a security and identity perspective TLS provide a tremendous value to Internet commerce. The ease of monitoring Internet traffic, spoofing Internet domains, and tricking individuals into providing sensitive information makes

identifying the server side of an Internet transaction important.

Public Key Infrastructure and Message-Oriented Middleware

Public Key Infrastructure (PKI) technology is widely used on the Internet with SSL communication. The basis for PKI is a certificate that is generated by an authorized certificate authority (CA). Digital certificates are discussed in Digital Certificates. However, SSL by itself is not enough protection so PKI and SSL are used together to provide for message-oriented middleware (MOM) authentication (Lingel, 2004). In an SSL handshake, the MOM manager first verifies that the certificate has been generated by a trusted CA and not been altered. The manager then creates a unique session key for this conversation, encrypts it with the subject's public key, and sends it back to the subject. The originator has the private key, so it will be the only process that can decrypt the session key. From that point, the session key is used. This guards against replay attacks. The private key equivalent to a password never goes out over the network. Certificates provide user names, who/what issued the certificate, the issue's digital signature, and activation and expiration dates

NETWORK-BASED AUTHENTICATION

As with application-based authentication, processes and procedures are needed to authenticate or verify users on a wired or wireless network. Examples of middleware for network based authentication are as follows:

- Lightweight directory access protocol (LDAP)
- Wired equivalent privacy (WEP)
- Virtual private networking (VPN)
- Internet protocol security (IPSec)
- Web services security (WS Security)

These protocols and services make use of many of the techniques already discussed, including digital certificates, CAs, smart cards, secure tokens, biometrics, or a combination of efforts that verify and authenticate the validity of each party involved in a transaction.

Lightweight Directory Access Protocol

The LDAP specification was developed at the University of Michigan in the early 1990s as middleware between PCs and X.500 directories. X.500 directories were based on global standards but were complex and overhead intensive. LDAP emerged as a standard to bridge the gap between end users and the complex X.500 directories. In the most basic of terms, LDAP provides a locator service for a person who may be listed in multiple locations on a network in different formats.

Although LDAP's original role was to interface with X.500 directories, it can interface with any directory that follows the X.500 standards. User access to network resources can be controlled by an LDAP accessible directory. The directory can be hosted by any number of database servers on the market today.

Recent advances in the LDAP specification have allowed the service to remain viable from a security perspective. The LDAP specification allows for encryption communication among multiple LDAP servers via SSL. In addition, extensions are available to allow for non-ASCII and non-English characters.

There are three main components to an LDAP environment; they are as follows:

1. **LDAP client:** The client portion can be hardware or software that can request information from an LDAP server. The standards based nature of LDAP allows for many vendors to create software to connect to LDAP servers. The LDAP client would be considered a *subject* as it is attempting to access data from the LDAP server. In addition, the LDAP client could be attempting to verify the identity of a user and, therefore, can also be considered a *principal*.
2. **LDAP server:** The LDAP server “listens” for LDAP requests on a network and translates the client requests into requests to the X.500 directory. The results from the X.500 directory query are then sent back to the requesting LDAP client to complete the lookup. The LDAP server can be considered an *object* as it is a service being accessed by a *subject*, the LDAP client.
3. **X.500 directory:** The X.500 directory can be any database that adheres to the X.500 standard. The database can house many thousands, if not millions, of records. As the databases are optimized for read transactions they perform exceptionally well. The X.500 directory houses *access* information for a particular *subject*.

The openness and standard based architecture of LDAP ensures the standard will be a viable mechanism to access large amounts of information using standard access methods. Microsoft’s Active Directory and Novell’s Novell Directory Services are both based on LDAP standards to provide security control for computer and user accounts in the enterprise.

Wired Equivalent Privacy

One of the fastest growing technology areas is wireless local area networks based on the Wi-Fi or wireless fidelity standards. These networks can be established quickly without the cost of a wired infrastructure with little of no technology knowledge. There are, however, drawbacks to the initial convenience of a Wi-Fi network. Early Wi-Fi networks lacked the availability of encryption. WEP was established to add encryption to Wi-Fi networks. However, the initial version was based on a 40-bit key and was easily compromised. More recent WEP standards based on a key length of 104 bits are less vulnerable to compromise and provide more security. Actually, 104-bit WEP is just as vulnerable, but it takes longer to attack. Refer to chapter 150 for an explanation of WEP.

WEP is a protocol used to encrypt information sent between access points and stations. Access points receive and transmit wireless signals, convert them into their wired counterparts, and send them to their destinations on the network. Stations are equipped with wireless

transceivers that allow access to network resources by converting network requests into radio signals that are passed to access points. WEP technology uses 40- or 104-bit secret keys on both access points and authentication stations and to encrypt information transmitted over the radio waves.

The station or PC is considered the subject and the principal. The access point is considered an object because it is being accessed by the station. For example, if a new station or PC attempts to connect via Wi-Fi to an access point where WEP is required, the following steps are necessary to authenticate the station:

1. The station or *subject* requests authentication to an access point or *object*.
2. The access point or *object* creates a random 128-byte message and forwards it to the *subject*.
3. The *subject* accepts the message, encrypts it with its WEP key, and sends the encrypted message back to the access point.
4. The access point decrypts the message with its WEP key and compares it to the original message.
5. If the original unencrypted message matches the unencrypted message from the *subject*, the *subject* is associated or authenticated with the access point.

After successful authentication, all wireless traffic between the subject and access point are encrypted with the same WEP key that is used for authentication.

There are several caveats to the above process. First, it is considered poor practice to use the same key for authentication and data encryption. Second, the WEP keys must be preshared and manually installed on every access point and potential subject. It should be noted that newer 802.11 protocols are fixing this requirement. The second step creates an administration problem when the keys are updated. As is true with Kerberos, when used alone, WEP security can be very insecure. However, when layered with multiple methods of authentication and encryption, wireless communication can be moderately secure.

Virtual Private Networking

VPN is replacing traditional dial-up modem pools. With a VPN, remote users typically connect to an Internet service provider (ISP) or a private IP-based network. Then they establish a secure connection with network servers via an encrypted tunnel. VPNs can also be used for secure communication across a LAN or WAN.

Hardware or software can be used to create and maintain the encrypted tunnels on public networks. In many organizations, a hardware solution is used to create “always-on” VPN tunnels with remote offices or trading partners. VPN tunnels based on software are often used to connect home offices or individuals who travel.

VPN tunnels require two connections. First, a common network connection is required. Usually the Internet is used, but any common network can be used. Second, an encrypted connection between the two parties is established, commonly called a tunnel. In both the hardware and software configurations, the tunnel provides access

to all applications and services located on the destination network. Of course, additional layers of security may be installed to protect sensitive data. Because of the many ways a VPN connection could be established and maintained, most VPN products are not compatible from one vendor to another.

The remote VPN client is considered the *subject* as well as the *principal*. It is considered the *subject* because it is attempting to access data or services from the destination network and the *principal* because the destination VPN service must verify the identity of the remote VPN client. The *object* could be any number of applications, network services or data the remote VPN client is attempting to access.

Establishing VPN tunnels is a cost-effective way for an organization to extend network services without the cost of expensive leased lines or slow modem pools.

Internet Protocol Security

The Internet protocol security (IPSec) is widely used to establish secure virtual private network communications over IP networks. IPSec allows for preshared or dynamically created keys to create an encrypted tunnel on an open or unsecured IP network. IPSec secures and authenticates network traffic on both public and private IP networks such as the Internet, preestablished VPN connections, or company-to-company extranets. IPSec is unique because it functions at the network layer of the OSI model. Encapsulation of data is supported through the Internet key exchange (IKE) protocol. Operating at the network or IP layer, IPSec offers companies a large amount of flexibility in supporting configurations and applications.

In a typical configuration, software is installed on a remote user's computer, preshared keys are exchanged and communication software is configured. Within minutes the end user can have full access to all network services and applications.

Internet key exchange (IKE) is a key-sharing protocol that follows the public/private key pair used to mutually authenticate both parties of an IP conversation. See the chapter titled Public Key Infrastructure for details. Before data can be securely shared, a security agreement (SA) must be established. The SA defines all the security parameters and keys the session will use. To ensure data are securely transmitted, IKE uses a two-phase approach to communication. During the first phase, also called the main mode, a secure authenticated channel is established. This phase includes policy negotiation, exchange of public keys, and authentication. Typical Phase I communications include the following:

1. Negotiation details of the encryption and integrity algorithms and authentication methods.
2. Key public key exchange of base information for the Diffie-Hellman key determination algorithm.
3. Authentication via a Diffie-Hellman key exchange. Without successful authentication, communication will not proceed. The master key is used, in conjunction with the negotiation algorithms and methods, to authenticate identities.

Phase 2 of the communication requires an established SA from phase 1 to operate. The first step of Phase 2 is for both of the IKE participants to negotiate a mutually acceptable IPsec policy. These policies are locally established and if there is no common policy this phase will fail. After the peers agree, the keying material is agreed on and the IPSec SAs are established. Future communication in this tunnel is encrypted and keys for the encryption are changed based on the mutually acceptable policy.

Web Services Security

First, it is helpful to understand Web services before describing WS-Security. Web services create a layer of middleware as part of a service-oriented architecture (SOA) to enforce policies for services, such as security, routing, and workflow. Web services are also referred to as SOA middleware. Applications based on Web services plug into the middleware layer to support application reuse of components and service and to make it easier to compile Web services into composite applications (Fontana, 2004). The SOA includes shared services, control, and a common security model and interface language. Current interest in SOA is not indicative of a new technology but rather another iteration of existing concepts (Bednarz, 2004). Earlier attempts at popularizing SOA, which included CORBA, were hindered by a lack of standard middleware and APIs. Web services can be the link that makes SOAs mainstream.

Some key aspects of Web services are that Web services are based on top of prevalent Internet-related standards (http, XML, etc.) rather than on particular, less prevalent, architectures or implementations. The problem with CORBA, which is also an architecture for distributed objects and services, is that both the client and the server need to use CORBA. DCOM components can interact only with other DCOM components (without some bridging technology). Web services, however, have no such architecture or implementation dependencies and work better in highly heterogeneous environments.

WS-Security provides a mechanism for associating security tokens with messages, but no specific type of security token is required by WS-Security. It is designed to be extensible and support multiple security token formats. WS-Security improves protection through message integrity, message confidentiality, and single message authentication. These mechanisms work with numerous different security models and encryption technologies.

Additionally, WS-Security describes how to encode binary security tokens. The specification describes how to encode X.509 certificates and Kerberos tickets as well as how to include opaque encrypted keys. It also includes extensibility mechanisms that can be used to further describe the characteristics of the credentials that are included with a message (Atkinson et al., 2002). See the chapter entitled Digital Certificates for more information.

GLOSSARY

Access Refers to the tasks carried out on an object, such as read, write, modify, delete, and so on.

Access Control Only authorized (or intended) users can gain access to a network or application. Users have only

the level of access, or least privilege, needed to accomplish authorized tasks.

API A set of standards and protocols by which a software application can be accessed by other software or for communication between application programs.

Application Communication Middleware Middleware used to communicate among applications, software services, and components.

Application Communication Middleware Architecture Facilitates and simplifies the communication between diverse, distributed applications.

Authentication The process of providing a private piece of information or token to establish whether a subject is who or what its identifier (e.g., username) claims it is.

Authorization The process of determining whether to allow a subject access to a specific resource service or other subject.

Availability User access to data files or applications that are stored on networked computers. Information and systems are protected against disruption.

Certificate Authority (CA) An entity that issues digital certificates and vouches for the binding between the data items in a certificate, such as X.509 certificates.

CIA triad Refers to confidentiality, integrity, and availability of information and computing resources.

Common Object Request Broker Architecture (CORBA) An architecture for creating, distributing, and managing distributed program objects in a network.

Confidentiality Sensitive information is protected against disclosure.

Distributed Component Object Model (DCOM) Microsoft's proprietary distributed object architecture, which it developed instead of adhering to CORBA.

Encryption The process of changing a message (a *plaintext*) into meaningless data (a *ciphertext*).

Enterprise Application Integration The systematic tying together of disparate enterprise applications.

Integrity Information and systems are protected against unauthorized modification.

Kerberos A ticket-based authentication protocol based on symmetric-key cryptography.

Kerberos Ticket A certificate issued by an authentication server, encrypted using the server key.

Message Oriented Middleware (MOM) Application communication middleware that sends messages among software components. Applications using MOM can be deployed on multiple platforms using multiple programming languages.

Middleware Software and APIs that act as intermediaries among application programs and services, such as gateway software between LAN-based database servers and mainframe databases. This software layer provides application, component, and data access communication.

Object The data, service, or application that is being accessed by a subject.

Object Request Broker (ORB) In a network of clients/servers on different computers, a client program (an object) can request services from a server program or object without having to understand where the server

is in a distributed network or what the interface to the server program looks like.

Open Unprotected, such as an open network.

Packet A collection of data that is transmitted as a bundle across a network connection.

Packet Switching The process of routing and transferring packets of data via a network.

Plaintext A message in human-readable form.

Platform A combination of computer hardware and operating system software.

Portability The capability to move software across different platforms.

Principal Either a subject or object whose identity can be verified (e.g., a workstation user or a network server).

Private Key The key that a communicating party holds privately and uses for decryption or completion of a key exchange.

Protocol A set of rules for communication or rules for managing the network, transferring data, and synchronizing the states of network components. Protocols enable independent technology components to communicate with each other.

Public Key The key that a communicating party sends publicly.

Server A computer that provides shared services to computer workstations over a network (e.g., file server, print server, and mail server). In TCP/IP, a server accepts and responds to the requests of a remote system, called a client.

Single Sign-On (SSO) Technology Makes it possible for a user to enter his/her credentials only once and remain authorized within the network until logging off.

Subject A person (user) or application that requests access to data, a service, application, and so on.

Web Services Security (WS-Security) Provides a mechanism for associating security tokens with messages, thus improving protection through message integrity, message confidentiality, and single message authentication.

FURTHER READING

The importance of security middleware is increasing. Security middleware are ever-evolving layers of network and data services. These services reside between the network and more traditional applications. Their role is to manage security, access and information exchange, and the sharing of distributed resources, such as computers, data, and networks. Despite its security features, middleware has become the target of attack. A case

in point—intruders penetrated servers hosting GNOME, an open-source project offering interfaces and development tools to Linux users. This attack has demonstrated that intruders depend not only on vulnerabilities within operating systems but also increasingly on applications, databases, Web servers, and middleware (Franklin, 2004).

INTRODUCTION

The Internet is a rather loose assemblage of individual networks; there is little in the way of overall administration. The individual networks are owned by a huge number of independent operators. Some of these are major corporations with large, high-capacity networks; others are private individuals operating tiny networks of two or three computers their homes. Between them these networks employ just about every networking technology yet invented. The great strength of the Internet is that it allows these diverse networks to act together to provide a single global network service.

The interactions between a network and its neighbors are, in essence, both simple and robust. This makes for easy extendibility and fueled the early growth of the Internet. New participants needed only to come to an agreement with an existing operator and set up some fairly simple equipment to become full players. This was in great contrast to the situation within the world of telephone networks, where operators were mostly large and bureaucratic and where adding new interconnections required complex negotiation and configuration and, possibly, international treaties.

This chapter is organized into four main sections. I begin with a discussion of network interconnection and how a new service, the IP service, enables it to be achieved. In the second section, I look at how useful applications can be built on the IP service. Next I take a more detailed look at how the IP service is provided in practice. Finally I take a brief look at how the Internet is developing into a “multiservice” network capable of carrying many types of traffic.

NETWORK INTERCONNECTION—THE IP SERVICE

The Internet story began in the early 1960s with the invention of the idea of sending data through computer networks in discrete lumps (called “packets”) rather than as continuous streams of bits. In general, large objects such as computer files would need to be chopped up into several packets and reassembled at the destination. A major early experiment in packet-switching was the ARPANET, instigated by Leonard Kleinrock, Lawrence G. Roberts, and others, and sponsored by the U.S. Department of Defense. By the end of 1969, the ARPANET was up and running, with four computers connected. The network grew over the next few years and began to support applications such as file transfer and electronic mail. In 1972, Bob Kahn, who had been influential in ARPANET design, began to turn his attention to network interconnection or “interneting.” One of Kahn’s key insights was that there would, in the future, be many independent networks, each based on a different technology. He recognized that it would be impossible to require all these networks to be compatible with the ARPANET way of doing things. Instead he designed an open “internetworking architecture.” Essentially, networks could do what they wanted internally, but if they wanted to interwork with other networks they would need to implement the interworking architecture as well. Kahn, in collaboration with Vint Cerf, went on to flesh out these basic ideas. They devised a set of rules called the *transmission control protocol* (TCP), which specified how two computers should cooperate to provide reliable delivery of data across the internetwork. Shortly after, it was recognized that not all applications would

want the same levels of reliability guarantees, so TCP was split into two parts: one part provided reliability and retained the name TCP, whereas the other part dealt with the delivery of packets and was called the *Internet protocol* (IP). TCP and IP have survived, unaltered in most important respects and continue today—a tribute to their designers in the early 1970s.

The ideas of Kahn and Cerf were soon put into practice in a three network “internet” consisting of the ARPANET itself, a packet radio network, and a packet satellite network. The latter gave the internetwork an international reach with a node run by Peter Kirstein at University College London in the United Kingdom. Originally it was thought that one day there might be perhaps 100 participating networks. The invention of local area networks (LANs) in the 1980s changed all that and brought an explosive growth in the number of participating networks that, today, are numbered in hundreds of thousands. In 1986 the U.S. National Science Foundation funded a backbone network linking five supercomputing centers. This network (NSFNET) grew into the first real Internet backbone with connections to many countries around the world. By 1995 it was clear that the Internet, for many years a research and academic network, had a major commercial future, and NSFNET’s backbone role was handed on to a set of linked commercial network providers.

Network Technologies and the Services They Provide

The fundamental components of the Internet are *packet networks* (called simply *networks* for the remainder of this chapter). This term indicates any technology that is capable of transferring data packets from one computer to another; Figure 1 shows an abstract view of such a network. Usually many computers are attached to the network, which consequently provides them with *addresses* that can be used to specify the source and destination of packets. Most of the computers connected to networks are classified as hosts. These are computers that run programs; desktop PCs and servers come into this category. A few computers provide functions related solely to network operation. For example, *gateways, routers, or bridges* relay packets between networks.

There is a huge variety of technologies that fit into this general model. For example, local area networks (LANs) such as Ethernet (Metcalfe & Boggs, 1976) use so-called medium access control (MAC) addresses. These are 48-bit

addresses allocated by the manufacturers of the interface cards that are plugged into the hosts. The “network service” provided by a LAN is simple: a computer constructs a packet, including a destination MAC address, and asks the network to deliver it—exactly like posting a letter. This is termed a *connectionless* (CL) service. A rather different style of service is provided by, for example, asynchronous transfer mode (ATM) (Vetter, 1995) networks. In these networks, there is an initial negotiation phase during which the computer tells the network what kind of data it wants to send and the address of the destination. This gives the computer the opportunity to specify the quality of service (QoS) it requires (bounds on throughput, transit delay, etc.). The network must decide whether it can meet the request. If it can, it tells the computer that a “connection” has been established to the destination and that data transfer can begin. This is similar to making a telephone call in which one dials a number and establishes a call before speech can begin and is termed a *connection-oriented* (CO) service. Addresses in CO networks are used only during the connection setup phase.

Interconnection via “Convergence”

Virtually all networking technologies provide services similar to those just described, even though the mechanisms they use to implement the service may be radically different. Within these broad categories, however, there are many awkward differences: each technology imposes its own limit to the size of packet that may be sent, each has its own idiosyncratic addressing scheme, some technologies allow subtle control of QoS, whereas others do not and so on. These differences pose difficulties for network interconnection. We cannot simply take a packet from one network and forward it onto the next; all sorts of subtle transformations would be needed. The solution is “convergence.” We invent an abstract network service and, for each networking technology, we provide “convergence functions” to implement the abstract service. Through these means we make all networks look the same and the interconnection problem becomes manageable.

The Internet Protocol—A Convergence Protocol

The IP provides a convergence function. Version 4 of the protocol (still the most widely deployed) and the abstract network service it implements are specified in RFC 791 (Postel, 1981a) published in 1981. (Many Internet RFCs,

Figure 1: An abstract view of a network. Computers, termed *hosts* have physical interfaces to the network. These interfaces have addresses. The network is capable of delivering packets to hosts identified by their addresses.

Figure 2: Internet Protocol addresses allocated to network interfaces. In this case, the first 16 bits of the IP address identify the IP network. Thus there are three IP networks: 142.38, 128.16, and 131.24.

or requests for comment, are cited in this article. All are available online on the Web site of the Internet Engineering Task Force: <http://www.ietf.org/rfc.html>) The service is a simple CL one that allows single packets (called IP datagrams) to be sent to destinations identified by “IP addresses.” An IP address is a 32-bit quantity that is divided into two portions. The first portion, the “network prefix,” identifies an “IP network” (sometimes now called an “IP subnetwork”). The second portion identifies an interface on that network. The 32 bits are normally written as four decimal bytes separated by dots (e.g., 128.16.5.2).

Hosts, IP Networks, and Routers

Figure 2 shows the network from Figure 1 set up to implement the IP service. Each interface has now acquired an IP address in addition to its original “technology-based” address. To make things a little more concrete, we will assume the networks are LANs, in which case the “technology-based” addresses will be MAC addresses. An important point is illustrated here: An IP network is an abstract thing and does not necessarily correspond one-to-one with a physical network. In Figure 2 we see one physical network partitioned into two IP networks (128.16 and 131.24). The reverse is also possible with several physical networks operating as a single IP network. Traffic is relayed between one IP network and the next by devices called *routers* (the term *gateway* was used in early Internet documents and survives to some extent).

The basic algorithm for delivering an IP datagram to its destination is broadly as follows:

```
If (destination network prefix == "my
network prefix),
    send datagram direct to its destination
    across the local physical network
else
    choose a suitable router
    send datagram to router across the local
    physical network
```

This algorithm is executed by the source host and, if necessary, by a succession of routers along the path to the destination. Thus a datagram sent from host 128.16.5.2 in Figure 2 to host 128.16.5.3 would be sent directly, whereas one to host 131.24.8.1 would be sent to router interface 128.16.5.1. Note that this router interface belongs to the same IP network as the source host, a requirement of classical IP operation. To make the configuration in Figure 2 complete we have had to add a second router (R2) so that the hosts in the 131.24 IP network can communicate with the rest of the world. This router is mandated solely by the Internet routing architecture; it provides no additional physical connectivity.

The step in the algorithm “choose a suitable router” is easily stated but less easily implemented. Sometimes there will be several possible routers, and hosts and routers must maintain “routing tables” indicating which router is the best one to use as the “next hop” on the path to a particular IP network. Because there are hundreds of thousands of IP networks in the world, maintaining such tables can be a problem. In practice, most tables contain entries for just a few “local” IP networks. Datagrams for all other networks are sent to a single “default” router that, it is hoped, will know what to do with them. (Routing is discussed in more detail under Making the IP Layer Work.)

IP Addresses

We have assumed that the network prefix part of the IP address is 16 bits. This means we can have 16 bits to identify the individual interfaces on each network a total of 2^{16} (= 65,536), which is a large number of interfaces to have on one network. Therefore, the IP designers decided there should be three classes of IP address to suit the requirements of small, medium, and large networks. For small networks, the network prefix was 24 bits and the host part 8 bits, allowing 256 hosts (in fact, it is 254 because one was used for “this host” and another for local

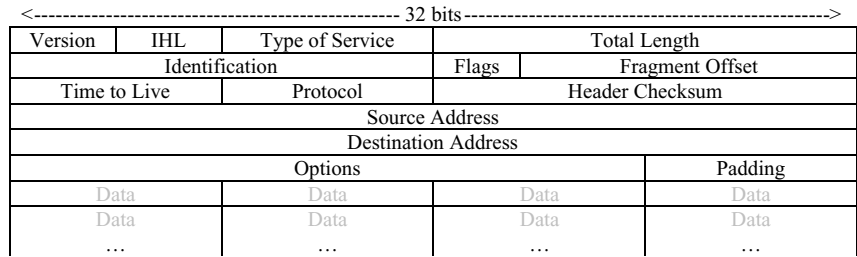

Figure 3: Internet protocol datagram header format. Note the 32-bit source and destination IP addresses. The remaining fields are discussed briefly in the text.

broadcast). Obviously routers needed to know how many bits there were in the network prefix because these are the bits they look up in their routing tables. This information was encoded in the first few bits of the address according to the following scheme, where *N* indicates the network prefix and *H* the host part:

```

Class A  0NNNNNNN  HHHHHHHH  HHHHHHHH  HHHHHHHH
Class B  10NNNNNN  NNNNNNNN  HHHHHHHH  HHHHHHHH
Class C  110NNNNN  NNNNNNNN  NNNNNNNN  HHHHHHHH
    
```

As the Internet grew, and more organizations requested IP network addresses, this scheme proved problematic. Class B networks were in short supply and many were inefficiently used because few organizations approached 65,536 hosts. Class C networks, though in abundant supply, were too small for many organizations. Multiple class C networks could be issued but this meant that the organization would need multiple entries in Internet routers instead of the single one that would have sufficed had a class B network been available. Potentially this would lead to much larger tables in routers and consequent inefficient operation. Consequently, the class-based scheme has been abandoned in favor of one that allows the network prefix to be of arbitrary length. This scheme is discussed under Making the IP Layer Work. (Note that Class D addresses also exist. These relate to multicast transmission and are discussed in a later section.)

The Internet Assigned Numbers Authority (IANA) is the top-level authority for allocating IP addresses. IANA delegates authority over blocks of addresses to regional authorities who, in turn, allocate blocks to Internet service providers (ISP). Finally ISPs assign IP addresses to end users.

The IP Datagram and the Service It Offers

The basic IP service is simple; a host constructs a packet of data and gives this to the IP service along with the IP address of the destination. The IP service then makes its “best effort” to deliver the datagram. The service offers no guarantees of success, however. It may lose the datagram without informing either the source or the intended destination, delivery may be subject to arbitrary delay, two datagrams dispatched to the same destination may be misordered on arrival—it may even deliver two copies of one datagram. If an application running in a host finds this rather cavalier attitude toward service unacceptable, it is up to the application to do something about it. For example, many applications exploit the TCP (Postel, 1981b), which keeps track of wayward datagrams, retransmits missing ones, and ensures sequenced delivery.

(More details on TCP are provided under Building on the IP Service.)

In fact, simplicity is the IP service’s greatest strength and one of the main reasons for its considerable success. A simple convergence protocol is easy to implement, which encourages its deployment on as wide a range of technologies as possible. Having only minimal features in the network service maximizes flexibility for applications running in hosts. For example, some applications may happily tolerate the occasional lost datagram, especially if this avoids problematic costs and delays imposed by retransmission. If the network service itself took on the responsibility for retransmission these applications would suffer. Thus the design exemplifies the end-to-end argument as propounded in Saltzer, Reed, and Clark (1984).

IP datagrams themselves have a simple structure consisting of a header (typically 20 bytes) plus a “payload,” the data the datagram is carrying across the Internet. The header format is shown in Figure 3. The fields are interpreted as shown in Table 1.

Implementing the IP Service

The IP datagram delivery algorithm given earlier includes the phrase “send datagram direct to its destination across the local physical network.” We must specify how this is to be done for each network technology. The three main issues involved in this are discussed next.

Encapsulation in “Native” Formats

Each network technology specifies its own packet format. Usually this consists of a header, which often contains addresses, followed by the data payload, perhaps followed by a checksum used to detect errors. In essence, encapsulation means we construct our IP datagram and make this the payload of the packet. Figure 4 shows this in the case of Ethernet (note that it is common to refer to Ethernet “frames” rather than “packets”). Encapsulation would be similar for the other LAN technologies that have been standardized by the IEEE. CRC (cyclic redundancy check) is a checksum intended to discover transmission errors.

It is important to remember the strict division of labor here. The Ethernet technology pays no regard to the payload; it is interested only in the Ethernet header and the CRC. Likewise, Internet technology—routers and so on—is interested only in the IP datagram and its header.

In practice things may be slightly more complex than Figure 4 suggests. An Ethernet may be carrying other protocols in addition to IP datagrams. Systems processing incoming Ethernet frames need to be able to determine what protocol the frame is carrying. This entails the insertion

Table 1 Meanings of the IP Header Fields

Internet protocol (IP) version	4 for IPv4, 6 for IPv6
IHL	The length of the IP header (normally 5 32 bit words)
Type of service	This is discussed in the section on quality of service
Total length	Total length in bytes (including the header)
Identification, fragment offset	Used to implement fragmentation
Flags	Bits used to mark special status of a datagram
Time to live	A counter that is reduced by one by each router through which the datagram passes; when it reaches zero, the datagram is discarded (normally an error message is returned to the source), ensuring misrouted datagrams do not circulate forever
Protocol	A number to identify the protocol that this datagram is carrying (Transmission Control Protocol, User Datagram Protocol, etc.)
Header checksum	Used to pick up transmission errors that might corrupt header fields.
Source/destination addresses	Discussed earlier
Options	Rarely used (space precludes discussion here)

of another header between the MAC and IP headers. This header will include a “protocol identifier,” a “well-known” number indicating “this is an IP datagram.”

Some technologies require special treatment. ATM, for example, uses small packets, called cells, each of which carries 48 bytes. An associated standard, ATM adaptation layer 5 (AAL5), explains how a larger packet, an IP datagram, for example, can be fragmented into cells and re-assembled at the destination.

Address Resolution

Each network technology has its own addresses; in this chapter, these are termed *physical addresses*. Obviously a technology understands its own physical addresses; no networking technology understands IP addresses, however. These are processed exclusively by the convergence function. Once the IP delivery algorithm has determined whether an IP datagram can be delivered direct or whether it must be sent to a router, we are left with the problem of determining the correct physical address to use. The business of mapping from an IP address to the corresponding physical address is called *address resolution*. Two techniques are used to achieve this:

1. Most LANs have a “broadcast service.” All systems attached to the LAN will receive and process a frame sent to the MAC broadcast address. For address resolution a frame is sent to the broadcast address containing an address resolution protocol (ARP) (Plummer, 1982)

request for the desired IP address. The host that recognizes the specified IP address as its own replies with an ARP response containing its own MAC (physical) address.

2. For nonbroadcast network technologies it is normal to deploy an ARP server that maintains a table of mappings. Attached systems register their mappings with the ARP server at boot time. Systems that need to resolve IP addresses send ARP requests to the server and receive ARP responses.

In both cases, mappings are cached by the requesting system for future use.

Fragmentation

Each network technology imposes its own limit on the number of data bytes that may be carried in a frame, referred to as the maximum transfer unit (MTU). These limits pose problems for IP because the path to a destination may traverse dozens of networks and the system that originates the IP datagram knows only the first hop of the route. Consequently, it cannot know the smallest MTU on the complete path (the “path MTU”). In IP version 4 (IPv4), this is solved by allowing hosts and routers to fragment datagrams. An IP datagram that is too large will be split into two or more smaller IP datagrams (each complete with its IP header). The destination host will reassemble the original IP datagram from the various fragments.

Unfortunately fragmentation is not an efficient procedure. Suppose the originating system generates a series of

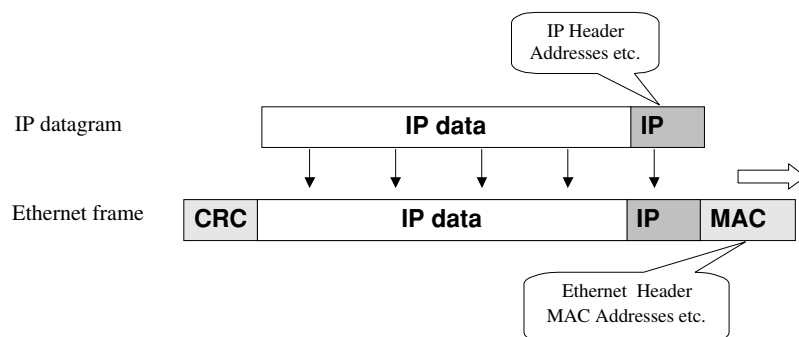

Figure 4: Simple encapsulation of an Internet protocol datagram in an Ethernet frame; the datagram simply becomes the payload of the frame.

IP datagrams of length 1600 bytes and somewhere along the path there is a network with an MTU of 1500 bytes. Every IP datagram will be split into two fragments, doubling the work for the remaining routers along the path. If the originating host knew the path MTU in advance, it could have divided its data into 1500-byte pieces, avoiding fragmentation and causing less work for the routers. A second problem arises if one fragment of a datagram is lost. Reassembly will not now be possible so all the work done by the networks and routers in delivering the other fragments will have been wasted.

The modern approach is to avoid fragmentation in routers by probing the network to discover the path MTU. This can be done by sending IP datagrams with a flag set that means “do not fragment.” A router that is unable to forward such an IP datagram because it exceeds the MTU for the next hop network must discard it. When it does so, it sends an Internet control message protocol (ICMP) message (discussed under Management in the IP Layer) back to the originating host explaining what has happened. The originator can then try again with a somewhat smaller IP datagram. This is the approach favored in the latest version of IP, IP version 6 (IPv6), which actually prohibits fragmentation in routers.

BUILDING ON THE IP SERVICE

It is clear that the service provided by IP is inadequate for some applications. Several IP datagrams may be needed to carry one Web page. We care that all these datagrams are delivered exactly once and in the right order. There are many applications that have similar requirements. Rather than each of them inventing its own mechanisms to meet them a common protocol—TCP—is used.

TCP—The Transmission Control Protocol

TCP is an automatic repeat request (ARQ) protocol; such protocols send packets of data that each include a sequence number. It is up to the receiver to check the sequence numbers, ensure that all packets have arrived, and reorder them if necessary. The receiver sends “acknowledgment” packets back to the transmitter. The transmitter retransmits packets that are not acknowledged sufficiently promptly. In the TCP case, the packets are termed *segments*, each of which is carried in an IP datagram. Each segment consists of a TCP “header” (containing the sequence and acknowledgment numbers) that may be followed by a block of data (see Figure 5). At any instant there are likely to be data bytes that have been sent but not yet acknowledged. A limit, termed a *window*, is set on the number of these bytes. This window is specified by the receiver in the acknowledgments it sends. By reducing this window the receiver may slow down or even stop the flow of data. This flow control mechanism is essential in preventing a slow receiver from being overwhelmed by a fast transmitter.

The TCP protocol, although it uses the IP service, is independent of it. The components that implement the IP service, including all the routers, are interested only in the IP header—the fact that a particular IP datagram is carrying a TCP segment is of no importance whatsoever to

Figure 5: A transmission control protocol (TCP) segment carried in an Internet protocol (IP) datagram. Coincidentally, both the TCP and IP headers are normally 20 bytes long. The data part may be any length subject to a limit imposed by the IP protocol and the network technology in use. See also Figure 4.

these components. The components that are interested in TCP are the pieces of software that implement the logic of the TCP protocol. These exist in the end systems or hosts; typically such software is supplied as part of an operating system such as Linux or Windows.

This independence between the TCP “layer” and the IP “layer” is illustrated in Figure 6. TCP is just one possible “transport protocol” and will be used for most applications that require reliable, sequenced delivery. Logically we can think of the two TCP modules in the hosts as exchanging segments and acknowledgments directly with each other (represented by the broken, horizontal arrow). Physically, however, a TCP module must pass its segments down to the local IP module (also a piece of software within the operating system) that will wrap it in an IP datagram and send it on its way. The IP module at the receiver will unwrap the IP datagram, retrieve the TCP segment, and pass this up to the local TCP module. This is represented by the vertical arrows.

TCP’s Role in Congestion Control

A weakness in the Internet architecture is the limited control over congestion it affords. Just as in road transport networks, congestion occurs when too much traffic attempts to pass through a particular point. Were the IP layer CO, there would be an opportunity to refuse new connections if these seemed likely to overload some router along the path. The Internet’s basic CL service has to accept all the traffic that is thrown at it, however, and do the best it can. TCP can help alleviate this problem. As part of its normal operation a TCP module becomes aware of dropped or delayed IP datagrams because these manifest themselves as missing or delayed TCP acknowledgments. When these occur, TCP concludes (usually correctly) that congestion is occurring and employs a “congestion control” algorithm attributable to Jacobsen (1988). This algorithm results in TCP temporarily slowing its data transmission rate. If all the TCP connections passing through the congested router behave in this way, the congestion should be relieved.

This mechanism has been observed to work well in practice. Unfortunately there has been a recent growth in real-time multimedia applications that, typically, use user

Figure 6: The fundamentals of the Internet architecture. The Internet protocol (IP) layer provides convergence, allowing many network technologies to take part. It also provides the relaying operation from router to router toward the destination host. Above IP comes the transport layer, which is where TCP fits. This layer is entirely the responsibility of the hosts.

datagram protocol (UDP; Postel, 1980) rather than TCP. UDP is almost a null protocol and lacks all of TCP's reliability and congestion control mechanisms, leaving such issues to the applications themselves. Efforts are being made to endow such applications with "TCP-like" behavior, but it seems unlikely that this alone will suffice to deal with the congestion problem. Some kind of resource management inside the Internet seems essential; approaches to this are outlined in the final section of this chapter.

Ports—Identifying Applications and Processes

Hosts are identified by IP addresses. Assuming we know the IP address of our intended recipient, the IP layer will (usually) deliver our IP datagram successfully. We need also to identify a particular application, service or process present on the host, however. This is the role of transport layer ports. Here one can draw a close analogy with telephone extensions; the telephone number (IP address) identifies the building, the extension number (port) identifies an individual within the building. All Internet transport protocols include source and destination ports in their headers; these are simply 16-bit integers.

A client/server model of communication is assumed; the client is the piece of software that initiates requests, and the server software waits and responds to client requests as these arrive. Public services usually use "well-known" ports (see Table 2). Thus, when a browser (client)

requests a page from a Web server, the TCP segments it sends will have the destination port set to 80 in the TCP header. The operating system on the server host will have a table that tells it that port 80 is the WWW server. It will ensure that the WWW server software receives the incoming data and processes it. The client system chooses a source port. It should choose a value that is not currently in use for any other purpose. This source port will be used as the destination port in any replies from the server.

Other Internet Transport Protocols

Some applications do not need the reliable sequenced delivery provided by TCP, especially because TCP buys this reliability at the cost of delays when retransmissions occur. A great strength of the Internet architecture is that such applications can select a different transport protocol. The simplest is the UDP, which adds nothing to the basic IP service; however, its simple header does include the ports necessary for application selection. UDP is a popular choice for delay-sensitive, loss-tolerant applications and also for applications that just need to send one message and get one reply. It is sometimes favored by applications that work mostly within a LAN; for example, the SUN Network File System (NFS) can use UDP instead of TCP.

Several other protocols are in widespread use, including the real time protocol (RTP; Schulzrinne, Casner, Frederick, & Jacobson, 1996), which provides sequence numbering and time stamping for applications such as streamed audio and video. Sometimes two transport protocols are used in tandem: RTP is often carried inside UDP datagrams; transport layer security (TLS; Dierks & Allen, 1999), which provides authentication and confidentiality, may be used in conjunction with TCP.

Table 2 Some "Well-Known" Transport Ports and Associated Protocols

Service	Protocol	"Well-Known" Port
HTTP (Web server)	TCP	80
FTP (FTP server)	TCP	21
Telnet (remote rlogin)	TCP	23
SMTP (e-mail)	TCP	25
DNS (name and address mappings)	UDP	53

Note. A client wishing to contact one of these services will use these as the "destination port" in the messages it sends. DNS = domain name service; FTP = file transfer protocol; HTTP = hypertext transfer protocol; SMTP = simple mail transfer protocol.

Naming Internet Objects

We have seen that IP addresses provide globally unique labels for the interfaces between computers and the Internet. Such numeric labels, such as telephone numbers, are efficient for computers but not especially memorable for humans. They are also liable to change according to technological diktat—for example, when a computer is moved to a new IP network. Furthermore, the Internet makes many other sorts of object accessible—networks, e-mail accounts, files, and so on—and we need globally unique labels for these. Internet domain names (DN; Mockapetris,

Figure 7: A portion of the domain name tree.

1987a) solve these problems by providing a systematic way of generating globally unique and reasonably user-friendly names. Like other schemes with similar objectives the DN scheme relies on a recursive devolution of authority over the namespace.

Figure 7 shows a portion of the domain namespace. Each node (leaf or nonleaf) represents a domain that consists of itself and all the nodes in the subtree beneath it. A fully qualified domain name is a concatenation of the labels on the path from a node all the way back to the root (e.g., *campagnolo.cs.ucl.ac.uk*). The authority for a zone is responsible for ensuring that no two sibling nodes have the same name. The top-level domains include the worldwide generic domains (*com*, *org*, *net*, *edu*, etc.), two United States-only generic domains (*mil* and *gov*), and country code domains (e.g., *us* for the United States and *uk* for the United Kingdom). Each authority has its own rules for name allocation and each may delegate authority over subdomains. For example, in the United Kingdom, the Department of Trade and Industry, which administers the “uk” domain, has allocated an “ac” subdomain and has delegated authority over it to a joint board of UK universities. This board has allocated domains, and delegated authority, to individual universities.

Although the principal use of DNs is the naming of computers and interfaces, they can be used for any purpose. Furthermore, there are no inherent relationships between domains and IP networks. It happens that the computer named “campagnolo” with address 128.16.23.3 belongs to the Computer Science department of University College London, an academic institution in the UK and its DN, *campagnolo.cs.ucl.ac.uk*, reflects this closely. There is nothing to stop the department from allocating the name to a computer on some other network in some other country, however; the name is theirs to use as they like.

The Domain Name System

The domain name system (DNS; Mockapetris, 1987b) is a distributed directory service that supports, among other things, the automatic mapping of DNs to IP addresses. Generally speaking, each domain must provide a computer on which runs a DNS nameserver that maintains a table of mappings for the names in its domain. This is

termed the primary nameserver for the domain. The DNS protocol allows hosts to query these mappings and so to map names onto addresses. Local DNS servers hold mappings for local machines and answer queries for these directly. Nonlocal names are passed on to other DNS servers. Figure 8 illustrates this when a local nameserver cannot resolve the DN *www.ibm.com*. Steps 2 through 5 show the iterative mode; the query is passed to the *root* nameserver for the *com* domain which refers its questioner to a different nameserver. The local nameserver will cache the result of the query so that, next time around, we will see, at most, steps 1 and 6. As with all caching strategies, there is a danger that the cached information will become out of date, so a time-out is used. In addition to this, nameserver responses always contain a flag to indicate whether they are *authoritative*, that is, whether they come direct from a primary nameserver.

The DNS can answer a number of other queries. Especially important are “MX” mappings. These map a DN used in an e-mail address to the name of a host willing to accept mail for the domain. Thus an e-mail client wishing to deliver a message to *blogs@cs.ucl.ac.uk* can discover the mapping *cs.ucl.ac.uk* ⇒ *smtp.cs.ucl.ac.uk*.

Figure 8: Distributed operations in the domain name system. The name cannot be resolved by the local nameserver, which passes the query to the nameserver for the top-level (com) domain and so on.

Universal Resource Locators

Universal resource locators (Berners-Lee, Fielding, & Masinter, 1998) are the familiar URLs used on the World Wide Web. The URL format is flexible; however, most URLs that users encounter have the following format:

```
<protocol>://<domain name>/<local name>
```

The domain name is a DN as described in the previous section. It identifies a host on which runs a Web server program that has access to the resource (a file, for example) identified by local name. Although it is common for hosts used for this purpose to be given a DN starting “WWW,” there is no particular need for this, and any name will do. The protocol indicates the application protocol to be used when contacting the WWW server. These days this is usually the hypertext transfer protocol (HTTP; Fielding et al., 1999), described in a later section. It is still quite common, however, to see FTP, the original Internet file transfer protocol (Postel & Reynolds, 1985).

Internet Applications

Like transport protocol modules, applications are implemented by software residing in hosts. Application software exchanges messages across the Internet. In the most widely used applications, these messages are formatted using structured ASCII text. For example, a browser application (Internet Explorer, Netscape, etc.) uses HTTP to retrieve information from a Web server. An example of an HTTP “GET” request message is the following:

```
GET http://www.cs.ucl.ac.uk/research/index.htmlHTTP/1.0
Authorization: Basic QWxhZGRpbjpvGVuIHNLc2FtZQ==
```

HTTP employs TCP in the transport layer. Therefore HTTP messages like the one above (encoded into binary using ASCII codes) will form the data part of a TCP segment. If all goes well, the HTTP response will include the file “index.html”. Typically this is likely to be too big to fit into a single TCP segment, so several will need to be sent. Other familiar applications (e.g., FTP for file transfer and SMTP for e-mail; Klensin, 2001) use similar protocols. Designing such protocols is a matter of deciding what messages need to be sent, under what circumstances each needs to be sent, and specifying the format to be used.

Some application protocols provide generic services on which specific applications can be built. Among this group are the remote procedure call and remote invocation protocols such as CORBA and Java RMI. These adopt an object oriented model with one part of the application invoking operations on objects on a remote host. Each operation requires parameters to be sent and results to be returned. CORBA and Java RMI provide general mechanisms for handling these aspects.

In most operating system environments applications exist in user (rather than kernel) space. To operate they need to interact with the transport layer modules that usually reside in the kernel. The operating system will provide a set of system calls to support basic operations such as opening a TCP connection, sending or receiving a block of data, and so on. The so-called socket system calls, which originated with Berkeley Unix, are a widely adopted standard.

MAKING THE IP LAYER WORK

The previous sections established the basic components of the Internet architecture:

- An Internet layer, which allows IP datagrams to be sent to destinations identified by IP addresses
- A transport layer, which enhances the Internet layer service to provide a service satisfying an application’s requirements; a variety of transport protocols exist, each of which resides exclusively in hosts and operates end to end
- An application layer, which includes multiple applications, each of which employs a suitable transport layer

This section considers the operation of the Internet layer in more detail.

IP Routers

The basic algorithm for IP delivery has already been described. Every IP router implements this algorithm and applies it to each IP datagram it receives. The router must make such a “forwarding decision” for every IP datagram it receives. The router must look at the destination IP address, extract the network prefix, and look this up in its routing table. As a result of this lookup, the router will know the IP address of the “best” next-hop router (or host). Once this has been accomplished, all necessary fragmentation, encapsulation, and address resolution can be performed and the IP datagram dispatched. This style of operation is called “incremental routing” because each router concerns itself only with the next hop of the route and not with the complete route.

In this section a second look at network prefixes is taken and how routing tables can be maintained is considered.

IP Networks, Subnets, and Supernets

Recall that an IP network is a logical entity—a collection of interfaces in which all IP addresses share a common network prefix. As mentioned above, the three principal IP address classes defined in the original architecture proved insufficiently flexible. Consequently, today, the length of the prefix is specified explicitly. Two notations are in use:

1. The length is appended to the address, for example, 128.16.0.0/20 indicates a 20 bit prefix.
2. A “subnet mask” is used. This is an IP address with 1s in place of all the network prefix bits and 0s otherwise. The mask for the scheme above would be 255.255.240.0 (11111111.11111111.11110000.00000000 in binary).

To accommodate this scheme, modifications were needed to the operation routers so that each routing table entry included a prefix length as well as the network address. When routers communicate routing information to other routers they must now include the prefix lengths.

This scheme offers plenty of flexibility. For example, an ISP might be allocated a block of addresses 128.16.0.0/16 (a class B address under the old scheme). The ISP can then partition these addresses into portions of sizes suitable

for its customers. Thus they might derive sixteen 20-bit networks as follows:

```
128.16.0.0/20    (10000000.00010000.00000000.00000000)
128.16.16.0/20  (10000000.00010000.00010000.00000000)
128.16.32.0/20  (10000000.00010000.00100000.00000000)
...
128.16.240.0/20 (10000000.00010000.11110000.00000000)
```

Smaller partitions are then possible. For example, the final 20-bit network could be split into four 22 bit networks as follows:

```
128.16.240.0/22 (10000000.00010000.11110000.00000000)
128.16.244.0/22 (10000000.00010000.11110100.00000000)
128.16.248.0/22 (10000000.00010000.11111000.00000000)
128.16.252.0/22 (10000000.00010000.11111100.00000000)
```

Allocating addresses in this hierarchical way may have a further benefit—that of address aggregation. It may well be that all traffic for the ISP’s customers is routed through a single router owned by the ISP. If such is the case, Internet routers need have just one routing table entry for the ISP (128.16.0.0/16 in the example above) and this will serve for all the ISP’s customers.

Subnets

Partitioning is not solely an issue for ISPs. An organization that has been allocated a single address block may, nevertheless, want to install internal routers. These may be needed to allow interconnection between two dissimilar network technologies such as Ethernet and ATM. Another motivation might be the desire to partition a large LAN into several smaller LANs; large LANs can suffer from many “collisions” as multiple hosts compete to send traffic. The classical IP delivery algorithm requires that distinct network prefixes must be used on either side of such routers. This can be achieved by the organization partitioning the allocated space into several smaller IP subnets. For example, if the organization has been allocated the block 128.16.252.0/22, which allows about $2^{10} = 1024$ hosts, they may decide to partition this into four 24-bit subnets each with up to $2^8 = 256$ hosts. Of course, none of this will be effective unless all the routers and hosts involved know that 24-bit network prefixes are in use. They must be told this explicitly—an extra piece of configuration information for each participating system.

Note that these subnets are an internal matter. To the outside world the network just described still appears as a single 22-bit IP network. Thus the advantages of address aggregation are preserved.

Supernets

In the example above, the ISP began its partitioning with the block 128.16.0.0/16—effectively an old class B address. However, with care, it is also possible to make similar use of the old class C addresses. Table 3 shows 16 class C IP network addresses chosen so that they share the same first 20 bits.

In the literature, this is referred to as an IP supernet, with address 210.50.160.0/20. Once allocated, supernets can be further partitioned or subnetted exactly as other

Table 3 16 Class C IP Network Addresses Sharing the Same First 20 Bits

11010010	00110010	10100000	210.50.160
11010010	00110010	10100001	210.50.161
11010010	00110010	10100010	210.50.162
11010010	00110010	10100011	210.50.163
...
11010010	00110010	10101111	210.50.175

networks. Once more the address aggregation benefit can be seen as we now need just one routing table entry for the supernet rather than 16 entries for the individual class C networks.

Supernets, subnets, and explicit network prefix lengths are all part of a scheme termed classless interdomain routing (CIDR; Fuller, Li, Yu, & Varadhan, 1993).

Routing Tables

Figure 9 shows a configuration of networks and subnets that we can use to illustrate the use of routing tables. (In reality, there would be many more hosts; most have been omitted for clarity). We assume this configuration is operated by a single administration that has decided to partition the network 128.16.0.0/16 into several subnets. The main partition is into three 20-bit subnets, two on the main site and one for a set of remote machines that are accessible via ISDN (integrated services digital network). (Note that ISDN is not an IP network; it merely provides links between a router on the main site and those at the remote sites.) The “remote” subnet is further partitioned. This kind of sub-subnetting assists with routing.

Consider the transmission of an IP datagram from host *darhu* on the main site to host *mavic* on remote site B. The routing table on *darhu* can be very simple (Table 4). Our datagram for *mavic* (128.16.23.2) matches the default entry and so will be forwarded to *router1*. *Router1* is the main router giving access to the rest of the Internet. Its routing table could be large but must include at least the entries shown in Table 5. These include entries for the two local subnets and the entire remote subnet; notice that there is no need to have separate entries for each individual remote site. Our datagram matches the third entry and so will be sent to *router2*. *Router2* does need to distinguish between the various remote sites (Table 6). Here ISDN1 and ISDN2 represent the two ISDN calls. These are dial-up calls and would be managed so that they were only set up when data needed to be transferred. Our datagram matches the third entry and so will be sent to the router called *dawes*.

Suppose now that *mavic* is important so that we wish to have a permanent connection to it rather than relying on ISDN; we might lease a line to provide a permanent point-to-point link between *mavic* and *router2*. We would now need to modify *router2*’s table as follows (Table 7):

In Table 7 we now have a special entry for *mavic* (note that there is no need to put anything in the “next hop” column because there is only one possible destination at the other end of the leased line). Our datagram now matches two entries; there is a 24-bit match for the third entry and

Figure 9: An IP network (128.16.0.0/16) partitioned into two subnets for the main site (128.16.0.0/20 and 128.16.64.0/20) and one for remote sites (128.16.16.0/20). The remote site subnet is further partitioned into two 24-bit subnets.

Table 4 Internet Protocol Routing Table for Host *darhu*

Network	Interface	Next Hop
128.16.0.0/20	Ethernet	Direct
Default	Ethernet	128.16.5.150

a 32-bit match for the fourth entry. This is a common situation and the tie-break rule is “choose the longest prefix match.”

In some cases another factor is included in the forwarding decision, a metric signifying the cost of a particular route. This can be used to choose between two otherwise equivalent routes to a destination. Many metrics can be used. The simplest is a hop count, an estimate of the number of routers along the route to the destination. Other possibilities are estimates of delay, error rate, or throughput along a particular route. Some systems maintain multiple metrics and choose which one to use according to the QoS to be given to the datagram (this is discussed in more detail in the section on Traffic Management in the Internet). If we are using a dynamic routing protocol (see Routing Information), the metrics may vary with time to reflect changing network conditions.

It is clear from this discussion that the forwarding decision can be complex. Because this decision must be made

Table 5 Internet Protocol Routing Table for Router 1

Network	Interface	Next Hop
128.16.16.0/20	Ethernet2	128.16.64.28
128.16.0.0/20	Ethernet1	Direct
128.16.64.0/20	Ethernet2	Direct

for every datagram passing through a router, its efficiency is crucial to router performance. Router manufacturers expend a great deal of effort in devising clever ways of speeding up the forwarding decision and so increasing the throughput of their systems.

Routing Information

It is crucial to Internet operation that information in routing tables is both timely and accurate. If routers have inconsistent information, it is possible for a datagram to circulate among a group of routers without ever reaching its destination—a “routing loop.” The problem is compounded by the fact that the Internet is controlled by thousands of independent and autonomous administrations. A section of the Internet run by a single administration is called an autonomous system (AS). An AS is free to decide for itself how to manage routing internally. It may employ “static routing,” whereby routes are worked out by hand and the corresponding routing tables are installed in all the administration’s routers. Alternatively, the administration may decide to adopt a “dynamic routing protocol” that enables routers to exchange information on the current state of the network and so derive routing tables according to some algorithm. Most routers within an AS have detailed knowledge only of networks and subnets

Table 6 Internet Protocol Routing Table for Router 2

Network	Interface	Next Hop
128.16.64.0/20	Ethernet	Direct
128.16.20.0/24	ISDN1	128.16.20.14
128.16.23.0/24	ISDN2	128.16.23.1
Default	Ethernet	128.16.64.1
...

Table 7 Modified Internet Protocol Routing Table for Router 2

Network	Interface	Next Hop
128.16.64.0/20	Ethernet	Direct
128.16.20.0/24	ISDN1	128.16.20.14
128.16.23.0/24	ISDN2	128.16.23.1
128.16.23.2/32	Leased	—
Default	Ethernet	128.16.64.1
...

belonging to the home AS. Traffic for a network in a “foreign” AS will be sent, by default, to a router that acts as an “exterior gateway,” that is, one that has a link to an exterior gateway belonging to a neighboring AS. These exterior gateways exchange information on which networks they can reach. These exchanges enable exterior gateways to learn plausible routes for reaching any network on the entire Internet.

Dynamic Routing and Routing Protocols

The original Internet architects were keen to ensure that, as far as possible, the Internet would be self-managing. For example, if some Internet component failed or its performance was degraded, the network should automatically reconfigure so as to direct traffic away from the problematic component. Dynamic routing protocols can help to achieve this. Early work on the ARPANET adopted a routing protocol of a class called “distance vector.” These work as follows.

Periodically each router receives reports from its neighbors containing estimates of the neighbors’ “distances” from other networks. The information in these reports is combined with information about local links so as to derive a new routing table. For example, if a router measures its current distance to neighbor X as 10 and X reports its distance as 100 from network Y, this means that Y is reachable via X at a distance of 110. Various measures of distance have been tried. The original ARPANET algorithm used queue length—the number of datagrams awaiting transmission on a link. The routing information protocol (RIP; Malkin, 1998), which is still in widespread use, uses a simple hop count. Changes

occurring in network state are reflected in local measurements made by routers. These, in turn, are reflected in the information sent to neighbors in the next periodic routing update. Unfortunately, this means that many periodic updates must take place before all routers become aware of a change in network state. Until this occurs routers will have an inconsistent view of network state and routing loops can occur. This and other problems with distance vector algorithms has led to widespread adoption of an alternative class of algorithm called link state. The “open shortest path first” (OSPF; Moy, 1998) routing protocol is of this type.

In a link state algorithm each router measures the state of its local links; again, various measures of “distance” could be used. This information is then flooded to all other routers in the network. The result is that each router receives link state information from all other routers and from this information a routing table is calculated. Because all routers receive the same information, routing loops should not occur. Routing table calculation usually employs an efficient algorithm attributable to Dijkstra (1959).

Routing protocols such as RIP and OSPF are used within an AS and are referred to generically as “interior gateway protocols.” Another class of protocol, “exterior gateway protocols,” serves to exchange routing information between ASs [e.g., border gateway protocol (BGP); Rekhter & Li, 1995]. These protocols carry “reachability” information—lists of networks known to an AS and for whom it is prepared to carry traffic. Many issues, including commercial and security issues, have an impact on what is included in such lists.

The Physical Structure of the Internet

The Internet has a loose structure. Its topology is mainly a consequence of perceived commercial need being satisfied by a network service. The result is a broadly hierarchical structure; however, with some operators concentrating on providing “core” networks, others concentrating on connecting private users, and still others providing transit between users and the core. Figure 10 illustrates a possible configuration.

The core networks [called national service providers (NSP) in the United States] compete with each other to

Figure 10: High-level Internet structure. The networks shown may have complex structure internally. Each is run by a separate administration and is an “autonomous system” in Internet terminology.

carry Internet traffic. They include internetMCI, Sprint-Link, PSINet, and UUNet Technologies. They have high-capacity links between their routers—capable of operating at gigabits per second and more. NSPs connect with each other in two ways:

1. Through independent “Network Access Points” (NAP). These are commercial operations and provide high bandwidth switching between networks. They are generally confined to a small geographical area (e.g., a single building) and consist of high-speed networks such as gigabit Ethernet that host routers belonging to the NSPs. NAPs are sometimes called metropolitan area exchanges (MAEs).
2. Through private “peering” arrangements. These are direct connections between routers belonging to the NSPs.

Regional Internet service providers (ISPs) are next in the hierarchy. As the name suggests, they cover a smaller geographical area than an NSP. To provide a service, they must connect to an NSP. This may be either direct or through an NAP. Local ISPs connect end users to the Internet. This may be via dial-up, ADSL, and so on (for many private users) or leased line (for corporate users).

Naturally all this must be paid for, and the ultimate source of revenue are the customers of the ISPs. It is not easy to discover precisely how money flows between the providers because such information is commercially sensitive. In principle anyone could construct an NSP or ISP and negotiate with existing operators to obtain interconnections. Existing operators may or may not welcome the newcomer—it is all a matter of commercial policy.

Peering arrangements vary. Two operators may simply agree to carry each other’s traffic on a quid pro quo basis, or there may be payments in one direction or the other. Possibly an operator may agree to carry only certain traffic, based on source or destination for example. DIFFSERV (discussed in a subsequent section) will make all this more complex because it allows packets to be marked for special treatment. Operators will need to establish service-level agreements and accounting procedures to deal with this.

Continual improvements have been made in access technology that carries traffic between the customers’ premises and the ISP. Much of this exploits the existing telecommunications infrastructure. The public switched telephone network (PSTN), in conjunction with MODEMs and ISDN, provides the ubiquitous dial-up service. This service provides ISPs with a convenient charging model based on “connect time” but takes no account of the volume of datagrams sent and received (and hence the real load imposed on the network). The point-to-point protocol (PPP; Simpson, 1994) is used over these connections; it provides access control and delimits datagrams on the wire. Faster access can be provided by asymmetric digital subscriber loop (ADSL) and cable modems that exploit telephone wiring and television cable, respectively. With these technologies, the full path from the customer’s equipment to the ISP often involves other technologies such as Ethernet and ATM. Standards exist that specify how PPP may be used over these technologies, and

this is evidently desirable because of PPP’s access control and, not least, its familiarity (this does result in somewhat baroque architectures, however).

Variations on the Theme—Firewalls, Tunnels, Virtual Private Networks, Network Address Translation, and Proxies

The Internet architecture developed in an environment in which maximum openness and wide connectivity were principal objectives. Furthermore, the network was small, and there seemed to be few architectural limits to expansion. The situation has now changed; wide connectivity is frequently seen as a security threat, and the recent vast expansion has seen the depletion of the IPv4 address space. In this section, I discuss some adaptations (some would say distortions) of the architecture in response to this changing situation.

It is common to deploy a firewall router, which selectively discards datagrams. Such routers are placed so as to control access between a site and the wider Internet, usually with the aim of improving security. Control can vary in complexity. A simple control is to specify which ports can and cannot be used. For example, allowing only destination port 80 on outgoing datagrams effectively restricts outgoing traffic to World Wide Web requests. Controls may also operate on IP addresses and protocols. Firewalls may be operated by ISPs as well as end users. The aim then is either to protect end users from attack or to promote the ISP’s commercial interests by restricting the activities available to some classes of user.

A way of exploiting the Internet while preserving independence from it is to build a virtual private network (VPN) from IP-in-IP tunnels. Figure 11 shows such an arrangement in which an organization has three widely spaced sites each with its own network of computers and

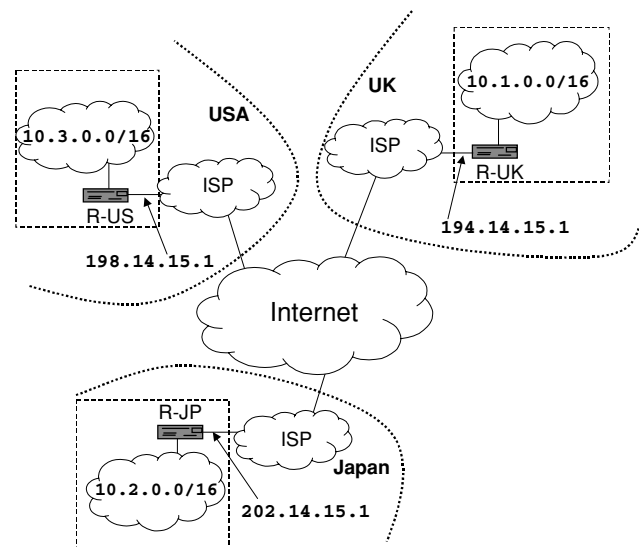

Figure 11: A virtual private network built on the Internet. An organization with three sites finds the Internet to be a cost-effective way of providing connectivity between them. The arrangement allows traffic to flow between the sites but excludes traffic to or from the wider Internet.

a connection via a router to a local ISP. Hosts on the organization's networks are allocated addresses from a network specifically designated to be private (such addresses should never appear on the "real" Internet). A datagram sent by a host on the U.S. site to one in the United Kingdom will be routed to the router *R-US*. This router, like the other two, has a real IP address allocated by the local ISP. Its routing table tells it that the datagram must be sent to the router *R-UK*. To achieve this datagram, complete with its header, becomes the data part of a new datagram with destination address 194.14.15.1. When the datagram reaches *R-UK* it is "unwrapped," and the original datagram is forwarded on to the United Kingdom network. If desired, the three external routers can be configured to disallow all traffic to or from the rest of the Internet. A further refinement is to use "secure tunnels" by exploiting the IPSec standards (Atkinson & Kent, 1998; discussed under IP security) and encrypting the tunneled datagrams.

The private address space can also help a site that has insufficient addresses for local hosts; for example, many consumer ISP contracts allocate just one IP address per customer even though the customer may have more than one host requiring an IP address. This problem can be solved in part by network address translation (NAT).

Figure 12 shows one way of using NAT as specified in RFC1631 (Egevang & Francis, 1994). It shows a single "real" IP address being shared by several hosts on a local network, each of which has a "private" IP address. As packets leave the site, the NAT gateway changes their source addresses in the IP header to the real IP address that has been assigned. The reverse transformation must be applied to the destination addresses of incoming packets; the problem is to know which private IP address should be selected. This is achieved by including the transport protocol ports in the mapping. The mapping ensures that all source ports currently in use are distinct. These source ports will be the destination ports of incoming IP datagrams and can be used to select the correct mapping. Thus an incoming datagram with destination port 5095 will have its destination IP address and port set to 192.168.1.1 and 5042, respectively.

NAT is a rather ugly fix and breaks an architectural rule that IP addresses should identify the end points of a communication. Some applications, notably FTP, make use of this rule, and NAT gateways have to treat FTP specially as a consequence. The number of such special cases seems likely to increase in the future.

The NAT operation described is fine provided the applications act as clients, but suppose a user wanted to run a Web server on the machine with address 192.168.1.1. The NAT gateway would map this address so that the outside world sees the server running at address 126.16.5.2, which is fine. The user, however, would like the server to appear to listen on the "standard" WWW port, port 80. This means a permanent mapping in the NAT gateway is necessary so that 198.168.1.1 port 80 always maps to 126.16.5.2 port 80. This demonstrates that NAT gateways have a natural firewall capability; if the NAT gateway does not have a mapping for port 80, no incoming Web request can succeed.

It is in no one's interest to generate unnecessary Internet traffic. World Wide Web proxy servers situated on a customer or ISP network aim to confine a sizable portion of Web traffic to the local area. Proxy servers maintain a cache of popular, recently accessed Web pages. Browsers are configured so that Web requests are sent not to the true destination server but to the proxy. If the requested page has been cached, the proxy will respond; otherwise it will forward the request to the true destination. Mechanisms exist to ensure that any cached copy is adequately up-to-date, but problems still arise. A variation on this theme is the so-called transparent proxy. Here Web requests are intercepted and redirected to a proxy server even though the user has not requested it and the browser has not been configured to permit it. This unwarranted interference with traffic has been justified on grounds of efficiency but is a clear breach of the Internet end-to-end principle. Problems, when they arise, are likely to be mysterious and intractable.

Multicast IP

Several modern applications require data to be delivered to multiple destinations, including multiway conferencing and video distribution. A network service that does this efficiently is called a multicast service. Many of the networks on the edges of the Internet are LANs, and these have inherent support for multicast. The aim of multicast IP is to route multicast datagrams across the Internet in a way which ensures they reach all the LANs where there are destination hosts. Efficient multicast should never send more than one copy of an IP datagram between two routers. It should be the job of routers to replicate an IP datagram and forward copies down multiple paths as necessary. The mechanisms for achieving this were developed mainly by Deering (1998). From a user's point of view,

Figure 12: Network address translation. The private IP addresses and ports used locally are mapped to/from real IP addresses and ports as they pass through the NAT router.

Figure 13: Multicast delivery to local area network hosts.

the model resembles that of a radio transmission where, to receive, one must “tune in” to a frequency. The Internet analog for a frequency is a multicast group address. Hosts wishing to receive multicasts to a particular multicast group address have to inform the network that they wish to do so. This “user to network signaling” is handled by the Internet group management protocol (IGMP; Fenner, 1997). Multicast addresses look like ordinary IP addresses, which means there is no problem with carrying them in the source and destination fields of IP datagrams. They are class D addresses with the following format:

Class D 1110XXXX XXXXXXXX XXXXXXXX XXXXXXXX

If a router on a LAN receives an incoming datagram with a multicast address (e.g., 224.20.5.1), it has to decide whether to multicast the datagram on the LAN. If there is at least one member of the 224.20.5.1 group on the LAN, the datagram must be multicast; otherwise, it should be dropped. For example, Figure 13 shows hosts on a LAN belonging to two multicast groups (224.20.5.1 and 224.20.5.8). Any datagram to either of these addresses must be multicast on the LAN. The router discovers group memberships on the LAN through IGMP.

Multicast Address Resolution

For transmission on a LAN to take place, the IP multicast address must be resolved to a LAN multicast address. In the case of Ethernet, for example, an algorithmic procedure is used that forms a MAC address as

```
<00000001000000000101111002> + <low-order
  23 bits of the IP multicast address>
```

This is not a one-to-one mapping, and it is possible to end up with two IP multicast groups on a LAN mapped to the same MAC multicast address. This is unfortunate but not disastrous. It means that a host that has joined the group with address 224.20.5.1 will also receive datagrams intended for (e.g.) 224.148.5.1 and will have to filter these out with software.

Multicast Routing

A routing mechanism is necessary to ensure that all transmissions to a multicast address reach the correct set of routers and hence the correct set of LANs. In common with the normal Internet strategy, this mechanism has to be robust in the face of network failures. This can be

achieved by minimizing the state information retained by routers and allowing this information to be continually refreshed, which requires an efficient dynamic multicast routing protocol. This turns out to be a difficult problem to crack and is still the subject of much research.

Several multicast routing protocols make use of information held by routers as a result of their normal unicast (host-to-host) operation. For example, a router employing a link-state routing protocol has enough information to be able to calculate a shortest path route from any source to any destination. By calculating shortest paths from a multicast source to all known destinations, a reasonably efficient multicast tree can be constructed. All routers involved should calculate the same tree so that no problems with loops result from inconsistencies. As it stands, this technique will deliver multicast datagrams to all destinations, including those that have no group members. This is solved by allowing routers to send “prune” messages saying, “do not forward datagrams for this address to me.” The multicast extensions to open shortest path first protocol (MOSPF; Moy, 1994) is of this type. The distance vector multicast routing protocol (DVMRP; Waitzman, Partridge, & Deering, 1998) uses similar ideas but is based on a distance vector unicast routing protocol. Another protocol, protocol independent multicast (PIM; Estrin et al., 1997), uses similar techniques when many group members are concentrated in an area (dense mode) but a different technique when members are widely distributed (sparse mode).

IP Security

Many applications, especially in e-commerce, require security. In particular, they require strong authentication of the participants in a transaction and, possibly, traffic confidentiality. The basic Internet architecture and infrastructure is far from secure, for example:

1. In the normal mode of operation users have no control over the route taken by their datagrams. Thus their traffic may pass through insecure networks where it is subject to eavesdropping or modification.
2. No guarantees are given about the origin of data arriving at a host. The source IP address in the datagram header cannot be relied on because it is trivially easy to spoof.

Figure 14 shows some possibilities for adding security within the Internet architecture; each has its advantages and disadvantages:

1. Applications themselves can be provided with security extensions. This is exemplified by the secure hypertext transfer protocol (S-HTTP; RFC 2660), which extends the HTTP protocol used on the WWW and Pretty Good Privacy (PGP; RFC 2440), which may be used to secure e-mail. This approach benefits from being “end-to-end” and independent of the lower layers that are not required to provide any security assistance. Further, the specific security mechanisms used can be carefully tailored to the requirements of the application. The disadvantage is that each application must be treated

Figure 14: The basic Internet architecture (cf. Figure 6) showing some options for introducing security facilities: (1) as an extension to an application protocol; (2) as a sublayer in the transport layer; (3) as a sublayer in the Internet layer.

separately, both in terms of specifying the security extensions and implementing them.

2. A security sublayer may be provided to the transport layer. This is the approach used in the secure sockets layer (SSL), developed by Netscape, which was the basis for the transport layer security standard (TLS; RFC 2246). This is likely to be provided within the operating system and, once installed, is available for use by all applications. Applications may still need some modification so that they correctly invoke TLS features but this is likely to involve much less work than in 1. “End-to-end” benefits still accrue because no modification is required to the underlying IP layer. However, the facilities provided may not meet the requirements of all applications. Thus, for example, the general facilities provided by TLS do not meet all the requirements for e-commerce and this has resulted in the definition of a further transport sublayer secure electronic transaction (SET; SET 1997) by Visa and MasterCard. Further, different sublayers may be needed for different transport protocols. Thus TLS works with TCP but not with UDP.
3. A security sublayer may be provided to the IP layer. The great benefit of this approach is that security facilities become available to all Internet applications and transport protocols. There are also major management benefits in that traffic may be forced to conform to a locally defined security policy. For example, one could configure a system so that all Internet traffic must be encrypted or that all traffic for a particular application must be authenticated. The enforcement of such a policy is entirely the responsibility of the security sublayer and requires neither cooperation nor modifications to applications. This is the approach of the IPsec standards (RFC 2401) that are discussed briefly below and more fully in Part 3 of this volume.

IPSec

A fundamental concept in the Internet security architecture (IPSec; Kent & Atkinson 1998) is the security association (SA). The granularity of a SA may vary; at one extreme a SA may be one-to-one with a particular user-level session and at the other an SA may cover all traffic between two sites. There is an initial handshaking phase between source and destination during which the parameters of the SA are negotiated. These parameters include details of the precise security mechanisms and options to

be used (in fact, IPsec SAs are simplex, so, in general, a pair must be set up.)

IP datagrams carrying IPsec traffic have an extra header immediately following the IP header. Two types of headers are possible:

1. An authentication header (AH) is used when just authentication is required. This header includes a digital signature for the source of the datagram.
2. An encryption security payload (ESP) header is used when authentication and confidentiality is required. It includes parameters relevant to the encryption algorithm. The header is followed by the encrypted payload and an authentication trailer that has a function similar to that of the AH.

Figure 14 shows an IP security sublayer implemented solely in the hosts. This corresponds to the case of IPsec operating in transport mode. In this mode it is only the payload of the IP datagram that can be protected by encryption; the IP header fields, including the source and destination addresses, are sent in plain text. Clearly this must be the case because routers along the path to the destination must not be required to do any special IPsec processing—it is not practical to demand that all routers in the Internet change to accommodate security. Consequently, in transport mode, an eavesdropper may still identify source and destination hosts and so carry out traffic analysis. (Note that this deficiency is also present when confidentiality is provided by application extensions or transport sublayers.) However, in the case of IPsec transport mode, the source and destination IP addresses *are* authenticated so that IP address spoofing attacks are defeated.

IPsec can also operate in tunnel mode. This finds particular application in conjunction with VPNs built from IP-in-IP tunnels as described earlier. In tunnel mode, security is applied in a “security gateway” that might be implemented in a firewall router. A VPN might deploy security gateways at each site and would establish SAs between them. A datagram passing out through such a gateway forms the payload of a new, secured datagram whose destination IP address is that of the appropriate destination security gateway. In this case whole of the “inner” datagram, including its source and destination addresses, can be protected by encryption so that host

identities are concealed. Tunnel mode may be attractive from a management point of view because it allows the security policy for a site to be implemented all in one place.

It should be noted that the various architectural approaches to implementing network security outlined above are not mutually exclusive. For example, IPsec does not meet the particular requirements addressed by SET. Conversely, SET does not conceal IP addresses. Therefore, in certain circumstances, the two may be employed together.

Mobile IP

There is a difference between wireless and mobile. A host on a wireless LAN may move physically around a building, but, as long as it remains on the same LAN, it has not moved as far as the Internet is concerned—it can still be reached by the same route. For the Internet, mobility occurs when a host moves to a location served by a new router. When this happens, the mobile host's IP address is wrong because its network prefix remains that of its "home" IP network. Unless this is tackled, the host will not receive IP datagrams because these will be routed to the home network. The problem is solved by means of two agent processes (see Perkins, 1996). The newly arrived host registers itself with the "foreign agent" (FA). If it is willing to accept the newcomer, the FA contacts the "home agent" (HA), which resides on the home network. From this point forward, all incoming packets are intercepted by the HA and forwarded to the FA; this uses IP-in-IP tunneling similar to that used in a VPN. The resulting route (source \Rightarrow HA \Rightarrow FA \Rightarrow mobile host) may be inefficient. The scheme is effective, however, because it requires no changes to be made to fixed hosts and routers.

Management in the IP Layer

ICMP

ICMP is the Internet control message protocol (Postel, 1981c). ICMP messages are used mainly to convey information about errors or conditions that require attention. There are many message types including the following:

- Echo request and response, used to probe hosts and routers to check whether they are alive and responding; The "ping" program, available on most systems, employs these messages
- Time exceeded, used to indicate that an IP datagram has been discarded by a router because its TTL field has reached zero

- Destination unreachable and host unreachable, used by routers to indicate discard for a variety of reasons.

The weakness of the ICMP mechanism is that its messages suffer the same problems as do other IP datagrams, thus one can never be sure they will be delivered. They can be regarded as providing useful hints about the nature of problems but cannot be relied on.

Host Configuration

To operate, an IP host needs several pieces of information, including its IP address, the address mask for the local network, the IP address of the local DNS server, and the IP address of at least one router. Configuring all this information by hand on a network with thousands of hosts would be an administrative nightmare. The dynamic host configuration protocol (DHCP; Droms, 1997) provides a solution. When a host starts up, it broadcasts an IP datagram requesting a DHCP server. Assuming such a server is present, it will reply with the relevant information. In many cases, the IP address allocation will be dynamic. This allows a pool of IP addresses to be shared among a larger number of hosts. Only those currently connecting to the Internet need be allocated addresses, which goes some way to tackling the shortfall of addresses in IPv4.

The IPv6

A major motivation for a new version of IP was the shortage of IPv4 addresses. IPv6 (Deering & Hinden, 1998) addresses are four times as long, which should give enough addresses for the foreseeable future. (If one IPv6 address is allocated each microsecond, the addresses will last for 10^{25} years). Other major driving factors were mobility, which requires multiple address allocations as a host moves through the Internet; ease of configuration so that simple devices can be plugged in and work without human intervention; security; and better support for different qualities of service.

The IPv6 header is shown in Figure 15. Despite the fourfold increase in address length, the header is just 40 bytes. This is something of an illusion, however, because some functions (e.g., security) require an additional "extension header."

The traffic class and flow label fields relate to QoS issues. Traffic class is used within the DIFFSERV scheme to indicate one of several predefined traffic classes. IPv6 routers should understand these classes and prioritize datagrams appropriately. The flow label relates to the finer grained INTSERV scheme. It is used by a host to mark a

Figure 15: Internet protocol version 6 header.

stream of related IP datagrams, which should be accorded a previously negotiated priority. These schemes are explained in the next section.

IPv6 wraps up several add-ons to IPv4 and makes these formally part of the protocol. These include ICMP, IGMP, DHCP, and IPsec. It has a much richer address structure that allows much greater scope for address aggregation; whereas IPv4 simply allows a collection of hosts to be aggregated into an IP network, IPv6 allows a hierarchy of aggregations. For example, one scheme has a “top-level” identifier followed by a “next level” identifier (probably denoting a particular site), a site identifier (like an IPv4 subnet), and an interface identifier (like an IPv4 host part).

The service provided by IPv6 is essentially unchanged, and the overall architecture remains as before; IPv6 provides simple datagram delivery, and the end-to-end layers (transport and application) build on this. To date IPv6 deployment has not been widespread. The two protocol versions can and do coexist, however; and pockets of IPv6 are beginning to emerge. It seems possible that the emergence of more powerful wireless devices such as “third-generation” mobile phones may see a ballooning of demand for IP addresses and a consequential rapid deployment of IPv6.

TRAFFIC MANAGEMENT IN THE INTERNET

For some time it has become clear that the basic “best efforts” IP service was not suitable for all applications. This is particularly so for applications with tight constraints on delay. These applications require some stronger guarantees on the maximum end-to-end delivery times for their IP datagrams (i.e., they require specialized QoS). This translates into a requirement for priority treatment by the routers through which their traffic passes. Several problems need to be addressed:

- How can applications tell the routers their requirements? We need some form of “signaling” between applications and the routers.
- How can routers identify which IP datagrams require which treatments?
- Can we build routers that can give different priorities to different applications so that their QoS requirements are met?

INTSERV

The Integrated Services (INTSERV) initiative (Braden, Clark, & Shenker, 1994) was the first attempt to address these problems. It introduced the concept of a “flow”—a sequence of IP datagrams all headed to the same destination(s) and all requiring the same QoS. An application which requires special QoS for a flow engages in an explicit negotiation with the network routers it will use. The resource reservation protocol (RSVP) (Braden, Zhang, Berson, Herzog, & Jamin, 1997) is employed for this signaling. The source sends an RSVP message describing the flow in terms of its peak and mean rates. The receiver then calculates the capacity that routers should reserve to meet the delay requirements. It then sends a

reservation message asking all the routers along the path to reserve the required capacity. Of course the capacity might not be available, in which case an error message will be sent back to the receiver. In a CO network, this negotiation would be done only once, when the connection is set up. In the CL Internet, it must be repeated at intervals to cope with changing traffic patterns, changing routes, and so on.

During negotiation the source indicates how the flow is to be identified. This can be a combination of source and destination IP addresses, protocol identifiers, and ports. This means that routers have to look at multiple header fields (and know something about transport protocols) to determine to which flow an IP datagram belongs, which will certainly slow things down. IPv6 includes a 20-bit flow label field into which a (hopefully) unique value can be placed. This may enable routers to classify incoming IP datagrams by examining only one field.

DIFFSERV

It is now recognized that the INTSERV approach, used alone, is appropriate only for small networks. The problem is that hundreds of thousands of flows are likely to pass through routers on core networks, and managing all these is impossible. What is needed is something much more coarse grained that allows routers to implement a few “behaviors” suited to broad classes of traffic. This is the approach used in the differentiated services (DIFFSERV; Blake et al., 1998) scheme. The “type of service” field in the IP header, now renamed the DIFFSERV field, is used to indicate the class to which an IP datagram belongs. A router has only to look at this field to know which behavior should be applied.

Effectively DIFFSERV allows the Internet to offer several classes of service to its users. The basic class offers the familiar “best efforts” service and would be relatively cheap. Traffic with tight delay constraints would use a class guaranteeing very high priority—and would pay accordingly. For this to work, ISPs must have mechanisms in place to count packets belonging to each class so that appropriate charges can be made. They must also negotiate service level agreements with neighboring networks to ensure there is an onward commitment to treat high-priority traffic appropriately. Furthermore, the guarantees offered with respect to a particular traffic class cannot be completely open ended; sources will have to agree to keep the rate at which traffic is generated within prenegotiated bounds. Traffic will have to be “policed” to ensure that these bounds are respected. Despite these complications, there now seems to be momentum behind DIFFSERV that should lead to wide deployment.

Although DIFFSERV was originally seen as an alternative and more scalable approach to INTSERV and RSVP, the two can be seen as complementary. For example, RSVP may be used to request reservation of resources for a DIFFSERV service class. RSVP also has a role in traffic engineering in conjunction with MPLS.

Performance Issues

Traffic volumes continue to increase as do the capacity of networks and links; new applications require tighter

bounds on delay. This has a number of implications for the engineering of Internet components:

- Host operating systems need better real-time performance. Some popular operating systems are poor in this regard and contribute a major proportion of end-to-end delay.
- Routers, especially core routers, must handle increased traffic volumes. At the same time, they are expected to classify IP datagrams on the basis of the DIFFSERV field and process accordingly. Coping with this increased rate and volume of per-datagram processing is challenging for router manufacturers. One approach, multiprotocol label switching (MPLS; Rosen, Viswanathan, & Callon, 2001), attempts to exploit the fact that a whole stream of IP datagrams is likely to require the same processing. MPLS labels such streams through the use of an additional field. Once a stream has been labeled, routers have only to look at the label to determine the route, the priority, and so forth.
- Generally, transmission rates increase while end-to-end delays remain constant. Thus ARQ protocols such as TCP must operate in an environment in which many more segments may be sent before an acknowledgment can be expected. This can lead to inefficient operation; some enhancements have been made to TCP to combat these.

CONCLUSION

The Internet is built through the implementation of a common service—the IP service—on its constituent networks. This is a minimalist service providing little more than basic connectivity. Keeping the IP service simple leaves maximum flexibility to the applications that may choose transport protocols suited to their needs. Many applications require reliable, sequenced delivery of data. These applications may employ the TCP protocol that satisfies these requirements and, additionally, assists with the management of congestion.

The IP service itself is based on the use of routers that relay traffic between networks. The routes followed are not normally predetermined and may vary with network load. IP addresses identify hosts and the IP networks to which these belong. Correct assignment of IP addresses is essential to Internet operation. Internet expansion has put pressure on the original addressing scheme. This has led to work-arounds such as NAT and, ultimately, to a much more flexible scheme within IPv6.

The management of congestion remains an issue and has an impact on newer, delay-sensitive applications. Initiatives such as DIFFSERV address the needs of such applications and are intended to lead to an Internet capable of carrying multiservice traffic having a variety of QoS requirements.

The early history of the Internet was characterized by the following philosophy: keep the network simple, and put the complexity in the hosts. More recently, commercial pressures have encouraged providers to add complexity to the network so as to offer “enhanced” services to their customers; firewalls, NAT gateways, tunnels, and proxies all reflect this strategy (and all bring awkward problems in their wake). At the same time, it is proving

difficult to persuade providers and customers to support ostensibly more elegant enhancements such as IPv6, IP multicast, and IPSec. Thus we see a tension between Internet architects who wish to defend and build on the elegance of the original design and commercial interests who have customers to serve and need solutions that can be deployed straight away. One must hope that this tension will continue to be creative.

GLOSSARY

Autonomous System (AS) A collection of hosts, networks, and routers operated by a single administration.

Routing within an AS is the sole responsibility of the AS administration. Routing between ASs uses a standardized exterior gateway protocol such as BGP.

Border Gateway Protocol (BGP) A protocol used to exchange routing information between autonomous systems at their edges (AS). The information indicates which ASs are reachable from the sending AS.

DIFFSERV An initiative aimed at providing quality of service control on the Internet by classifying traffic into a few broad categories. Each category is then given appropriate treatment by routers.

Dynamic Host Configuration Protocol (DHCP) A protocol that allows a host to obtain Internet configuration information from a server. DHCP is especially applicable when a host is first switched on and needs to obtain its IP configuration.

Domain Name (DN) A unique name that is used to name an object in the context of the Internet, for example, www.bluffco.com.

Domain Name System (DNS) A hierarchical system of servers that provides a directory service for the Internet. Each server manages part of the domain name space and communicates with other domain name servers to look up names in “foreign” domains.

File Transfer Protocol (FTP) The standard protocol on the Internet for transferring files between hosts. Its role has, to some extent, been usurped by HTTP.

Gateway In the context of the Internet, a gateway is an alternative name for a router.

Host A computer attached to a network on which applications run.

Hypertext Transfer Protocol (HTTP) The protocol used by a Web browser to retrieve information from a Web server.

Internet Control Message Protocol (ICMP) A protocol that provides simple management capabilities alongside the Internet Protocol. ICMP is used mainly for reporting problems and errors.

Internet Group Management Protocol (IGMP) The protocol used by hosts to manage their membership of IP multicast groups.

Internet Protocol (IP) The protocol that governs basic data delivery on the Internet. It defines the format of the IP datagram complete with its source and destination addresses. IP will attempt to deliver the datagram to the intended destination but will not attempt to recover any errors that may occur.

INTSERV An initiative aimed at providing quality of service control on the Internet through explicit reservation of resources.

IP Datagram A packet formatted according to the rules of the Internet protocol.

IPsec A protocol that can add confidentiality, integrity, and authentication to the Internet protocol.

IPv4 Version 4 of the Internet protocol. The version employed in the overwhelming majority of today's Internet traffic.

IPv6 Version 6 of the Internet protocol; A new standard that incorporates greatly expanded addressing and solutions to mobility, multicast, security, management, and configuration problems.

Network Address Translation (NAT) A scheme that allows several hosts to share a single "real" IP address.

Packet A combination of data plus control information that is treated as a unit by a data communication network.

Port A number that identifies a particular application or service available on a host.

Resource Reservation Protocol (RSVP) A signaling protocol that allows hosts to reserve Internet resources to obtain a desired level of quality of service.

Router A device that relays IP datagrams among networks. It determines where to send the datagram by referring its destination address to a routing table.

Transmission Control Protocol (TCP) A protocol that provides reliable, sequenced, flow-controlled data exchange between hosts. Common applications such as file transfer and the Web use TCP to provide the reliability they need.

User Datagram Protocol (UDP) A simple protocol that allows an IP datagram to be sent to a particular port on a particular host. UDP does not enhance the IP service in any way.

INTRODUCTION

It is difficult to imagine modern living without the Internet. It connects all kinds of computers systems from supercomputers, costing millions of dollars, to personal computers, worth no more than a couple of hundred. The networks that connect them are varied, from wireless to wired, from copper to fiber. All of this is enabled by protocols and software collectively known as the *TCP/IP Internet protocol suite* or simply *TCP/IP*.

TCP/IP is an open system. Its protocol specifications are public documents freely downloadable. Many of the implementations of the protocols are also open source. TCP/IP details constitute one or more college courses on computer networks. Entire textbooks have been written on the topic that this chapter is attempting to cover. Our goal is to present the practical TCP/IP landscape as it is today. This chapter describes the core protocols known as IP; TCP; essential protocols named UDP, ARP, ICMP, and DNS; and a few application protocols based on these. This chapter also highlights the security issues.

LAYERS

A computer system communicates with another system by sending a stream of bytes. The communication is actually between a process running on one system and one running on the other system. The two processes communicate information in a preagreed form known as a protocol. Computer protocols are easier to understand as a stack of layers, each layer providing the functionality needed by the layer above it. In each layer, there are one

or more protocols. There are three models of layers: the OSI, the DoD, and the “hourglass” models.

The OSI Model

The OSI model is officially recognized by the ISO (International Standards Organization). The OSI (open systems interconnection) model of computer networks has seven layers.

1. The bottom-most layer provides the physical means of carrying the stream of bits. Ethernet, Fast Ethernet, Wireless 802.11, T-carrier, DSL (digital subscriber line), and ATM are examples of this layer. All media are considered functionally equivalent. The differences are in speed, convenience, and cost. Converters from one media to another exist and make it possible to have different physical layers in a computer network.
2. The data link layer takes the raw stream of bits of the physical layer and, using its encoding functionality, sends and receives a meaningful message unit called a frame and provides error detection functions. A frame includes checksum, source and destination addresses, and data. The frame boundaries are special patterns of bits. Software of this layer will retransmit a frame if it is damaged, say because of a burst of noise on the physical layer. The data link layer is divided into the media access control (MAC) sublayer, which controls how a computer on the network gains access to the data and permission to transmit it, and the logical link control (LLC) sublayer, which controls frame synchronization,

flow control, and error checking. The data link layer describes the specification of interface cards to specific types of networks (e.g., Ethernet, and token ring). Example protocols from the TCP/IP suite that occupy this layer are SLIP and PPP.

3. The network layer accepts messages from the source host, converts them into packets of bytes, and sends them through the data link. This layer deals with how a route from the source to the destination is determined. This layer also deals with congestion control. The IP, address resolution protocol (ARP), reverse ARP (RARP), Internet control message protocol (ICMP), and IGMP belong to this layer.
4. The transport layer transfers data and is responsible for host-to-host error recovery and flow control. The TCP and UDP belong to this layer. UDP provides “connectionless service” and TCP provides “connection-oriented service.”
5. The session layer establishes, manages, and terminates connections between the programs on the two hosts that are communicating. The concepts of ports and connections belong to this layer.
6. The presentation layer provides independence from possibly different data representations of the host machines. The HTTP (hypertext transfer protocol), FTP (file transfer protocol), telnet, DNS, SNMP (simple network management protocol), NFS (network file system), and so on belong to this layer.
7. The application layer supports the end-user invoked programs. FTP, HTTP, IMAP (Internet Message Access Protocol), NTP (Network Time Protocol), POP (Post Office Protocol), rlogin (Remote Login), SMTP (Simple Mail Transfer Protocol), SNMP, SOCKS, telnet, X-Window, Web services, and so on are part of this layer.

The DoD Model

The practical world of TCP/IP networking was in full use by the time the OSI model was formulated. Its unofficial model is referred to as the TCP/IP model, the DoD (U.S. Department of Defense) model, or even more simply the Internet model. The DoD model organizes the networks into four layers.

1. The link (or network access) layer deals with delivery over physical media. This layer maps to the data link and physical layers of the OSI model.
2. The network (or Internet) layer deals with delivery across different physical networks that connect source and destination machines. IP, ICMP, and IGMP are in this layer.
3. The transport (or host-to-host) layer deals with connections, flow control, retransmission of lost data, and so on. TCP, UDP are in this layer.
4. The application (or process) layer deals with user-level services, such as SMTP, FTP, rlogin, SSH, SSL, POP, and HTTP. This layer corresponds to the session, presentation and application layers of the OSI model.

Figure 1: The hourglass model.

The Hourglass Model

Internet protocols can be described as following an hourglass model (Figure 1) with IP at the neck of the hourglass. The hourglass illustrates dependencies among the underlying networks, IP, and the applications.

Protocol Stack

The computer network literature talks of protocol stacks. Each item in the stack is a layer of software that implements a collection of protocols. In Figure 2, the relative heights indicate the level of functionality and the dependency of the layers. Except for the layer marked “physical” all others are software layers. The protocol stack is an integral component in a modern operating system.

In each protocol, there is a stream of bytes known as a frame, a datagram, a packet, or a segment depending on the “level.” The data unit of each layer is encapsulated by the layer below it, similarly to how sheets of paper are enclosed in an envelope. Each layer adds control information typically prefixed to the data before passing on to the lower layer. An application data unit (AP) is encapsulated by the TCP layer, which prefixes a TCP header TCPH as (TCPH (AP)). The IP layer encapsulates it as (IPH (TCPH (AP))), where IPH is the IP header. Assuming Ethernet, it encapsulates it as (EH (IPH (TCPH (AP)))) FSC, where EH is the Ethernet header and FSC is a frame check sequence generated by the Ethernet hardware.

Lower Layers

The OSI physical, data link, and network layers are collectively called the lower layers. In this section, we describe a few prominent entries from the lower layers.

Figure 2: Protocol stack.

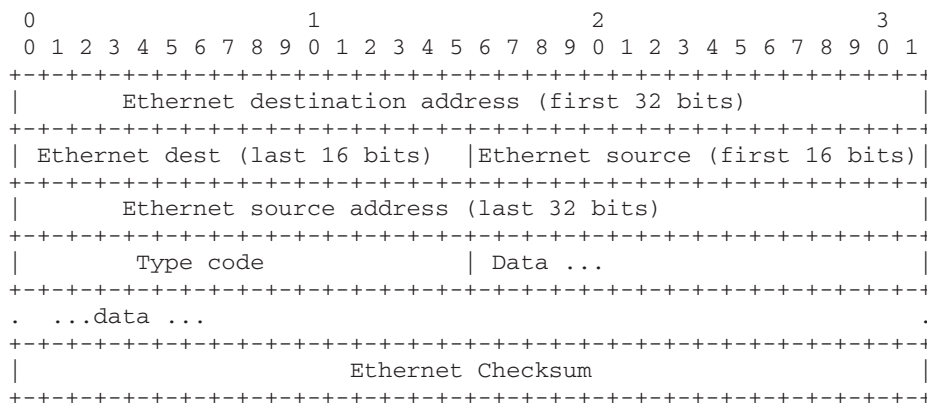

Figure 3: Ethernet frame.

Ethernet

Ethernet can support IP and other protocols simultaneously. There are variations of Ethernet, and the plain Ethernet now refers to 10-megabits-per-second (Mbps) transmission speed, Fast Ethernet refers to 100 Mbps, and Gigabit Ethernet refers to 1000 Mbps. The media varieties include the current twisted pair (100Base-T, with RJ45 connectors), the original thick coaxial system (10base5), thin coaxial (10base2), and fiber optic systems (10basesF). Ethernet has been standardized by the Institute of Electrical and Electronics Engineers as IEEE 802.3.

Ethernet Frames. We describe the content of data units as a rectangular diagram such as the one shown in Figure 3. The width of such a diagram is always 32 bits, numbered from 00 to 31. The unit's digits of these bit indices are shown in the second row and the tens digits are shown in the first row.

An Ethernet controller is assigned a 48-bit MAC address by the factory. For communication among humans, the MAC address is written with each byte in hexadecimal, separating bytes with either a hyphen or a colon, as in 00-0A-E6-9B-27-AE. Every Ethernet frame has a 14-byte header that includes the MAC addresses of the source and destination and a 2-byte type code (see Figure 3). The type code identifies the protocol family (such as IP, ARP, and NetBEUI). The data field is from 46 to 1500 bytes in length. Following the data, there is a checksum computed by the Ethernet controller for the entire frame. Every device is expected to listen for Ethernet frames containing their destination address. All devices also listen for Ethernet frames with a wild-card destination address of FF-FF-FF-FF-FF-FF, called a broadcast address. When these packets are received by the Ethernet network interface card (NIC), it computes the checksum and throws the packet away if an error is detected by the checksum. If the type code is IP, the Ethernet device driver passes the data portion of the frame up to the IP layer of the OS. Under OS control, the NIC can be put into a so-called promiscuous state wherein the NIC listens to all frames regardless of their destinations.

Unswitched (Shared) Networks. All hosts attached to an Ethernet are connected to a shared signaling medium.

Ethernet signals are transmitted serially, one bit at a time, over the shared medium that every attached host can observe. When a frame is sent out on the Ethernet, every controller on the local unswitched network can see the frame. Thus, Ethernet is a broadcast medium. To send data, a host waits for the channel to become idle and then transmits its frame. All hosts on the network contend equally for the transmission opportunity. Access to the shared medium is governed by the MAC mechanism based on the carrier sense multiple access with collision detection (CSMA/CD) system. This ensures that access to the network channel is fair and that no single host can lock out other hosts. If two or more devices try to transmit at the same instant, a transmit collision is detected, and the devices wait a random (but short) period before trying to transmit again.

Switched Networks. Today a typical end user connects to a full duplex switched Ethernet that uses switches instead of hubs to connect individual hosts or segments. A hub is an OSI physical layer device. It transmits the frames received from one port to all other ports it has. A switch is an OSI data link layer or network layer device. It builds (“learns”) a table of ports and the MAC address it is connected to, reads the destination address of each frame, and forwards a frame it receives to only the port connected to the destination MAC address. Switched Ethernets extend the bandwidth by replacing the shared medium of legacy Ethernet with a dedicated segment for each station. Switched networks use either twisted pair or fiber optic cabling, with separate conductors for sending and receiving data. Collision detection is not necessary because the station and the switch are the only devices that can access the medium. End stations and the switch can transmit at will achieving a collision-free environment. Switched Ethernets also mitigate sniffing. However, many commercial switches can be “overwhelmed” into behaving as though they are hubs.

IEEE 802.11 a/b/g Wireless Networks

This section briefly describes wireless networks known as the IEEE 802.11 family (<http://www.ieee802.org/11/>). For a detailed treatment, read chapter 44: Wireless Local Area Networks. The 802.11a operates at a theoretical maximum

Figure 4: An IEEE 802.11 MAC header.

speed of 54 Mbps, 802.11b at 11 Mbps, and 802.11g at 54 Mbps.

Stations and Access Points. A wireless network station provides a radio link to another station. The station has a MAC address, a world-wide-unique 48-bit number, assigned to it at the time of manufacture, just as wired network cards do. An *access point* (AP) is a station that provides frame distribution service to stations associated with it. Each AP has a 0- to 32-byte-long service set identifier (SSID) that is used to segment the airwaves for usage. The AP itself is typically connected by wire to a LAN.

Frames. A dot-11 frame consists of a MAC header (see Figure 4) followed by a frame body of 0 to 2312 bytes and an FCS. There are three classes of frames. The *management* frames establish and maintain communications. The *control* frames help in the delivery of data. The *data* frames encapsulate the OSI network layer packets. These contain the source and destination MAC address, the BSSID, and the TCP/IP datagram.

Authentication and Association. Data can be exchanged between the station and AP only after a station is authenticated and associated with an AP. The association is a two-step process. A station that is currently unauthenticated and unassociated listens for management frames known as Beacon frames. The station and the AP mutually authenticate themselves by exchanging authentication management frames. In the second step, the station sends an association request frame, to which the AP responds with an association response frame that includes an association ID to the station. A station can be authenticated with several APs at the same time but associated with at most one AP at any time.

WEP and IEEE 802.11i. Wired equivalent privacy (WEP) is a shared-secret key system encrypting the payload part of the frames transmitted between a station and an AP. The WEP is intended to protect wireless communication from eavesdropping and to prevent unauthorized access

to a wireless network. Unfortunately, WEP is insecure. The IEEE 802.11i was ratified in 2004. It provides robust encryption and authentication.

Asynchronous Transfer Mode

Asynchronous transfer mode (ATM) is widely deployed as a backbone technology. ATM uses 53-byte fixed-length packets called cells for transport. A 48-byte payload divides the data into different types. The ATM layer contains 5 bytes of additional information, referred to as overhead. Information is divided among these cells, transmitted, and then reassembled at their final destination. ATM is connection oriented. ATM itself consists of a series of layers. Its physical layer is based on various transmission media that range in speed from kilobits per second to gigabits per second. The layer known as the adaptation layer holds the bulk of the transmission.

Serial Line Internet Protocol

A serial network is a link between two computers over a serial line, which can be a dial-up connection over telephone lines or a direct connection between the serial ports of two computers. Serial line Internet protocol (SLIP; RFC 1055) defines the encapsulation protocol, just as an Ethernet frame envelopes an IP packet. Unlike Ethernet, SLIP supports only the IP and not multiple protocols across a single link. The serial link is manually connected and configured, including the specification of the IP address. SLIP provides no mechanisms for address negotiation, error correction, or compression. However, many SLIP implementations record the states of TCP connections at each end of the link, and use header compression that reduces the size of the combined IP and TCP headers from 40 to 8 bytes.

Point-to-Point Protocol

Point-to-point protocol (PPP; RFC 1661, RFC 2153) replaces the older SLIP, and is an encapsulating protocol for IP and other protocol datagrams over serial links. The encapsulation and framing adds 2, 4, or 8 bytes depending on the options chosen. PPP includes a link control protocol

(LCP) that negotiates the encapsulation format, sizes of packets, authentication methods, and other configuration options. The CCP (compression control protocol) used by PPP negotiates encryption. The IP control protocol (IPCP) included in the PPP configures the IP address and enables the IP protocol on both ends of the point-to-point link.

Point-to-Point Tunneling Protocol

Point-to-point tunneling protocol (PPTP) encapsulates PPP packets into IP datagrams. Its use is in providing virtual private networks (VPN). After the initial PPP connection to a PPTP server, a PPTP tunnel and a PPTP control connection are created. Tunneling is the process of sending packets of a certain protocol embedded in the packets of another protocol. PPTP uses an enhanced generic routing encapsulation (GRE) mechanism to provide a flow- and congestion-controlled encapsulated datagram service for carrying PPP packets.

INTERNET PROTOCOL

The details of IP and TCP are not directly experienced by the ordinary user unless a network sniffer is used. Nevertheless, it is crucial to understand these before attempting to understand the application protocols.

IP [RFC 791] delivers a sequence of bytes from a source host *S* to a destination host *D*, even when the hosts are on different networks, geographically vastly separated. The byte sequence and the destination are given to the IP layer by the upper layer. The IP layer forms an IP datagram from the sequence. An IP datagram consists of an IP header followed by a transport layer data. The IP layer software discovers routes that the packet can take from *S* to various intermediate nodes, known as routers, ultimately arriving at *D*. Thus, IP is routable. Each datagram travels independently even when the host *S* wishes to send several datagrams to *D*; each datagram delivery is made independently of the previous ones. The route that each packet takes may change. The sender, the receiver, and intermediary routers treat a datagram independently of others. Thus, IP is connectionless. The IP layer is designed deliberately not to concern itself with guaranteed delivery (i.e., packets may be lost or duplicated), but instead it is a “best effort” system. The ICMP described later aids in this effort.

IP Addresses

An operating system during boot-up assigns a unique 32-bit number known as its IP address to each NIC located in the host system. There is no rigid relationship between the Ethernet MAC address and the IP address. The IP address is obtained either by looking it up in a configuration file or via dynamic host configuration protocol (DHCP). The IP addresses are carefully controlled worldwide. The IANA, Internet Assigned Numbers Authority (www.iana.org), assigns the so-called public IP addresses to organizations and individuals upon application.

Dotted Quads and Octets

IP addresses are typically written in a dotted-quad notation, such as *a.b.c.d*, where *a* is the first byte, *b* the second,

c the third, and *d* the fourth byte. Each of *a* to *d* is an octet, a number in the range 0 to 255.

Three address ranges known as class A, class B, and class C are of importance. In a class A address, the 0-th bit is always a 0, bits 1 through 7 identify the network, and bits 8 through 31 identify the host, permitting 2^{24} hosts on the network. In a class B address, the bit 0 is always a 1, bit 1 is always a 0, bits 2 through 15 identify the network, and bits 16 through 31 identify the host, permitting 2^{16} hosts on the network. In a class C address, bits 0 and 1 are both 1 always, bit 2 is a 0 always, bits 3 through 23 identify the network, and bits 24 through 31 identify the host, permitting 2^8 hosts on the network.

CIDR Nomenclature /24

Note that in each range of IP addresses assigned to a LAN segment, we use the smallest IP address to refer to the network itself, and the highest address as the broadcast address for the segment.

The classless interdomain routing (CIDR) model, first published in 1993, solves the problems of efficient utilization of IP address space (RFC 1520). Class C, with a maximum of 254 host addresses, is too small, whereas class B is too large to be densely populated, and making routing tables more compact.

A subnet is a collection of hosts whose IP addresses match in several bits indicated by the ones in a sequence of 32 bits known as a subnet mask, also written in the dotted-decimal notation. Thus, 255.255.255.0 is a mask of 24 ones followed by 8 zeroes. Because of this structure, the mask is also written as /24. Nodes and routers use the mask to identify the address of the network on which the specific host resides. The address of the network is the bitwise AND of the IP address and the mask. The host ID is the bitwise AND of the IP address and the complement of the mask. Occasionally, a network node *X* needs to discover certain information from other nodes, but the node *X* does not know the addresses of these others. In such situations, *X* broadcasts using special destination IP addresses. The direct broadcast address of *X* is the address whose host ID is all ones and whose network address equals that of *X*. The limited broadcast address is 255.255.255.255.

Public and Private Address Ranges

The following three blocks of the IP address space is intended for private internets: 10.0.0.0 to 10.255.255.255 (10/8 prefix, class A) 172.16.0.0 to 172.31.255.255 (172.16/12 prefix), and 192.168.0.0 to 192.168.255.255 (192.168/16 prefix, class C). That is, on the Internet at large, there must never be IP packets whose source or destination addresses are from the above ranges.

Most operating systems are internally structured to depend on the presence of a network layer. To facilitate this, the address 127.0.0.1 is assigned as the so-called address of the localhost (spelled as one word) and 127.0.0.0 as the localnetwork (spelled as one word). Packets sent to this address do not actually travel onto the external network. They simply appear as received on the local (artificial) device. When a machine is physically moved from one network to another, we must reassign an IP address that belongs to the new network. This is one of the problems that mobile IP solves.

Figure 5: IP header.

IP Header

An IP header is a sequence of bytes that the IP layer software prefixes to the data it receives from the higher layers. The resulting IP header plus the data is given to the lower layer (e.g., the Ethernet card device driver). The byte layout of IP headers is shown in Figure 5. The header may or may not have the IP Options field. Except for this field, all other fields are fixed in length as shown. Minimally (i.e., without the options), the IP header is 20 bytes in length. With IP options, an IP header can be as long as 60 bytes. IPv is the version number of the protocol; currently it is 4. IP version 6 is discussed later. The value of IHL multiplied by 4 is the length of the IP header in bytes. The type of service field specifies the “relative urgency” or importance of the packet. Total length is a 2-byte field giving the length, in bytes, of the entire packet including the header, options (if any), and the packet data.

Thus, the maximum length of an IP datagram is 65535 bytes. (IP over Ethernet limits this to 1500.) The identification field, flags, and fragment offset are used to keep track of the pieces when a datagram must be split up as it travels from one router to the next. IP fragmentation is discussed further below. The time to live (TTL) is a number that is decremented by 1 whenever the datagram passes through a router node. When it goes to 0, the datagram is discarded, and an error message is sent back to the source of this packet. The protocol field identifies the protocol of the data area. The header checksum field is a one’s complement arithmetic sum of the entire header viewed as a sequence of 16-bit integers. The source address is the datagram’s sender IP address, and destination address is the IP address of the intended recipient. The IP options may or may not be present. When present, its size can be one or more bytes.

Routing Protocols

When the source S and the destination D are on the same network, we have a direct delivery of the packet that does not involve routers. When the two hosts are not on the same network, in general, there can be multiple paths between the source and destination. Because of failures, maintenance, and other reasons, the intermediate nodes

known as routers may come on or off during the delivery of packets. Thus, consecutive packets sent by a host S to a destination D may (have to) travel entirely disjoint routes depending on how the network is connected. The typical network host has only one NIC and hence is on only one network, and sending and receiving of network traffic is secondary to its main functionality.

Routers are specialized computer systems whose primary function (often their sole function) is to route network traffic. Routers must have multiple NICs, each on a separate network. A router examines the destination IP address of a packet and consults its routing tables that record information regarding where to deliver a packet next so that definite progress is made in moving the packet closer to its final destination. Routers are layer 3 devices.

Every network host (including routers) has a routing table, which can be visualized as a table of two columns: To send the packet to a final destination given in column 1, send the packet to the next hop whose IP address is given in column 2. The size of such a table can be greatly reduced by parametrizing the column 1 by its network address and also by including a default row in the table that acts as a catch-all. The default row indicates the next hop IP address for any packet whose destination network address does not match that of any other row. Once the next hop IP address is determined, the router uses the lower layer address (such as the Ethernet MAC) to deliver the packet to the next hop.

The routing table of an ordinary host rarely changes from boot-up to shut down. The tables of routers, however, must be dynamic and adjust to changing conditions, perhaps by the millisecond, of the Internet. Routing protocols keep the routing tables up-to-date. The Internet is a network of autonomous networks. Interior gateway protocols (IGPs) maintain the routing tables within an autonomous network. Routing information protocol (RIP) and open shortest path first (OSPF) are examples of IGPs. Border gateway protocol (BGP) is the most common protocol in use for routing among autonomous networks.

IP Fragments

When datagrams are too large to be sent in a single IP packet, because of interface hardware limitations, for

example, they can be split up by an intermediate router unless prohibited by the Don't Fragment flag. IP fragmentation occurs when a router receives a packet larger than the maximum transmission unit (MTU) of the next network segment. All such fragments will have the same identification field value, and the fragment offset indicates the position of the current fragment in the context of the pre-split-up packet. Intermediate routers are not expected to reassemble the fragments. The final destination will reassemble all the fragments of an IP packet and pass it to higher protocol layers (such as TCP or UDP).

Mobile IP

As the mobile network host moves, its point of attachment may change, and yet to maintain existing transport-layer connections, it must keep its IP address the same.

The mobile node uses two IP addresses. The home address is static and is used to identify TCP connections. The care-of address changes at each new point of attachment. Whenever the mobile node moves, it registers its new care-of address with its home agent. The home agent redirects the packets to the current care-of address by constructing a new IP header that contains the care-of address as the destination IP address. This new header encapsulates the original packet, causing the home address to have no effect on the routing of the encapsulated packet until it arrives at the care-of address. When the packet arrives at the care-of address, the effect of this "tunneling" is reversed so that the packet once again appears to have the home address as the destination IP address. Mobile IP discovery of the care-of address uses an existing standard protocol called *router advertisement* (RFC 1256). A router advertisement carries information about default routers, and in addition carries further information about one or more care-of addresses. Home agents and care-of agents typically broadcast these advertisements at regular intervals (say, once every few seconds). A mobile node that needs a care-of address will multicast a router solicitation. An advertisement also informs the mobile node whether the agent is a home agent, a care-of agent, or both and therefore whether it is on its home network or a care-of network and about special features provided by care-of agents (for example, alternative encapsulation techniques).

The registration of the new care-of address begins when the mobile node, possibly with the assistance of the care-of agent, sends a registration request to the home address. The home agent typically updates its routing table. Registration requests contain parameters and flags that characterize the tunnel through which the home agent will deliver packets to the care-of address. The triplet of the home address, care-of address, and registration lifetime is called a binding for the mobile node. The home agent authenticates that registration was originated by the mobile node.

Each mobile node and home agent compute an unforgeable digital signature using one-way hash algorithm MD5 [Message Digest 5 (RFC 1321)] with 128-bit keys on the registration message, which includes either a time stamp or a random number carefully generated. Occasionally a mobile node cannot contact its home agent. The mobile node tries to register with another home agent

by using a directed broadcast IP address instead of the home agent's IP address as the target for the registration request.

TRANSMISSION CONTROL PROTOCOL

TCP (RFC 793, RFC 3168) offers a client process a connection to a server process. This connection needs to be established, as needed. Once this connection is established, the TCP protocol guarantees the correct (both in content and in order) delivery of the data. TCP sends its message content over the IP layer and can detect and recover from errors. TCP, however, does not guarantee any speed of delivery, even though it offers congestion control.

Ports and Connections

Port numbers are used by the transport layer for multiplex communication between several pairs of processes. To each message, this layer adds addresses, called port numbers. The port numbers would have been assigned by the OS to certain processes. Thus, a connection is uniquely identified by a quadruple: source and destination IP addresses and source and destination port numbers. In this context, we often say quintuple, including the specific protocol (TCP/UDP/etc.) in use as the fifth element to make it clear that the port namespaces for UDP and TCP are separate. The IP addresses are supplied by the IP layer.

The ports 0-1023 are reserved for specific well-known services provided by privileged processes. For example, HTTP officially uses port 80, telnet officially uses port 23, and DNS officially uses port 53. The *dynamic* or *private* ports range from 1024 to 65535. Client processes and non-standard services are assigned port numbers by the operating system at run time. On most computer systems, there is a list of these port numbers and service names in a file named etc/services.

Reliable Transmission

TCP requires that every segment include an acknowledgment of the last data segment received in the other direction. TCP is a *sliding window* protocol with time-out and retransmits. If the sender does not receive an acknowledgment within the time-out period, it retransmits the segment. Acknowledgments are piggybacked on reply data. The window size specifies the number of bytes the receiver has as buffer space. The sender continues to send and slides the window ahead as long as acknowledgments are being received for bytes within the window.

TCP messages, called *segments*, are sent as one or more IP datagrams. A TCP header follows the IP header, supplying information specific to the TCP protocol. Figure 4 contains the details of the TCP segment. The letters [U|A|P|R|S|F] in the fourth row of the segment are abbreviated names for control bit flags: URG, urgent pointer field significant; ACK, acknowledgment field significant; PSH, push function; RST, reset the connection; SYN, synchronize sequence numbers; and FIN, sender is finished with this connection. These are further explained below.

The sequence number, together with the acknowledgment number, serves as a ruler for the sliding window protocol. While establishing the connection, the SYN flag

is set to 1, and the client and the server exchange their initial sequence numbers.

The acknowledgment number is valid only when the ACK bit is set. This field contains the value of the next sequence number the sender of the segment is expecting to receive. Once a connection is established, this is always included. The DataX number multiplied by 4 is the number of bytes in the TCP header. This indicates where the data begin. Window size is described under Congestion Control. Urgent pointer is valid when URG is 1. Its value is a positive offset from the sequence number in this segment. Options, if any, are given at the end of the TCP header and are always a multiple of 8 bits in length. All options are included in the checksum. An option can be just a single byte, or it can be a byte of option-kind, followed by a byte of option-length and the actual option-data bytes. The option-length counts the two bytes of option-kind and option-length as well as the option-data bytes.

State Diagram

A TCP server process starts its life by passively opening a port and starts to listen to connection attempts from clients. This process causes a number of changes in the information maintained by the TCP layer software. These transitions are described by the state diagram shown in Figure 5. Below we describe two handshakes that establish a connection and close a connection.

Three-Way Handshake

This establishes connection between the initiating node (say A, the client) and the receiving node (say B, the server) of packets as follows:

1. A: "I would like to talk to you, B." A sends a packet with SYN = 1, and the initial sequence number (ISN) chosen by A to B.
2. B: "OK, let's talk." B replies with a SYN + ACK packet (i.e., SYN = 1, ACK = 1, acknowledgment number = sequence number received + 1, and SYN = 1 with sequence number set to the ISN of the server). If B was unwilling, it responds with a RST = 1 packet refusing the request for service. At this point, the state of the connection is known as *half-open*.
3. A: "Thanks for agreeing!" A sends a packet with ACK = 1, acknowledgment number = ISN of B + 1, SYN = 0, sequence number = previous sequence number + 1. The sequence number for SYN = 1 can be a zero, but that is not secure, so the sequence number is randomly chosen.

Here is an example where the client is on port 1037 establishing a connection with a service on port 80 (typically HTTP).

SYN	ACK	src	dst	sequence-number	acknowledgement-number
1	0	1037	80	102723769	0
1	1	80	1037	1527857206	102723770
0	1	1037	80	102723770	1527857207

Four-Way Handshake

This terminates a previously established connection, between A and B, as follows:

1. A sends to B a packet with FIN = 1, which indicates "no more data from A." This flag is used when closing a connection down the normal way. The receiving host B enters the CLOSE WAIT state and starts the process of gracefully closing the connection. Each end of the connection sends a packet with the FIN = 1. The receiver is expected to acknowledge a received FIN packet by sending a FIN = 1 packet.
2. B sends to A a packet with ACK = 1, acknowledging the FIN packet received.
3. B sends to A another packet, but now with FIN = 1.
4. A sends to B a packet with ACK = 1. No further packets are exchanged.

So, four packets are used to close a TCP connection in the normal situation. This is a teardown of two *half-closes*.

Closing a connection can also be done by using the RST flag set to 1, which indicates to the receiver that a reset should occur. The receiving host accepts the RST packet provided the sequence number is correct, and enters the CLOSED state and frees any resource associated with this instance of the connection. The RST packet is not acknowledged. A host H sends a connection resetting RST packet if host X requested a connection to a non-existent port p on host H, or for whatever reason (idle for a long time, or an abnormal condition, etc.), the host H (client or the sever) wishes to close the connection. Resetting is unilateral. Any new incoming packets for that connection will be dropped.

Timers

TCP depends on many timers that the host must maintain per (attempted) connection as it follows the state diagram (see Figure 7).

The connection establishment timer is started on receiving the first packet of the three-way handshake. A typical value of this timer is 75 s. If a time-out occurs, the connection is aborted.

A FIN-WAIT timer is started when there is a transition from the FIN-WAIT 1 state to the FIN-WAIT 2 state. The initial value of this timer is 10 min. If a packet with FIN = 1 is received, the timer is canceled. On expiration of the 10 min, the timer is restarted with a value of 75 s. The connection is dropped if no FIN packet arrives within this period.

TIMED-WAIT timer is started when the connection enters the TIMED-WAIT state. This is to allow all the segments in transit to be removed from the network. The value of the timer is usually set to 2 min. On expiration of the timer, the connection is terminated.

A retransmission timer is started when a segment is sent. Its value, known as RTO retransmission timeout, is dynamically computed (RFC 2988). If the timer expires before an ACK is received, the segment is resent, and the timer is restarted.

Figure 6: TCP header.

A persistence timer is used to detect if any window size updates were lost.

The KEEP-ALIVE timer lets us distinguish between the silences caused because there is no data to send from that caused by a broken connection. Setting a KEEP ALIVE timer allows TCP to periodically probe the other end. The default value of this timer is 2 hr. After the expiration of the timer, probes are sent to the remote end. The connection is dropped if the remote does not respond.

Flow and Congestion Control

The size of the sliding window is dynamically adjusted because of flow or congestion issues. Flow control prevents the sending process from overwhelming the receiving process. Each acknowledgment segment from a receiver advertises the buffer size it has available. If this size is larger than the current sliding window size, the sender can increase it. If it is smaller, the sender should decrease.

When a router begins to accumulate too many packets, it can send ICMP source quench messages to the senders of these packets. These messages should cause the rate of packet transmission to be slowed.

Congestion is a condition of significant delay caused by overload of datagrams at one or more routers. A congestion window size is dynamically computed by the sender based on network congestion. The TCP sliding window size is the minimum of the receiver window advertisement, and the congestion window. When a segment loss is detected, we assume that the loss is due to congestion, and the congestion window size is reduced by half. On observing that segments are not getting lost, the congestion window size is doubled. TCP congestion control has undergone major improvements resulting in TCP variants known as TCP Vegas, FastTCP, and so on that are soon to be adopted in actual implementations.

UDP, ICMP, DNS, ARP, AND RARP User Datagram Protocol

UDP (RFC 768, 1980) is a connectionless transport protocol. It is a thin protocol on top of IP, providing high speed but low functionality. Delivery of UDP datagrams

is not guaranteed. Nor can it detect duplicate datagrams. The UDP protocol is used mostly by application services where squeezing the best performance out of existing IP network is necessary, such as Trivial File Transfer (TFTP) and NFS and by the DNS.

The port numbers appearing in the UDP header (Figure 8) are similar to the TCP port numbers (see Figure 6), but the OS support required by UDP ports is much simpler and less resource consuming than that of TCP ports. The source port is the port of the sending process. When not meaningful, this field is set to 0. The destination port is the UDP port on the receiving machine, whose IP address is supplied by the IP layer. Length is the number of bytes in the datagram, including the UDP header and the data. Checksum is the 16-bit one's complement of the one's complement sum of the UDP header, the source and destination IP addresses obtained from the IP header, and the data, padded with zero bytes at the end (if necessary) to make a multiple of 2 bytes.

Internet Control Message Protocol

ICMP (RFC 792, 1981) manages and controls the IP layer, as in reporting network errors, such as a host or entire portion of the network being unreachable or a packet being directed at a closed port, reporting network congestion, assisting in trouble shooting, reporting time-outs, or forcing routing options. In general, much of the best effort in delivering IP datagrams is associated with ICMP. The purpose of the ICMP messages is to provide feedback and suggestions about problems, for example, when a datagram cannot reach its destination, when the gateway does not have the buffering capacity to forward a datagram, or when the gateway can direct the host to send traffic on a shorter route. To avoid the infinite regress, no ICMP messages are sent about ICMP messages. Also ICMP messages are sent only about errors in handling fragment zero of fragmented datagrams.

An ICMP message is sent as the data portion of an IP datagram. These IP datagrams are treated like all other IP datagrams. Each ICMP message begins with a 1-byte ICMP type field, which determines the format of the remaining data, a one-byte code field, and a 2-byte

checksum. If the ICMP message is reporting an error, these 4 bytes are followed by the first 8 bytes of the IP datagram causing the error.

The popular network utilities ping and traceroute use ICMP. The ping command sends several echo requests, captures their echo replies, and displays statistics about speed and datagram loss. The traceroute utility constructs IP datagrams with well-chosen TTL values and collects the time-exceeded ICMP messages to map a route from the source to a destination IP address. ICMP helps improve the performance of the network. For example, ICMP redirect messages from a router inform a host that a different router is more optimal than it is for certain destinations.

Domain Name Service

Because of the mnemonic value, humans prefer to work with host names such as gamma.cs.wright.edu, where *gamma* is the name of the host, and *cs.wright.edu* is the name of the domain the host is in.

The DNS name space is a tree hierarchy (RFC 1035). The top-most subtrees are the top level domains such as .com, .edu, .net, and .org, and the country code domains such as .in, and .us. Subtrees of these are known as subdomains. The leaves are the individual hosts. A *fully qualified domain name* is the sequence of labels, separated by a dot, on the path from a node to the root of the tree.

A *domain name server* maintains the name space as a database. It can delegate the maintenance of any subdomain to another server. A delegated subdomain in the DNS is called a *zone*. The parent server keeps track of such delegations. There are 13 *root servers* (in 2004; visit <http://www.root-servers.org>) located in the United States and other countries. Each name server has authoritative information about one or more zones but may also have cached, but nonauthoritative, data about other parts of the database. A name server marks its responses to queries as authoritative or not.

The database is a collection of *resource records*, each of which contains a domain name and four attributes. The time-to-live (TTL) value indicates how long a nonauthoritative name server can cache the record. The class attribute of the record is "IN" for Internet. The third attribute, the record type A, AAAA, MX, and PTR, identifies what is stored as the fourth attribute, known as data value. The data of an A record is an IP address, of an AAAA record is an IPv6 address, and so on. The primary function is to answer a query to translate a fully qualified domain name into its IP address. This is done by retrieving the A record. A reverse look-up (also called an inverse query) is to find the host name given the IP address. This is done by retrieving the PTR record. Some network services use this to verify the identity of the client host. The mapping of names to addresses is not one-to-one. It is possible to associate a name with multiple IP addresses thus providing load distribution. A single IP address can be associated with multiple names, one being a *canonical* name and others perhaps more mnemonic thus providing host aliasing. The MX records map a host name to the canonical host name of the mail server and its IP address.

The DNS *resolver* is a piece of software. Every host is configured with at least one local name server N if it is to

find hosts not listed in the etc/hosts file. Each host maintains a short cache table of fully qualified domain names to IP addresses. When a name is not found in either this file or this cache, the host enquires with N via the DNS protocol using the resolver. Either TCP or UDP can be used for DNS, connecting to server port 53. Ordinary DNS requests can be made with TCP, although UDP is used for normal operation. The protocol is stateless—all the information needed is contained in a single message.

An *iterative* DNS query to a name server D receives a reply with either the answer or the IP address of the next name server. If the name is in the local zone, the local name server N can respond to a query directly. Otherwise, N queries one of the root servers. The root server gives a *referral* with a list of name servers for the top-level domain of the query. N now queries a name server on this list and receives a list of name servers for the second-level domain name. The process repeats until N receives the address for the domain name. N then caches the record and returns the address or other DNS data to the querying host.

A *recursive* DNS query to D will make D obtain the requested mapping on behalf of the querying host. If D does not have the answer, it forwards the query to the next name server in the chain, and so on until either an answer is found or all servers are queried and hence returns an error code. Because recursive look-ups take longer and need to store many records, it is more efficient to provide a recursive DNS server for LAN users and an iterative server for Internet users.

Address Resolution Protocol

ARP (RFC 826, 1982) is typically used to determine the Ethernet MAC address of a device whose IP address is known (see Figure 9). This needs to be done only for outgoing IP packets, because IP datagrams must be Ethernet framed with the destination hardware address. The translation is performed with a table look-up.

Reverse ARP (RARP) (RFC 903) allows a host wishing to discover its own IP address to broadcast its Ethernet address and expect a server to reply with its IP address. The ARP cache accumulates as the host continues to network (see Table 1). If the ARP cache does not have an entry for an IP address, the outgoing IP packet is queued, and an ARP request packet that effectively requests "If your IP address matches this target IP address, then please let me know what your Ethernet address is" is broadcast. Once the table is updated because of receiving a response, all the queued IP packets can now be sent.

Table 1 A Small Portion of an ARP Cache

IP Address	Ethernet Address
130.108.2.23	08-00-69-05-28-99
130.108.2.1	00-10-2f-fe-c4-00
130.108.2.27	08-00-69-0d-99-12
130.108.2.20	08-00-69-11-cf-b9
130.108.2.10	00-60-cf-21-2c-4b
192.168.17.221	00-50-ba-5f-85-56
192.168.17.112	00-A0-C5-E5-7C-6E

The entries in the table expire after a set time period to account for possible hardware address changes for the same IP address. This change may have happened (e.g., because of the NIC being replaced).

ARP is an OSI layer-3 protocol, but it does not use an IP header. It has its own packet format as shown in Figure 7. The ARP request packet has zeroes in the target hardware address fields. It is broadcast on the local LAN without needing to be routed. The destination host sends back an ARP reply with its hardware address so that the IP datagram can now be forwarded to it by the router. An ARP response packet has the sender/target field contents swapped as compared to the request.

APPLICATIONS

Nearly all network applications are based on a client/server architecture where one process, the client, requests services from a second process, the server. Typically, the client and server processes are on different machines, but they need not be.

File Transfer Protocol, Telnet, and rlogin

The three application protocols described in this section are all based on TCP. They send authentication information and data in the clear (i.e., unencrypted) and hence are easily compromised by network sniffers. In addition, their authentication of host is simply the IP address. Consequently, utilities based on these protocols should not be

used in situations where security is a concern. The SSH described later provides near equivalent functionality at a higher level of security.

File Transfer Protocol

FTP (RFC 959, 1985) uses two TCP connections, one called the control connection and the other the data connection. The client can issue a number of commands on the control connection that change various settings of the FTP session. All content transfer occurs on the data connection. The FTP client opens a control connection to port 21 of the FTP server machine. This connection persists the entire session. The format of data passed over the control connection is the same as that of telnet NVT. The GET command requests for the transfer of the contents that the server has (popularly known as downloading), and the PUT command requests the server to receive and store the contents that the client is about to send (popularly known as uploading). FTP is an insecure protocol. User name, password, and all data are transmitted in the unencrypted form.

Passive and Active modes of FTP

The data connection can be opened in two modes. In the active mode FTP, the server initiates a data connection as needed from its port 20 to a port whose number is supplied by the client via the PORT command. In the passive mode FTP, the server informs the client a port number higher than 1024 that the server has chosen, to which the

Figure 7: TCP state diagram.

Figure 8: UDP header.

client initiates a data connection. Passive FTP is relevant in firewall setups that forbid initiation of a connection from an external host to the internal network.

Telnet

Telnet (RFC 854) establishes a TCP connection with a telnet server on the reserved port 23 and passes the keystrokes of the telnet client to the server and accepts the output of the server as characters to be displayed on the client. The server presents these keystrokes as input received from a pseudoterminal to the OS hosting the telnet server. Telnet defines a network virtual terminal (NVT) format as that which permits interoperability with machines that use different characters for common operations such as terminating a line and interrupting a run-away process. The telnet client typically maps the signal-generating keys of the keyboard to invoke the corresponding control functions of the NVT. The control functions are encoded as escape sequences of 2 bytes, the IAC (255), followed by the 1-byte code of the control function. Telnet uses the URGENT DATA mechanism of TCP to send control functions so that the telnet server can respond appropriately. Telnet is an insecure protocol. User name, password, and all data are transmitted in the unencrypted form.

rlogin

The rlogin protocol (RFC 1282) is similar in functionality to telnet and also operates by opening a TCP connection on the rlogin server machine at port 513. It is widely used between UNIX hosts because it provides transport of more of the UNIX terminal environment semantics than does the telnet protocol and because on many UNIX hosts it can be configured not to require user entry of passwords when connections originate from trusted hosts. Rlogin is an insecure protocol. User name, password, and all data are transmitted in the unencrypted form.

Secure Shell

SSH provides the functionality of telnet and rlogin but with greater security. There are three primary advantages in using ssh. (1) Telnet and rlogin do not authenticate the remote machine; SSH does. The SSH client maintains a database of server names and their authentication keys that the server offers the first time an SSH session is opened to the server. Subsequent SSH sessions compare the authentication key offered by the server with that stored in the client database. (2) The password that the user types as part of the login ritual is sent as clear text

by telnet and rlogin; SSH sends it encrypted. (3) The data being sent and received by telnet and rlogin is also sent as clear text; SSH sends and receives it in encrypted form. The main disadvantages are the following. (1) Encryption and decryption consumes computing and elapsed time. (2) If the remote system has been legitimately reinstalled, and the installer was not careful to use the same authentication keys for the host, a false alarm may be raised. (3) SSH is susceptible to man-in-the-middle attack.

Dynamic Host Configuration Protocol

DHCP [RFC 2131, 1997] consists of a protocol for delivering host-specific configuration parameters from a DHCP server to a host and a mechanism for allocation of IP addresses to hosts. The IP configuration parameters that DHCP can supply include subnet mask, a list of default routers, TTL, and MTU. A typical host will use DHCP soon after booting into the OS to configure its network. DHCP assumes that the IP layer software will pass the packets delivered to the NIC of the host even though the IP address has not been assigned yet. DHCP has three mechanisms for IP address allocation. In automatic allocation, DHCP assigns a permanent IP address to a client. In dynamic allocation, DHCP leases an IP address to a client for a limited period (or until the client explicitly relinquishes the address). In manual allocation, the IP address is assigned manually but is conveyed to the client via DHCP. Dynamic allocation is the only one of the three mechanisms that allows automatic reuse of an address that is no longer needed by the client to which it was assigned.

Hypertext Transfer Protocol

HTTP (RFC 2616, 1999) is at the core of the World Wide Web. The Web browser on a user's machine and the Web server on a machine somewhere on the Internet communicate via HTTP using TCP usually at port 80. HTTPS (RFC 2660, 1999) is a secure version of HTTP. A Web browser displays a file of marked-up text with embedded commands following the syntactic requirements of the hypertext markup language (HTML). There are several ways of invoking these commands, the most common one being the mouse click. Most of the clickable links displayed by a Web browser are the so-called links that associate a URL (universal resource locators) with a visible piece of text or graphic. URLs have the following syntax:

```
scheme://[userName[:password@]]serverMachineName
[:port]/[path]/[resource][?parm1=parma&parm2=
parmb].
```

Figure 9: An ARP request/response packet.

A simple example of the above is <http://www.cs.wright.edu/~pmateti/InternetSecurity>, where the scheme was chosen to be http, the port defaults to 80, and the path given is ~pmateti/InternetSecurity. A click on such a link generates a request message from the browser process to the Web server process running on the remote machine www.cs.wright.edu, whose name is obtained from the link clicked. The browser then displays the page it receives from the server.

HTTP Message Format

The request and response are created according to the HTTP message format, which happens to be a sequence of human-readable lines of text. The first line identifies the message as a request or response. The subsequent lines are known as header lines until an empty line is reached. Following the empty line are lines that constitute the “entity body.” Each header line can be divided into two parts, a left- and right-hand side, separated by a colon. The left-hand side names various parameters. The right-hand side provides their values. The request line has three components: a method (one of GET, POST, or HEAD), a URL, and the version number of HTTP (either 1.0 or 1.1) that the client understands. GET is the most common one among the methods. The POST method is used when the client sends data obtained from a user-filled HTML form. The HEAD method is used in program development. The response line also contains three components: HTTP/version-number, a status code (such as the infamous 404), and a phrase (such as Not Found, OK, or Bad Request). The entity body in a response message is the data, such as the content of a Web page or an image, that the server sends.

Authentication and Cookies

Web servers requiring user authentication send a WWWAuthenticate: header. The Web client prompts the user for a username and password, and sends this information in each of the subsequent request messages to the server. HTTP is stateless in that the HTTP server does not act differently to request based on previous requests. Occasionally, a Web service wishes to maintain a minor

amount of historical record of previous requests. Cookies (RFC 2965) create a stateful session with HTTP requests and responses. The response from a server can contain a header line such as “Set-cookie: value.” The client then creates a cookie stored on the client’s storage. In subsequent requests sent to the same server, the client includes the header line “Cookie: value.”

SECURITY

The TCP/IP suite has many design weaknesses so far as security and privacy are concerned, all perhaps because of the era (1980s) when the development took place; network attacks were unknown. For example, the ICMP redirect message, intended to improve routing performance, has often been used maliciously. In this section, we summarize some of these issues from a practical perspective. Some of these are protocol design weaknesses per se, whereas the rest are defects in the software that implements the protocols. All major OS have made improvements in their implementations of the protocol stack that mitigate or disable many of the attacks described below. Of course, the attack tools also improve.

Security Exploits

This section is an overview of security attacks in the core protocols. Space and scope considerations prevent us from discussing such attacks as the recent (2004) TCP reset attack leading to severe concerns in the routing protocol BGP used in large routers, and the Shrew denial of service attack exploiting the congestion control algorithms. Numerous chapters of this volume are devoted to a discussion of different subtopics of security. See, for example, chapters 137 (Hacking Techniques in Wired Networks), 138 (Hacking Techniques in Wireless Networks), and 150 (Network Attacks).

Sniffing

Sniffing is eavesdropping on the network. A (packet) sniffer is a wire-tap program. Sniffing is the act by machine S of making copies of a network packet sent by machine A intended to be received by machine B. Such sniffing,

strictly speaking, is not a TCP/IP problem, but it is enabled by the near-universal choice of Ethernet, a broadcast media, as the physical and data link layers. Sniffing can be used for monitoring the health of a network as well as capturing the passwords used in telnet, rlogin, and FTP connections. Attackers sniff the data necessary in the exploits described below.

Depending on the equipment used in a LAN, a sniffer needs to be run either on the victim machine whose traffic is of interest or on some other host in the same subnet as the victim. In the normal mode, an NIC captures only those frames that match its own MAC address. In the so-called promiscuous mode, an NIC captures all frames that pass by it. The volume of such frames makes it a real challenge for an attacker to either immediately process all such frames fast or clandestinely store them for later processing.

An attacker at large on the Internet has other techniques that make it possible to install remotely a sniffer on the victim machine.

Illegal Packets

Packets containing “unexpected” values in some of the fields are illegal in the sense that a legitimate sender would not have constructed them. Software in the receiver ought to check for such illegal packets, but legacy software was not cautious. Attackers have written special programs that construct illegal packets and cause the receiving network hosts to crash or hang. The so-called Ping of Death attack of 1996 sent an ICMP echo request (ping) packet that was larger than the maximum permissible length (2¹⁶-1).

TCP segments have a number of flags that have, collectively, a strong influence on how the segment is processed. However, not all the flags can be independently set or reset. For example, SYN FIN, SYN FIN PSH, SYN FIN RST, and SYN FIN RST PSH are all illegal combinations. Past implementations have accounted only for valid combinations, ignoring the invalid combinations as “will not happen.”

An IP packet should not have source address and port equaling the destination address and port. The 1997 attack tool called *land* exploited this vulnerability.

IP Fragment Attacks

A well-behaving set of IP fragments is nonoverlapping. Malicious fragmentation involves fragments that have illegal fragment offsets. A fragment-offset value gives the index position of this fragment’s data in a reassembled packet. For example, the fragments may be so crafted that the receiving host in its attempts to reassemble calculates a negative length for the second fragment. This value is passed to a function [such as `memcpy()`] that copies from/to memory, which takes the a negative number to be an enormous unsigned (positive) number. A pair of carefully crafted but malformed IP packets thus causes a server to “panic” and crash. The 1997 attack tool called *teardrop* exploited this vulnerability.

The RFCs require no intermediate router to reassemble fragmented packets. Obviously the destination must reassemble. Many firewalls do not perform packet reassembly in the interest of efficiency. These only consider the fields of individual fragments. Attackers create artificially

fragmented packets to fool such firewalls. In a so-called tiny fragment attack, two fragments are created where the first one is so small that it does not even include the destination port number. The second fragment contains the remainder of the TCP header, including the port number. A variation of this is to construct the second fragment packet with an offset value less than the length of the data in the first fragment so that upon packet reassembly it overrides several bytes of the first fragment (e.g., if the first fragment was 24 bytes long, the second fragment may claim to have an offset of 20). Upon reassembly, the data in the second fragment overwrites the last 4 bytes of the data from the first fragment. If these were fragments of a TCP segment, the first fragment would contain the TCP destination port number, which is overwritten by the second fragment. Such techniques do not cause a crash or hang of a targeted system but can be used to bypass simple filtering done by some firewalls.

Fragmentation attacks are preventable. Unfortunately, in the IP layer implementations of nearly all OS, there are bugs and naïve assumptions in the reassembly code.

IP Address Spoofing

The IP layer of the typical OS simply trusts that the source address, as it appears in an IP packet is valid. It assumes that the packet it received indeed was sent by the host officially assigned that source address.

Replacing the true IP address of the sender (or, in rare cases, the destination) with a different address is known as IP spoofing. Because the IP layer of the OS normally adds these IP addresses to a data packet, a spoofer must circumvent the IP layer and talk directly to the raw network device. IP spoofing is used as a technique aiding an exploit on the target machine. Note that the attacker’s machine cannot simply be assigned the IP address of another host T using `ifconfig` or a similar configuration tool. Other hosts, as well as T, will discover (through ARP, for example) that there are two machines with the same IP address.

IP spoofing is an integral part of many attacks. For example, an attacker can silence a host A from sending further packets to B by sending a spoofed packet announcing a window size of zero to A as though it originated from B.

TCP Sequence Number Prediction

TCP exploits are typically based on IP spoofing and sequence number prediction. In establishing a TCP connection, both the server and the client generate an initial sequence number (ISN) from which they will start counting the packets transmitted. Host Y accepts the packets from X only when correct SEQ/ACK numbers are used.

The ISN is (should be) generated at random and should be hard to predict. However, some implementations of the TCP/IP protocol make it rather easy to predict this sequence number. The attacker either sniffs the current SEQ+ACK of the connection or can algorithmically predict them.

Closing a Connection by FIN

The attacker constructs a spoofed FIN packet. It will have the correct SEQ numbers so that it is accepted by the targeted host. This host would believe the (spoofed) sender had no data left. Any packets that may follow from the

legitimate sender would be ignored as bogus. The rest of the four-way handshake is also supplied by the attacker. A similar connection killing attack using RST is also well known.

Connection Hijacking

Suppose X and Y have a TCP connection. An attacker Z can send packets to Y spoofing the source address as X, at a time when X was silent. Y would accept these data and update ACK numbers. X may subsequently continue to send its segments using old SEQ numbers, as it is unaware of the intervention of Z. As a result, subsequent packets from X are discarded by Y. The attacker Z is now effectively impersonating X, using “correct” SEQ/ACK numbers from the perspective of Y. This results in Z hijacking the connection: host X is confused, whereas Y thinks nothing is wrong as Z sends “correctly synchronized” packets to Y. If the hijacked connection was running an interactive shell, Z can execute any arbitrary command that X could. Having accomplished his deed, a clever hijacker would bow out gracefully by monitoring the true X. He would cause the SEQ numbers of X to match the ACK numbers of Y by sending to the true X a segment that it generates of appropriate length, spoofing the sender as Y, using the ACK numbers that X would accept.

The SYN Flood

The SYN flood attack occurred in 1996. In the TCP protocol as designed, there is no limit set on the time to wait after receiving the SYN in the three-way handshake. An attacker initiates many connection requests with spoofed source addresses to the victim machine. The victim machine maintains data related to the connection being attempted in its memory. The SYN+ACK packets that the victim host sends are not replied to. Once the limit of such half-open connections is reached, the victim host will refuse further connection establishment attempts from any host until a partially opened connection in the queue is completed or times out. This effectively removes a host from the network for several seconds, making it useful at least as a stepping tool to other attacks, such as IP spoofing.

Storm Creation

There have been several attacks that generate enormous numbers of packets rendering (portions of) a network ineffective. The attackers send source spoofed packets to intermediary machines. These amplify the numbers of packets into a “storm.”

ACK storms are generated in the hijack technique described above. A host Y, when it receives packets from X after a hijack has ended, will find the packets of X to be out of order. TCP requires that Y must send an immediate reply with an ACK number that it expects. The same behavior is expected of X. So, X and Y send each other ACK messages that may never end.

The attack tool of 1997, called *smurf* sends ICMP ping messages. There are three machines in smurfing: the attacker, the intermediary router, and the victim. The attacker sends to an intermediary an ICMP echo request packet with the IP broadcast address of the intermediary’s network as the destination. The source address is spoofed

by the attacker to be that of the intended victim. The intermediary puts it out on that network. Each machine on that network will send an ICMP echo reply packet to the source address. The victim is subjected to network congestion that could potentially make it unusable.

Legitimate applications or OS services can generate a storm of packets. On many systems, the standard services known as *chargen* that listens typically at port 19 and *echo* that listens typically at port 7 are enabled. *Chargen* sends an unending stream of characters intended to be used as test data for terminals. The *echo* service just echoes what it receives. It is intended to be used for testing reachability, identifying routing problems, and so on. An attacker sends a UDP packet to the port 19 with the source address spoofed to a broadcast address, and the source port spoofed to 7. The *chargen* stream is sent to the broadcast address and hence reaching many machines on port 7. Each of these machine will echo back to the victim’s port 19. This ping-pong action generates a storm of packets.

A related attack called *fraggle* uses packets of UDP *echo* service in the same fashion as the ICMP echo packets.

ARP Poisoning

ARP poisoning is an attack technique that corrupts the ARP cache that the OS maintains with wrong Ethernet addresses for some IP addresses. An attacker accomplishes this by sending an ARP response packet that is deliberately constructed with a “wrong” MAC address. The ARP is a stateless protocol. Thus, a machine receiving an ARP response cannot determine if the response is because of a request it sent or not.

ARP poisoning enables the so-called man-in-the-middle attack that can defeat cryptographic communications such as SSH, SSL [see chapter 65: SSL/TLS (Secure Sockets Layer/Transport Layer Security)], and IPSec. An attacker on machine M inserts him- or herself between two hosts A and B by (1) poisoning A so that B’s IP address is associated with M’s MAC address, (2) poisoning B so that A’s address is associated with M’s MAC address, and (3) relaying the packets M receives A from/to B.

ARP packets are not routed, and this makes it very rewarding to the attacker if a router can be ARP poisoned.

Route Spoofing

An attacker can spoof routing information by three main mechanisms.

In the first mechanism, an attacker sends an ICMP redirect packet with the source address set to the regular router. The packet also contains the “new” router to use. An ICMP route redirect is normally sent by the default router to indicate that there is a shorter route to a specific destination. A host adds a host-route entry to its routing table after some checking all of which ineffective. Unlike ARP cache entries, host route entries do not expire. Name servers are obvious targets for this attack.

In a second way, RIP-based attacks work by broadcasting illegitimate routing information to passive RIP hosts and routers via UDP port 520. In both of the above cases, the redirection can be made to any host chosen by the attacker.

Third, source routing allows the sending host to choose a route that a packet must travel to get to its destination. Traffic coming back to that host will take the reverse route. The attacker designs a route so that the packets go through his site.

DNS Spoofing

The DNS answers that a host receives may have come from an attacker who sniffs a query and answers it with misleading data faster than the legitimate name server answers. The attacked host may in fact be a DNS server. Such DNS spoofing results in DNS cache poisoning, and all the clients of this server will receive false answers. During the reconnaissance stage of an attack, DNS zone transfers help map the targeted network. Some of these issues are specific to a software package called BIND that implements the DNS service. The DNS protocol is improved in the DNSSEC, which is expected to be deployed widely by adding authentication.

Covert Channels

Covert channels are the principle enablers in a distributed denial of service (DDoS) attack. A DDoS attacker covertly distributes (portions of) his attack tools over many machines spread across the Internet and later triggers these intermediary machines into beginning the attack and remotely coordinates the attack.

Covert channels are possible in nearly all the protocols of the TCP/IP suite. For example, ICMP echo request packets should have an 8-byte header and a 56-byte payload. ICMP echo requests should not be carrying any data. However, significantly larger ICMP packets can be generated carrying covert data in their payloads. Covert channels can be setup using the ID field of IP packets, IP checksums, TCP initial sequence numbers, or TCP timestamps.

ICMP Exploits

The ICMP protocol is a simple protocol with one message per packet. ICMP is also one of the easiest to exploit. In addition to the exploits described above, namely smurfing, route redirection, and covert channels, it has enabled several other exploits via reconnaissance and scanning.

Finger Printing a System

An attacker wants to identify the exact version of an OS running on a targeted victim. Nuances in the TCP/IP stacks implemented in the various OS, and versions of the same OS, make it possible to remotely probe the victim host and identify the OS. Such probing deliberately constructs illegal packets, and attempts to connect to each port and observes the responses it gets. The tool called *nmap* is comprehensive in this regard.

Buffer Overflows in Servers

A large number of TCP/IP server programs suffer from a class of programming errors known as buffer overflows. Many of these server programs run with the privileges of a super user. Among the many servers that suffer from such bugs are several implementations of FTP servers, the ubiquitous DNS server program called *bind*, the popular mail server called *sendmail*, and the Web server IIS, to name a few. An attacker supplies cleverly constructed

inputs to such programs causing them to transfer control to executable code he or she has supplied. A typical code he supplies produces a shell that he can interact with from a remote machine with all the privileges of the super user.

Security Enhancements

A number of enhancements for TCP/IP have been made that are not yet in common use. Several of them (e.g., VPN and IP6) involve heavy use of encryption and require more computing power. As computing power in end-user hosts increases, we expect to see these universally deployed.

Several chapters of this volume are devoted to security enhancements. Virtual private networks (VPN) enable secure communication through public networks using cryptographic channels. See chapters 184 (Virtual Private Networks Basics) and 185 (VPN Architecture).

Authentication

Authentication is the process of verifying the credentials of a user, a node, or a service. Authentication protocols enable such procedures. Authentication protocols send or receive messages in encrypted form. Without encryption, it is like having a paper-thin door to a house. Some well-known authentication protocols are Kerberos, RADIUS, PAP and CHAP.

PAP [Password Authentication Protocol, (RFC 1334)] is a two-way handshake protocol designed for use with PPP. It sends the user name and password in plain text, obviously vulnerable to sniffing. CHAP [Challenge Handshake Authentication Protocol (RFC 1944)] is a three-way handshake protocol. The CHAP server sends the user client a challenge, which is a randomly generated sequence of bytes unique to this authentication session. The client encrypts the challenge using a previously issued secret key that is shared by both the client and CHAP server. The result, called a response, is then returned to the CHAP server. The CHAP server performs the same operation on the challenge it sent with the shared secret key and compares its results, the expected response, with the response received from the client. If they are the same, the client is assumed authentic.

IP6 and IPsec

The IP version 4 that currently dominates the Internet sends all its payload and headers in clear text. A determined attacker can install remote sniffers along every path that a communication from host B to host C and assemble full messages being sent at the application level. The IPsec protocol adds authentication and encryption. The IP version 6 includes IPsec and other enhancements to IP4. See chapters 63 (IPsec: Authentication Header and Encapsulating Security Payload) and 64 (IPsec: Internet Key Exchange).

TCP/IP Traffic Scrubbing

Scrubbing refers to forcing the TCP/IP traffic to obey all the rules of the RFCs. Reserved fields can be set to a random value; illegal combinations of flags are checked, and so on. Scrubbing is expected to be done not only at the originating hosts but also on the routers and especially in firewalls. Scrubbing adds to the computational burden of

the hosts. Because of hidden assumptions made by programs beyond the specifications of the RFCs, scrubbing may disrupt interoperability.

CONCLUSION

The Internet and the World Wide Web are based on a suite of protocols and software collectively known as TCP/IP. It includes not only the transmission control protocol and Internet protocol but also other protocols such as UDP, ARP, DNS, and ICMP, and applications such as telnet, FTP, Secure Shell, and Web browsers and servers. We surveyed these topics starting from the seven-layer OSI model to recent improvements in the implementations of the protocol stack and security.

GLOSSARY

Big Endian A 32-bit integer is stored in four consecutively addressed bytes a , $a + 1$, $a + 2$, and $a + 3$. In a big-endian system, the most significant byte of the integer is stored at a . In a little-endian system, the least significant byte is stored at a .

Byte A byte is a sequence of 8 bits. Viewed as an unsigned number, it is in the range of 0 to 255.

Checksum A checksum is a function of the sequence of bytes in a packet. It is used to detect errors that may have altered some of the numbers in the sequence. The IP checksum field is computed as the 16-bit one's complement of the one's complement sum of all 16-bit words in the header. For purposes of computing the checksum, the value of the checksum field is zero.

Client The process that establishes connections for the purpose of sending requests.

Connections In the connectionless communication, one process sends data to another without prior negotiation. The recipient does not acknowledge the receipt of the message, and the sender has no guarantee that the message is indeed delivered. In the connection oriented communication, there are three well-defined phases: connection establishment, data transfer, and connection release.

Datagram A sequence of bytes that constitutes the unit of transmission in the network layer (such as IP).

Frame The unit of transmission at the data link layer, which may include a header and/or a trailer, along with some number of units of data.

Host A device capable of sending and receiving data over a network. Often, it is a computer system with an NIC, but it can be a much simpler device.

Network A collection of links in which the hosts are connected either directly or indirectly.

Network Applications Programs that operate over a network.

Network Operating Systems These systems have network software built in and are aware of byte order issues.

Node A synonym for host.

Octet An 8-bit quantity on older computer architectures where the smallest addressable unit of memory was a word and not a byte.

Packet A generic term used to designate any unit of data passed between communicating entities and is usually mapped to a frame.

Process The dynamic entity that can be summarized as a "program during its execution on a computer system."

Program A file of binary data in a certain rigid format that is specific to each platform, capable of being both a client and a server. Our use of these terms refers only to the role being performed by the program for a particular connection rather than to the program's capabilities in general.

Protocol A formal and preagreed set of rules that govern the communications between two or more entities. The protocol determines the meaning of specific values occurring in specific positions in the stream, the type of error checking to be used, the data compression method, how the sender will indicate that it has finished sending a message, and how the receiver will indicate that it has received a message.

RFC Request for Comments documents are Internet standards, proposed designs, and solutions published by researchers from universities and corporations soliciting feedback and archived at <http://www.rfc-editor.org/>.

Server A process that accepts connections to service requests by sending back responses. It is also called a daemon.

Spoofing In IP spoofing, either the source or the destination address is fake. In DNS spoofing, a query receives fake response.

Tunneling The process of sending packets of a certain protocol embedded in the packets of another protocol.

FURTHER READING

TCP/IP details are part of many college courses on computer networks. There are several textbooks. Of these, the three authoritative volumes of Comer's Internetworking with TCP/IP are classic technical references in the field aimed at the computer professional and the degree student. Volume I surveys TCP/IP and covers details of ARP, RARP, IP, TCP, UDP, RIP,

DHCP, OSPF, and others. There are errata at <http://www.cs.purdue.edu/homes/dec/tcpip1.errata.html> *The Internet Book: Everything You Need to Know about Computer Networking and How the Internet Works* is a gentler introduction. The books listed above by Tanenbaum and Kurose and Ross are also popular textbooks. The book by Stevens discusses from a programming point of view.

Routing protocols are discussed briefly in the above books. The books by Halabi and Kurose and Ross cover this topic very extensively.

The HTTP protocol and related issues are thoroughly discussed in the books of Krishnamurthy and Rexford and Gourley and Totty.

The book by Denning and Denning is a high-level discussion of how the vulnerabilities in computer networks are affecting society. Mateti has an extensive Web site (<http://www.cs.wright.edu/~pmateti/InternetSecurity>) that has lab experiments and readings online. The book by Garfinkel and Spafford explores security from a practical UNIX systems view.

All the RFCs are archived at <http://www.rfc-editor.org/>. The Usenet newsgroup comp.protocols.tcp-ip is an active group and maintains a frequently asked questions (FAQ) document that is worth reading. The Technical Committee on Computer Communications of the IEEE Web site (<http://www.comsoc.org/>) maintains an extensive collection of conference listings. The *IEEE/ACM Transactions on Networking* is a peer-reviewed archival journal that publishes research articles.

The Web site www.cert.org issues timely and authoritative alerts regarding computer exploits and has a comprehensive collection of guides on security. The Web site <http://www.phrack.org> publishes detailed descriptions, often with ready-to-compile source code of vulnerabilities and tutorials.

INTRODUCTION

As with any advanced communications protocol, voice-over-Internet protocol (VoIP) brings with it many benefits along with offsetting negatives, including potential security risks and management issues. Whether provided over wire or wireless transmission, VoIP security poses unique risks and complexity. Its successful implementation requires compliance and compatibility with conventional telecommunications standards—whose basic designs date back to the early twentieth century—while it must “ride on” data transmission technologies of the Internet protocol (IP), whose basic designs were developed initially for time insensitive data during the very late 20th century. Complicating this is the increased wireless transmission with IP services, thus introducing some additional challenges. This chapter begins by explaining communications theory and conventional telephony, which predate the popularized Internet. They serve as a foundation for the VoIP, because almost all voice communications systems rely on those underlying theories. The chapter concludes with specifics of VoIP design and deployment, including addressing security concerns.

COMMUNICATIONS THEORY: BITS OF TRANSMITTED INFORMATION

Basic communications theory concepts form the building block of all communications applications and their understanding. VoIP is no exception. Communication is simply the transmission of information from one place (or device or person) to another, over a transmission network. Voice communications refers to transmitting the information contained in a voice signal. The distance traveled by a transmitted signal can be as short as from one chip

to another chip on a circuit board to across the street to around the world or even to the most distant galaxies in outer space. The basic principles are the same, whether the transmission medium is wires or wireless.

Bits: The Most Basic Form of Information

In digital parlance, a bit is the smallest measure of information (Newton, 1998). It is the amount of information required to distinguish between two equally likely possibilities or choices. A bit, shortened from the term *binary digit*, can be used as a building block for all information or messages and/or as a measure of information. A bit is typically given one of two arbitrary logical values (e.g., 1 or 0). By stringing together bits, complex messages can be formed representing familiar message forms, such as letters, sentences, text documents, voice signals, pictures, and movies.

The key to the successful binary transmission of any type of information is that the transmitter and receiver of the binary transmission must understand the same standardized vocabulary used to digitally encode the information. Without some context (i.e., knowledge of how the original information was encoded), all binary strings look the same—like strings of 1s and 0s. What differentiates one kind of transmitted binary string from another is a common understanding between the encoder (at the transmitter) and decoder (at the receiver) of what that bit string represents (e.g., text vs. voice) and how it was encoded (e.g., did it use ASCII, if it was text? Did it use a particular voice coder/decoder, if it is voice?)

The encoding vocabulary used for encoding text is primarily ASCII (Truxal, 1990). ASCII has 128 standardized combinations of seven bits to represent 128 characters, including upper- and lowercase letters, numbers,

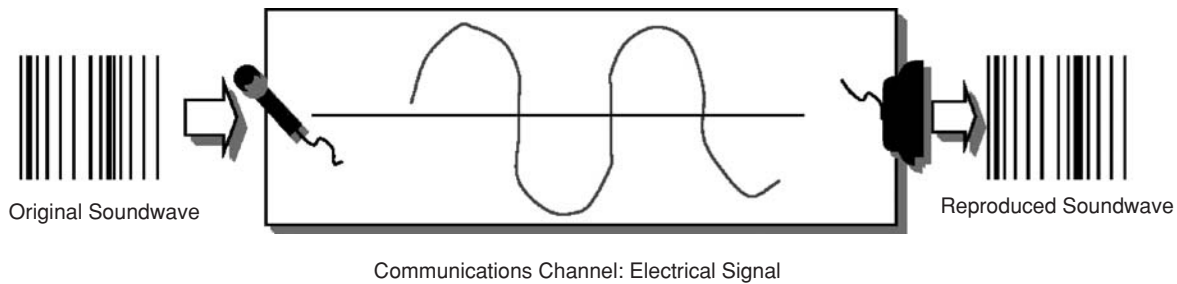

Figure 1: Transmission of a sound wave and its reconstruction.

and symbols. With such a universally understood binary text encoding scheme, we can transmit letters strung together to form large text documents that can be transmitted over digital transmission facilities, received, and ultimately displayed in distant locations.

Similarly, there are standardized voice communication encoding schemes that allow voice communication signals to be encoded as strings of 1s and 0s and then transmitted over data networks, received, and ultimately decoded and heard in distant locations. VoIP capitalizes on this ability, transmitting those strings of bits over a data network using the Internet protocol (IP).

Transmission of Voice Signals

Almost all voice communications signals begin as analog sound signals. An analog signal is one that is typically continuous in shape (i.e., no instantaneous changes in value) and analogous in shape to the original signal or physical phenomenon that created it (Newton, 1998). The physical signals that our bodies generate (e.g., sound and visual) and receive (i.e., sense) are analog (Truxal, 1990). This is very important in understanding the design of telephony systems, because almost all information transmitted in telephony is ultimately either originated and/or received by a human being.

When we speak or play an instrument, combinations of one or more waves of alternating compression and expansion of air are generated at the sound's source (e.g., the vocal chords in our throats or the reeds of instruments). Because sound energy in air does not travel well over long distances, long-distance communications requires that these sound waves be converted to alternate forms of energy by a transducer and then that signal energy be conveyed over a compatible transmission medium, such as an electronic transmission channel, which can maintain the signal's information integrity for transmission over long distances. For voice communications, the microphone of a telephone device is typically used to transform analog sound wave energy into analog electrical wave energy for transmission over a caller's local telephone wires.

To transform the electrical signal back to a sound wave at the receiving end of the transmission link so that the human ear can detect it, the analog electrical signal is applied to a "reverse microphone" transducer (such as an earpiece of a telephone). The "reverse microphone," or speaker, outputs physical patterns of compressed air corresponding to the original sound wave. The entire transformation from analog sound wave to analog electrical

signal and back to analog sound wave is illustrated in Figure 1.

The Characteristics of an Analog Voice Signal

Communications networks and their elements are designed to cost-effectively accommodate the signals they are intended to carry, with the least detectable degradation (e.g., distortion and delay). Telephony networks were optimized to carry analog voice signals over long distances using the most cost-effective technology available. However, the original designs were done from the late 1800s through the early 1900s and were influenced by the technology that was available at the time. Those voice-centric designs continue to influence telephony network design today so as to allow interoperation with established telephony networks, and the need for those established networks to be backwards compatible with older equipment (which sometimes dates back to the early 1900s).

A human voice signal is made up of alternating signal components of various frequencies, with most of its signal power within the range from 100 to 3400 alternating cycles per second. Although this range may vary somewhat from person to person, analog telephony networks were designed based on this assumption. Virtually all of the components of the telephone networks have been built to limit the frequencies transmitted to those in this voiceband. Any signal power carried on frequencies outside this voiceband is filtered out by the network equipment and, in turn, not transmitted.

This voiceband range is broad enough to allow a telephone listener both to recognize the person who is speaking and to understand what he or she is saying. High-fidelity devices, such as CDs and FM radio, transmit signal power over a wider range of frequencies (up to 10,000 cycles per second or more). With conventional telephony, any attempt to transmit sound from such devices would be filtered to include only the signal power in the voiceband frequency band. However, with the flexibility of VoIP, it is at least theoretically possible to cost-effectively deploy a customized high-fidelity telephony service that could coexist with voiceband VoIP services because the underlying IP network will transmit for a particular IP connection as much data (and therefore as much voice signal information) as the transmission bandwidth will allow (Skype).

Digitizing an Analog Voice Signal

Most long-distance transmission systems in use today (including those using VoIP) transmit voice signals digitally.

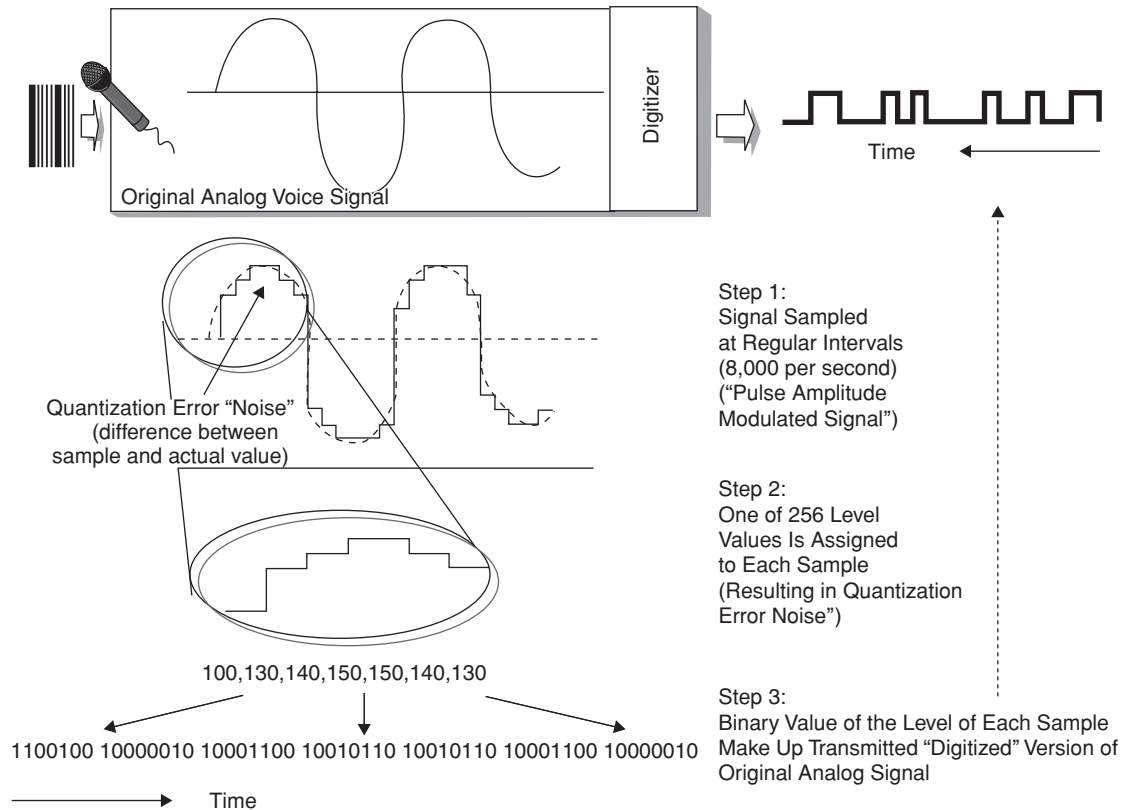

Figure 2: Digitization of a voice signal.

As mentioned, to transmit an analog signal digitally, its analog version must be transformed from its electrical analog form to a digital form, thus changing its representation from a varying electrical voltage to an equivalent string of discrete 0s and 1s. This transformation is done by a digitizer, sometimes referred to as an *analog-to-digital converter*, *A/D converter*, or *codec* (coder–decoder) (Newton, 1998; Truxal, 1990). A digitizer takes samples of the height (i.e., amplitude) of the incoming analog signal at regular time intervals (e.g., 8000 times per second). For each of these regularly timed signal measurements, the digitizer outputs a fixed-length digital number (expressed in terms of logical 0s and 1s) that corresponds to the size of the signal height measured for each sample (see, for example, Figure 2).

Depending on the digitizer, the number of bits that are used to represent each level of signal amplitude can vary. If eight bits are used to represent the measurements of each sample's height, then 256 height levels can be represented. The use of eight bits to represent each sample of a voice signal is fairly typical. The rounding error or difference between the height of each sample and the true height of the original signal at the sampled point is called *quantization error*.

If more than eight bits were used to represent each sample's amplitude, a larger number of discrete levels could be used to digitize a signal and, in turn, reduce the amount of quantization (or rounding error) noise. However, the additional bits for each sample would require additional transmission capacity with little offsetting benefit. Experience has shown that the human ear cannot

easily detect the noise created by quantization error with eight-bit sample encoding.

Generally, the minimum rate at which a codec must sample a voice signal is the Nyquist rate. Nyquist determined that for a sampled representation of a signal to accurately capture the entire range of frequencies in the original signal, the samples must be taken at a rate that is more than two times the highest frequency component of the original signal. Thus, to transmit a voice signal digitally and achieve the same performance as conventional analog telephony networks, the transmitted voiceband signal, with its highest frequency assumed to be 3400 cycles per second, must be sampled at more than 6800 samples per second. It is common to oversample a voice signal using a sample rate of 8000 samples per second.

With 8-bit encoding per sample, the digital equivalent of a voiceband signal that is sampled 8000 times per second requires 64,000 bits per second to be transmitted (8000 samples per second times 8 bits per sample). This is known as the G.711 standard. Codecs often incorporate techniques for reducing the transmitted bit rate from the base amount of 64,000 bits per second. Some of those techniques include (1) using nonlinear (logarithmic) sampling levels, (2) transmitting only changes in signal levels, and, (3) removing redundant information while maintaining signal quality and minimizing processing delay, (Castelli, 2002). Companding uses nonlinear sampling levels. Companding has the effect of decreasing the number of sample levels required by using a disproportionate greater number of sample levels in the most relevant amplitude range for the signal. Companding also has the

Table 1 Summary of Compression Algorithm Performance

Compression	Bandwidth (kb/s)	MOS score	Delay (ms)
PCM (G.711)	64	4.4	0.75
ADPCM (G.726)	32	4.2	1
G.728	16	4.2	3.5
G.729	8	4.2	10
G.723.1	6.3	3.9	30
G.7231.1	5.3	3.5	30

Note: Packet headers add an additional demand of about 2 to 20 kbps depending on codec, packet size, transmission protocol, and compression. Thus, for example, a 64-kbps sample signal may require 84 kbps to transmit because of packet header overhead. ALCATEL (2003). Source: Cisco, Understanding Codecs: Complexity, Hardware, Support, MOS, and Negotiation (2002) and Sanford (1999).

secondary effect of reducing the quantization noise in the amplitude range with the highest concentration of sample levels, compared to that in noncompanded digitized signals, for a given number of bits per sample. Differential pulse code modulation (DPCM) is another method used to reduce the number of bits transmitted without compromising quality. DPCM transmits only the changes in sample levels rather than absolute levels. Another variation on DPCM is adaptive pulse code modulation, which can halve the bit transmission requirements. The trade-off of using these algorithms is increased processing, along with commensurate increased delay associated with that processing time. Current compression algorithms can reduce the 64,000-bit-per-second transmission requirement for a voice signal to as low as 8000 bits per second without incurring a substantial increase in delay.

Table 1 summarizes some of the most popular voice compression algorithms used in Internet telephony. The frame of reference is the G.711 standard. Note that its MOS (mean opinion score, an objective measurement of the perceived quality of the received voice, which ranges from 0 to 5) is 4.4. Processing delay is negligible. All other compression systems are more efficient (less than 64 kb/s of bandwidth consumption per voice conversation) but exhibit additional processing delays, which may cause additional problems in long, echo-prone circuits. For wide area networks (WAN), the G.729 standard is one of the most popular, because it represents a reasonable compromise between efficiency and delay performance, at a modest 10 ms. The G.711 is most popular around the campus, where bandwidth cost is generally not an issue. An alternate codec to G.711 is G.722, which provides 7-kHz quality (i.e., twice baseband voice) in the same 64-kbps transmission requirement (Audin, 2004).

THE TELEPHONY NETWORK

The Communications Network Topology

From a user's perspective, a telephone network is a big cloud that connects the originating points for transmitted information with terminating points for transmitting information. A network is actually made up of nodes interconnecting transmission links to form transmission paths for the transmitted information to move along. The transmission links in a typical network may use different

transmission modalities (e.g., wire, wireless, and fiber). The nodes may contain electronic devices, such as switches, which establish a temporary or permanent path to be taken by the communicated information so as to enable the information to move from one link onto another link. Those nodes may also contain conversion devices that change the modality of the transmitted signal to allow it to pass between links using different modalities (e.g., connecting a wired link to a wireless link, an analog link to a digital link, or a fiber link to a copper wire link). See Figure 3.

Transmission Links

Transmission links, whether digital or analog, are typically carried over wire, fiber, or wireless medium (i.e., the atmosphere). Each physical medium has its own physical characteristics that limit the ability of the transmitted signal (whether analog or digitally encoded) to accurately and timely propagate.

Wire transmission medium includes wire pairs, coaxial cable, and even single wires (where the "return path" is the physical common ground). With wire transmission, a transducer varies the electrical pressure, or voltage, applied at the transmitting end of the transmission link in proportion to the signal to be transmitted. This varying voltage, in effect, pushes electrons on one wire and pulls electrons on the other wire. The electrons flow through a closed wire loop path to the node at the far end of the transmission link. At the far end of the transmission link, a transducer senses this electron movement, and pressures driving them, to recreate the transmitted signal or something corresponding to it.

Fiber links involve the transmission of communications using a light signal through a very high-quality, thin wirelike glass fiber. The signal is transmitted using a light transducer source [typically, a laser or light-emitting diode (LED)], located at the information source end of the transmission medium, that is turned on and then off or in varying intensities. Those variations are some function of the variations in the transmitted information signal. A "reverse" transducer at the far end node connected to the fiber link senses these variations in light intensity and ultimately deciphers the transmitted information.

Finally, wireless transmission links generate electromagnetic waves (such as radio and light waves) at the transmitting end that are propagated through the open

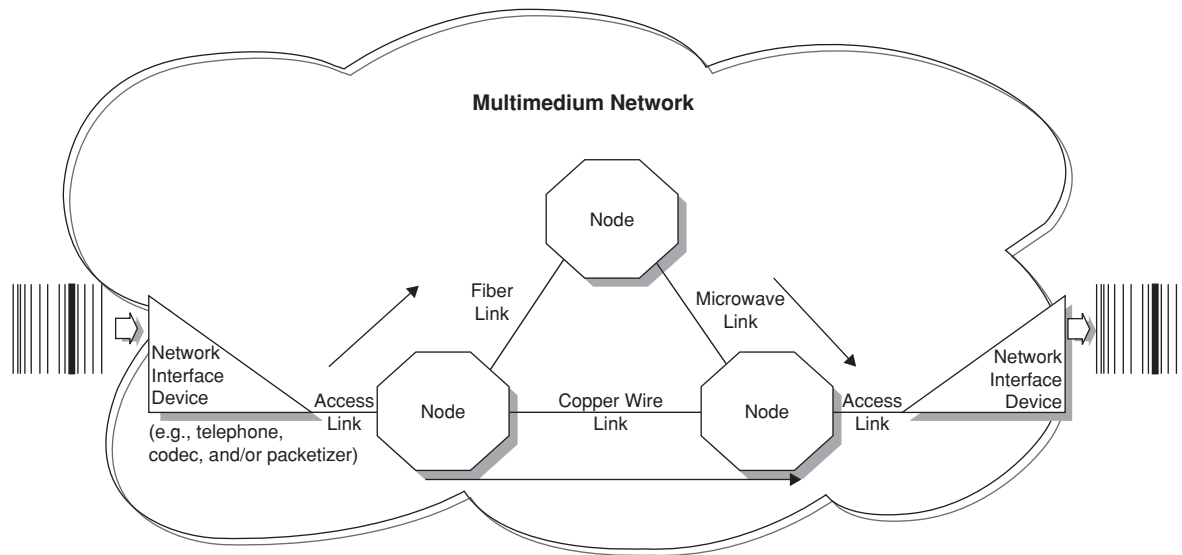

Figure 3: Multimedimum network.

atmosphere. Some physical characteristic of the transmitted electromagnetic signal is varied as a function of the information transmitted. A receiver-type transducer at the receiving end of the open-atmosphere medium detects these variations in radio or light waves and, in turn, can recreate the original signal and the information transmitted.

Transmission System Imperfections: Noise, Loss, and Delay

Each transmission link in a network, and each node connecting those links, introduces some amount of noise, loss, and delay into the transmitted signal. These physical transmission imperfections affect both digitally and nondigitally encoded signals that are transmitted over them. However, depending on whether the signals transmitted are in the analog or digital form, the transmission channel's physical limitations manifest themselves somewhat differently—as described later in this chapter.

Transmission noise that inevitably mixes into the transmitted signal during transmission causes the signal received at the far end of a transmission link to differ from the originally transmitted source signal. Transmission noise is typically uncorrelated with the original transmission signal. Where substantial noise is present, detection and, therefore, reconstruction of the original transmitted signal at the receiving end is more difficult or impossible. Transmission noise, when corrupting a digitally encoded signal, can result in a receiver falsely identifying some of the 1s as 0s and some 0s as 1s.

The ability of a receiver to accurately detect the characteristics of the original transmitted signal, and therefore to accurately reproduce it, is directly a function of the signal-to-noise ratio (or S/N ratio) of the received signal. As the noise added by the transmission link becomes very large in comparison to the power of the transmitted signal, more errors in detection will occur. Boosting the power of the original signal at the transmitting end of the link can increase the signal-to-noise ratio, but this is not always possible because of concerns about such

problems as crosstalk between adjacent channels and interference with other devices and systems. Special encoding schemes can be used to allow the receiver to check and/or correct for errors caused by random noise. The particular schemes for doing this error detection and correction are not important here, except to note that they all require the “overhead” of transmitting additional redundant information (and therefore additional bits) along with the digitally encoded version of the original signal.

There is one exception to the idea that noise is a bad thing. Specifically, a limited amount of noise may sometimes be intentionally *added* to a digitally transmitted voice signal during quiet periods, when neither party is speaking; otherwise the lack of noise could lead callers to perceive that the line has been disconnected.

Transmission loss refers to the loss of signal power as the original signal traverses a transmission link. Amplifying all or selected frequencies of the received signal at the receiving end of the link cannot always compensate for signal loss. For example, in the presence of noise, if there is significant overlap in the spectral power of the noise signal and the original signal, receiver amplification will tend to amplify the unwanted noise along with the original transmitted signal. The result would be little improvement in the receiver's ability to discriminate between the now amplified original transmission signal and amplified unwanted noise and thus accurately detect the signal. The frequency range over which the loss is relatively flat is known as the bandwidth.

Transmission delay (or latency) is a measure of how much later a signal is received compared to when it was transmitted. Delay can create two types of problems. The end-to-end transmitted signal delays can vary over the range of the signal spectrum. Spectral signal components of different frequencies can travel at different speeds, thus reaching the receivers at different times. For transmitted digital pulses, these differences in travel times can result in very distorted-looking versions of the pulses arriving at the receiving end as compared to the original signal. In turn, such delay distortion can make accurate detection

of the binary signal very difficult. If the delay distortion characteristics of a channel can be determined in advance, they can be somewhat compensated for at the signal detector. The second type of delay is a delay in the time it takes for the information transmitted (assuming it is accurately reproduced) to arrive at its ultimate destination. For voice conversations, this delay, if long enough, can make voice communications almost impossible. When the round trip delay in a transmitted voice signal reaches on the order of a half second, the receiving and transmitting parties begin to notice this delay in two ways. First, the parties at both ends begin to speak before the other finishes speaking (because each party doesn't accurately know when the other has finished speaking). Second, and more importantly, without special echo cancellation circuitry in place, the parties at both ends begin to hear their own voices echoed back to their ears. This occurs because the electronics of a typical telephone network cause the far end of almost every call connection to echo back a weakened version of the transmitted signal to the originating end. Without echo cancellation circuitry, this echo is always present, but it is not noticeable until the round-trip delay becomes long enough.

All of these deficiencies of a "raw" transmission channel can have the effect of reducing the channel capacity, or throughput, of a transmission link. Channel capacity refers to the theoretical upper limit on how much information, in terms of bits per second, can be transmitted through a channel (Wozencraft & Jacobs, 1965).

Circuit-Switched Connections of a Call in a Conventional Telephony Network

VoIP networks must interoperate with conventional circuit-switched networks, in particular the ubiquitous public switched telephone network or PSTN. A VoIP network that cannot interoperate with, and therefore exchange calls with, the PSTN would be of little value to

Figure 4: Circuit-switched connection between two links.

most telephone users. A network's value increases as it can be used to reach more users. Like other networks, the PSTN uses a hub-and-spoke architecture of transmission links and switches (Bell Laboratories, 1977/1983). Each user's telephone is typically connected by an individual circuit (usually referred to as a local loop) to a central office switching hub. In a small town, there may be only one central office, whereas in a large major metropolitan area, there could be several dozen central offices. In each central office hub, there is usually at least one switch. The switches used in traditional telephony are called circuit switches. A circuit switch will route a call over a dedicated path from one transmission link to another for the duration of the call (see, Figure 4). As described more fully below, this contrasts with the packet switching used in the Internet, which does not maintain a dedicated path connecting network links but instead passes information along shared "logical" paths on a packet-by-packet demand basis.

Originating the Call

As Figure 5 shows, when a caller picks up a telephone to make a call, the local switch in the caller's local central office (Node A) provides a dial tone that the caller

Figure 5: Conventional circuit-switched telephony network.

hears through the telephone. That dial tone indicates to the caller that the local telephone switch has seized his or her local telephone line and is ready to receive the digits of the telephone number that he or she wishes to dial. The processes of seizing the telephone line and returning dial tone are types of supervisory signaling.

The caller then enters, or dials, the telephone number of the called telephone. If the calling telephone is enabled with Touch-Tone signaling, the calling telephone signals to the local switch the digits dialed by using different combination of two Touch-Tones for each digit dialed. The routing information transmitted is called address signaling. The caller's local switch Node A detects these tone combinations and, in turn, determines the telephone number the caller is trying to call.

Circuit Switching to the Call's Destination

Each circuit switch has a routing look-up table for determining how to handle a call based on some or all of the calling and called numbers. If the local switch does not have adequate information in its routing tables to make a routing decision, most modern switches will hold the call and launch a packet data message to an external database (called a service management system or SMS). That message is routed from the switch to the SMS over a parallel data network called a Signaling System 7 (or SS7) packet network. The SMS returns routing instructions, via the SS7 packet network, to the switch that originated the routing query. The SS7 signaling standard came out of the conventional telephony industry.

If the local switch determines that the call needs to be connected to a local loop attached directly to that local switch, the switch will ring the local loop of the called telephone. At the same time, the switch returns a ringing sound signal to the calling party. Conversely, if the local switch determines that the called party's telephone is busy, the local switch returns a slow busy signal to the calling party.

As soon as the called party picks up its phone, the local switch creates a circuit-switched dedicated audio communications path between the calling party's local loop and the called party's local loop, thus completing a dedicated audio transmission path between the calling telephone and the called telephone. For the call's duration, that dedicated audio path is available for the transmission of voice signals, in both directions, between the calling and called party's telephones. If one or more of the links used to construct that path are digital, a codec in the connecting switch or other connecting device will make the necessary analog-to-digital conversion so that the voice signal may seamlessly traverse the boundaries between the analog and digital links.

If the called telephone's local loop is not directly connected to the calling telephone's local switch, the local switch must establish a connection to the called telephone through another switch or switches. For most modern PSTN switches, this requires that the originating switch launch an SS7 message, over the SS7 network, to reserve a path through other switches in the network for completing the desired communications path to the call's destination. If the far-end switch where the called party is located determines that the called party's line is busy, no circuit

connections will be made, the path reservation for the connecting links is dropped, and the originating switch will return a slow busy signal to the calling party. However, if the reason the call cannot be completed is network congestion, the originating switch will return a fast busy to the calling party.

If the called party's line is not busy and a complete path to the called party's line can be established, the called party's local switch rings the called party's telephone. While the called party's phone is ringing, the calling party's local switch is returning an audible ringing signal to the calling party. When and if the called party answers, the switches instantly circuit-switch together the links along the reserved path to complete a dedicated path between the calling and called telephones.

Finally, it should be noted that some switches communicate interoffice signaling information using non-SS7 interoffice signaling arrangements, such as in-band signaling. Regardless of the supervisory and address signaling arrangement used, the net result of establishing a communications path between the calling and called telephone will be the same.

VOICE-OVER-INTERNET PROTOCOL

VoIP literally refers to the transmission of a digitized voice signal using digital packets, routed using the Internet protocol or IP. The driving forces for using VoIP are beliefs in its cost savings, flexibility, and the growing desire to combine voice and data transmission on one network. See, for example, Morris (1998), Cisco, VoIP Primer (2003), and Matthew (2002).

How Voice-over-Internet Protocol Transmission Works

Because a VoIP call is transmitted digitally, it begins with a digitization process similar to that used in conventional telephony. First, the voice signal is sampled at a rate greater than the Nyquist sampling rate, and those samples are digitized. Whereas conventional circuit-switched telephony transmits the digitized samples in a constant stream of synchronized (i.e., equally spaced in time) digital samples, VoIP transmits the digitized voice communications samples in asynchronous (i.e., unequally spaced in time), sequentially numbered packets of data. Each packet (which may contain many voice samples) contains its own IP formatted address information, which allows it to be routed over an IP network. Unlike conventional telephony, where each sample follows the path of the sample before it, each of the IP packets containing several samples of voice data may take an independent path (which path is shared with other data packets) to its destination. With each packet potentially taking a different route, particularly under network congestion situations, the packets may arrive at their destination out of order (or sometimes not at all). At the far end, the IP and other routing information is stripped from the packet, the voice samples are temporarily collected in a buffer and reordered as required, and then, if all goes well, the original voice signal is reconstructed, albeit, slightly delayed. For VoIP technology to have the functionality and flexibility of conventional

Figure 6: VoIP network.

telecommunications, some form of call control, in the form of supervisory and address signaling, is required. Figure 6 shows the basic VoIP transmission scheme.

Voice-over-Internet Protocol Signaling

VoIP signaling refers to signaling that can be used over an IP network to establish a VoIP call. It provides the needed functionality of supervisory and address signaling. VoIP call signaling comes in two predominant competing schemes: H.323 and Session Initiation Protocol (SIP). Each satisfies the generic needs of telephonic calling; specifically, each provides for the following:

- The calling phone to address and signal to the called telephone

- The called telephone to be able to signal its availability for receiving calls
- Establishing a transmission path between the calling and called telephone
- The called or calling telephone to be able to signal to the other phone that it has hung up and the tearing down of the transmission path once the call is over.

Figure 7 shows a generic signaling progression for establishing a VoIP call that might occur using H.323-type centralized call control arrangement. First, the calling telephone dials the called telephone’s number (1). The calling phone forwards the dialed telephone number (address signaling) to a VoIP call controller—which is a special purpose server. That call controller does a lookup

Figure 7: VoIP H.323-type signaling system using central call control.

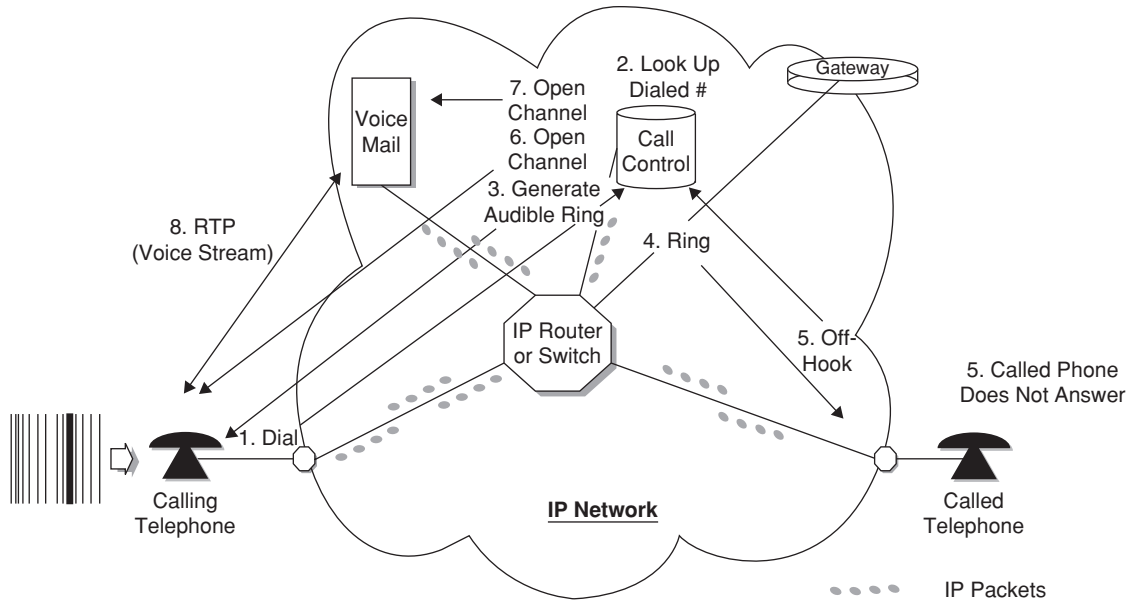

Figure 8: Called telephone unavailable with reroute to voice mail with H.323-type signaling.

(2) in a database for determining the IP address to reach the called telephone. If the called telephone is on the IP network, a call setup signal is routed to the called telephone to ring the called telephone (4). While the called telephone is ringing, a ringing signal is sent back to the calling telephone (3), which, in turn, generates a ringing sound in the caller's earpiece. When and if the called party answers the telephone, a series of signals to set up the channel path are returned to the calling and called telephones (5, 6, and 7).

A UDP/IP communications path is then set up between the calling and called telephone (8). The digitized voice is transported using the user datagram protocol (UDP) in the transport layer, with two protocols, RTP (real-time protocol) and RTCP (real-time control protocol), rather than TCP—which is often used by nonvoice data. UDP is connectionless and can transport data packets without acknowledging their receipt. UDP is nonstop with less address information overhead. The trade-off of using a UDP path is lower reliability than TCP. UDP packets may be dropped or arrive out of order, but if they do arrive they are more likely to arrive with less delay. This is a good trade-off for voice communications, which is reasonably tolerant to dropped packets (greater than 2 to 10%, with the lower tolerance where voice compression is used), but relatively intolerant to delay.

RTP over UDP provides packet sequence numbering, so out-of-order and/or missing packets are detectable at the far end. RTCP provides a separate signaling channel between the end devices (e.g., telephones) to allow exchange of information about packet loss, packet jitter, and packet delays, as well as additional information, such as the source's name, e-mail, phone, and identification [Real-Time Transport Protocol (RTP), 2001, August; Streaming Video Over the Internet, 2002].

Additional requirements for a commercial VoIP system include being able to produce information for billing and/or accounting for calls. Similarly, today's users

demand that it provide other features, such as Caller ID and voicemail. These capabilities may reside in the call controller, IP telephones, and/or other devices in the IP network. Figure 8 shows how voicemail can be provided with H.323.

H.323 vs. SIP

In addition to H.323, SIP is the major competing standard for VoIP signaling. They have both evolved to offer very similar feature capabilities.

H.323 takes a more telecommunications-oriented approach than SIP. SIP takes an Internet-oriented approach. H.323 is the older of the two (Doron, 2001; Paketizer, 2003). It was developed under the International Telecommunications Union (ITU), a telecommunications standards group, and has gone through various revisions. (ITU-T, Recommendation H.323, 2000). One of the latest versions of H.323 standard (H.323 v3) is very robust in that it covers many possible implementations. However, H.323 is considered more difficult to implement than SIP due to its use of binary encoded signaling commands.

H.323 v3 can be implemented with or without a call control server. Thus, an H.323 v3 end device (e.g., a telephone) can be designed to set up a call either through a call control server or directly with another end device without using an intervening call control server. An H.323 v3 call control server can be set up to relay the communications stream during the call, or the end devices can directly establish the communications RTP streaming channel between themselves. The call control server can be either stateless (i.e., not track a transaction or a session state) or stateful (i.e., track each transaction and/or call session state). The significance of this is that in the stateful configuration, H.323 v3 is not as scalable. Finally, H.323 v3 employs signaling protocols that can easily be mapped through a gateway for routing calls between the VoIP network and the public switched network.

Figure 9: VoIP call routed using SIP signaling.

SIP is a Web-based architecture that was developed under the Internet Engineering Task Force (IETF). Like URLs and Web e-mail, SIP's messages are in ASCII text format that follow the HTTP programming model (i.e., using a grammar similar to that used to create basic Web pages), resulting in slightly lower efficiency in transmitting signaling information, as compared to the more efficiently encoded binary H.323 signaling messages. Also, SIP is very extensible, leading many vendors to implement variations that may be somewhat incompatible [IETF, SIP, 2004; IETF, SIP RFC2543bis (J. Rosenberg et al.), 2002].

An address used for routing a SIP messages is of the form SIPAddress@xyz.com. As shown in Figure 9, when a phone wishes to originate a call, it transmits an ASCII SIP INVITE message (1) addressed to the SIP address of the called phone (e.g., sales@xyz.com., where xyz.com is the domain name of the SIP proxy server for the called phone). Using conventional domain name server (DNS) look-up, the Internet routes this e-mail-type message to the SIP call control server, which may act as either a proxy server or a redirect server for the domain of the dialed called telephone address (here, xyz.com). To determine where the telephone is located, the proxy server or redirect server will query a location server (2), which will return the routing directions. What happens next depends on whether the call controller is acting as a proxy server or a redirect server for the called telephone.

For a proxy server, the location server will return the IP address for the called telephone. Using that IP address, the SIP INVITE message will be directed to the called telephone (3) along with the calling telephone's IP address. The called telephone will then return a RING message to the proxy server (4), which then forwards that RING message to the originating telephone (5). When the called

phone answers, an OK message is returned (6 and 7), which includes the called telephone's IP address. Finally, the originating telephone (which now knows the IP address of the destination phone from the INVITE/OK message exchange) sends an ACK message to the IP address of the called telephone (8). The originating telephone then establishes an RTP communications link with the called telephone (9).

For a redirect server, the location server will return the redirected (i.e., forwarding) e-mail-style SIP address of the called telephone (e.g., sales@home.com or joe@home.com). The redirect server will then forward the INVITE request to the proxy or redirect server associated with that redirected address, and then the steps enumerated above will take place.

Each location server must track the IP address of each of the telephones in its SIP domain. Thus, each SIP telephone must register with its domain's location server via a registration server of its telephone service provider. An individual telephone can be registered with any registration server with which the user has a service arrangement. Registration binds each SIP telephone's IP address to its SIP address in its service provider's domain.

Note that a SIP call control server's primary purpose is to handle the routing of initial supervisory and address signaling information. Also note that, after the initial exchange of supervisory and address information, SIP end devices establish and maintain the communications channel without involvement of the SIP call control server. Like H.323 v.3, the SIP packets that carry the signaling messages almost always follow a different path from the path taken by the communications data. Finally, with SIP most of the intelligence resides in the end devices, as compared to being in the network, as is the case with conventional telephone networks and with H.323.

public Internet or PSTN could be registered to this universal, fully portable, single-number identifier of their registered owner, allowing mobility around both the PSTN and the public Internet.

The flexibility of the ENUM standards raise new issues of privacy (e.g., disclosure of services registered to the owner), security [e.g., relative ease of ability of unauthorized telephone devices to “impersonate” the true owner of a number and receive and/or originate calls with their identity (identity spoofing and IP spoofing)], and administration (see below for more on security issues). Also, final agreement between Internet and traditional telecom industry represented by the ITU is still pending.

Quality-of-Service Issues

Transmission and routing can introduce effects that degrade the quality of VoIP. VoIP signals are not immune to the deficiencies of the facilities that transport and route them. These deficiencies can cause packet loss, jitter, and delay.

Packet loss refers to the loss of packets containing some of the voice samples during transmission. The loss might be caused by high bit error rates in the UDP transmission channel, misrouted packets, and/or congestion causing intermediate routing devices to drop packets. Because voice transmission is very sensitive to delay, the reassembly of the voice signal at the receiving end of the call cannot typically wait for the retransmission of erroneous or misrouted packets. However, voice transmission has a high tolerance for packet loss—mainly because the ultimate receiver of the signal (the human ear and/or intervening codec) does a good job of interpolating (i.e., filling in the gap) where a packet has been lost. There is a limit to how much packet loss can be tolerated. That limit depends on several factors, including (1) the nature of the sound being transmitted, (2) the correlation in time between the packets lost (i.e., are they bunched together or widely dispersed in time), and (3) the randomness of the losses. Because they do such an efficient job of squeezing out redundancy, some codecs that use data compression algorithms are not able to recover from the loss of as few as two packets in a row.

Jitter can also contribute to lower quality. With IP traffic often taking multiple routes during high congestion periods and/or mixed in with bursty IP packet traffic, the interarrival times of the packets at the receiving end may be irregular and/or the packets arrive out of order. Jitter can be overcome by buffering the packets—that is, temporarily storing them long enough to reorder them before forwarding them to the decoder. However, buffering has the negative consequence of adding more delay.

Delay in the transmission of voice packets can be minimized in several ways. One is overbuilding the IP network (i.e., ensuring that there is always excess capacity in the IP network for all traffic, including during peak traffic periods). Alternatively, priority routing can be afforded to voice traffic, at the expense of lower priority data traffic—which is more tolerant of delays. Separate treatment of voice from data can be done by virtual segregation or physical segregation from lower priority traffic. The former can be done at either the network or data link layer. For example, segregation can be done at the data

link layer by using separate ATM channels for voice and data traffic and then assigning ATM-based priority treatment to the ATM channels carrying voice traffic. Where voice and data are mixed on the IP network, identifiers can be used to indicate to the intermediate network components (such as routers) that designated traffic (such as voice traffic) should be given priority.

An example of this last method is RSVP, the Resource Reservation Protocol. RSVP allows a VoIP application to request end-to-end QoS guarantee from a network. (Cisco, VoIP Call Admission Control Using RSVP, 2003.) If the guarantee cannot be provided, the call will not be allowed to go through. Where the guarantee cannot be secured, the traffic might be redirected to an alternate network or blocked (resulting in VoIP users receiving an “equipment busy” signal). At the current time, priority schemes such as RSVP typically do not work over the public Internet. This is because, among other reasons, the economic incentives are not there for intermediate Internet providers to honor any type of prioritization routing scheme, given that their reimbursement is the same for all traffic—regardless of its priority designation. Therefore the current market structure for public Internet backbone routing prevents the realization of a higher quality of service for VoIP traffic over the public Internet.

To differentiate themselves, some Internet backbone providers are introducing prioritization schemes such as MPLS-based networks, which are ATM-like in their attributes but operate at a mixture of layers 2 and 3 protocols in pure IP environments. As competition intensifies, public networks are expected to become friendlier to real-time services such as VoIP. Quality of service is discussed in detail elsewhere.

The Costs and Savings of Using the Voice-over-Internet Protocol

One source of VoIP’s cost savings over conventional telephony is its ability to employ transmission more efficiently because of both the extensive use of compression algorithms and the statistical nature of its information transmission. However, such efficiencies will tend to be most significant to private networks and/or network providers whose transmission networks are capacity constrained.

A second source of VoIP’s cost savings is lower capital cost per call using lower cost switching devices (i.e., Internet routers and switches). Again, networks with sunk investments in conventional technology with excess capacity would derive little benefit from such savings.

A third source of VoIP’s savings is lower costs of administration, particularly in enterprise environments. A good deal of administrative cost is incurred in enterprises to accommodate the movement of telephone users within the enterprise. Each time a user moves to another office or enters or leaves the firm, the routing tables and directory of a conventional telephone system must be updated, often manually. VoIP’s self-registration feature eliminates these administrative costs.

A fourth source of VoIP’s savings comes from the “economies of scope” that VoIP can achieve by its ability to intermingle with other traffic on data networks, eliminating the need to segregate voice and data traffic, as is often done with conventional telephony. These savings are

most easily exploited in the LAN and WAN enterprise environment or by data-centric carriers who wish to combine their voice and data traffic. Administrative savings also come from eliminating the conventional regime of separate administrative staffs for voice and data.

Finally, VoIP traffic on a data network looks like any other data on that network. This allows some carriers and enterprise users to avoid some of the economically distorting taxes that local, federal, and foreign regulatory regimes place on pure voice traffic, but not on data traffic. It is important to remember that the realization of these savings are application specific and may not be realized in every situation (see, e.g., Morris, 1998; "Cisco Seeks Bigger Role in Phone Networks," 2003).

One thing to keep in mind is how shifting from conventional telephony to VOIP changes how telephony is managed. Specifically, conventional telephony involves the management of transmission facilities dedicated to telephony services. Thus, the telephony management personnel must not only be concerned with managing the terminal devices that provide telephony services, they must also be concerned with the management and installation of the transmission and intermediate switching facilities (i.e, the OSI Layer 1 and higher) that are dedicated to telephony services. With VoIP, telephony service management is simplified because it is treated as simply another application riding on an existing data network. VoIP involves only OSI levels 5 through 7. Thus, VOIP telephony management does not have to deal with installation and maintenance of the underlying physical transmission and switching layer. However, voice services require higher transmission reliability (e.g., 99.99% availability) and, in

turn, the lower OSI layers (levels 1 through 4) must be designed and managed to assure that the voice-grade reliability goal for the VoIP application is maintained. In other words, when properly engineered, there are indirect costs imposed on the lower OSI layers that carry VoIP because of the presence of the higher demands of VOIP.

Security Issues for the Voice-over-Internet Protocol

Security is a concern with VoIP, particularly because of the distributed nature of the call control, much of which is handled between end devices (see U.K Advisory, 2004; CERT Advisory, 2004). Some of the things that make certain configurations of VoIP attractive (e.g., self-registration of end devices, mixing voice with data traffic over an IP network, and software-controlled PCs acting as end devices) are also the sources of VoIP's vulnerability. Security issues, listed in Table 2, include the following: (1) eavesdropping, (2) toll fraud, (3) caller identity spoofing (4) IP spoofing, (5) replay, (6) message integrity, (7) viruses and (8) denial of service attacks (Cisco, SAFE: IP Telephony Security in Depth, 2003; Cisco, Security in SIP-Based Networks, 2003).

Eavesdropping refers to an unauthorized party "listening" to the packets and, in turn, being able to listen to the voice conversation. This problem exists with both VoIP and conventional analog/digital voice communications. In both cases, the simplest method of preventing this problem is to encrypt the digital signal at its source, the originating telephone. The problem encryption brings is overhead and computational load, which can introduce

Table 2 Network Security Issues and Their Solutions

Issues	Possible Solutions
Eavesdropping: Unauthorized interception of voice packets or Real-Time Transport Protocol (RTP) media stream and decoding of signaling messages (one particular attack is known as "Voice Over Misconfigured Internet Telephones" or "vomit").	Encrypt transmitted data using encryption mechanisms like Secure RTP.
Toll fraud.	Caller authentication and security codes.
Caller identity/packet spoofing: Impersonation of a legitimate user transmitting data.	Send address authentication (for example, endpoint IP and/or MAC addresses) between call participants.
IP Spoofing.	Use spoof mitigation filters at Level 3 switches and ISP edge, and stateful firewall.
Replay: The retransmission of a genuine message so that the device receiving the message reprocesses it.	Encrypt and sequence messages; in SIP this is offered at the application-protocol level by using CSeq and Call-ID headers.
Message integrity: Ensuring that the message received is the same as the message that was sent.	Authenticate messages by using HTTP Digest, an option supported on SIP-enabled phones and the SIP Proxy Server.
Viruses, Trojan Horses that Cause Network Overload, Unintended actions by devices, or Crashing of Devices.	Segregate voice from data segments, and don't use PC's as telephone devices.
Denial-of-service (DoS) attacks: Prevention of access to a network service by bombarding proxy servers or voice-gateway devices on the Internet with inauthentic packets.	Configure devices to prevent such attacks.

Sources: Cisco, SAFE: IP Telephony Security in Depth 2003; Cisco, Security in SIP-Based Networks 2003.

delay. Also, encryption can create problems for law enforcement agencies where they have a warrant to wiretap a telephone conversation.

Toll fraud is the problem of unauthorized persons making telephone calls over the network. This can be caused by unauthorized users originating calls on the IP network either on legitimate phones or over illegitimate phones. As with conventional telephony, this can be combated with security codes and other authentication methods.

Identity spoofing refers to a hacker tricking a remote user into believing he or she is talking to the person he or she dialed on the IP network, when, in fact, he or she is talking to the hacker. Again, security codes and other authorization methods are helpful here.

IP spoofing refers to theft of IP identity, where one end device is able to convince the IP network that its IP address is the same as a legitimate device's "trusted" IP address. This allows the device with the fraudulent IP address to intercept calls and/or perform toll fraud using that IP address, as well as launch attacks on the network. Spoofing the IP address of a gateway allows eavesdropping on telephone calls.

Infrastructure threats that are security threats to the data on an IP network are also threats to VoIP traffic. These include the following: denial of service attacks and viruses (which can crash or tie up critical network terminals and equipment) and message integrity (i.e., the alteration of the messages between transmission and receiving) (Cisco, Security in SIP-Based Networks, 2003; Steinklauber, 2003).

Some generally accepted recommendations for minimizing many of these security problems are to disable self-registration of VoIP end devices after initial network installation, to segregate voice from data traffic at level 2 or 3 using some form of secure "tunneling" (such as a VPN) where possible when traversing "external" infrastructure such as the public Internet, and to use a stateful firewall at the PSTN gateway. As noted, segregating data from voice services also provides the added benefit of maintaining different quality of service for data and voice.

CONCLUSION

VoIP holds great promise where the convergence of data and voice can occur. Internetworking and overcoming QoS issues remain some of the biggest challenges.

GLOSSARY

Analog Signal A continuous signal that, at any point in time, can have an infinite number of possible values and that is typically analogous in some characteristic to another signal or physical phenomenon.

Asynchronous Transfer Mode (ATM) A network transfer method, employed at the data link layer (level 2), for high-speed switched packet routing, which can establish virtual channels with a specified QoS.

Channel Capacity The theoretical upper rate limit, in bits per second, at which information can be transmitted over a transmission channel.

Circuit Switch A switch that makes a temporary or permanent dedicated transmission path between two transmission links that are attached to that switch, based on signaling information received prior to establishing the dedicated path.

Digital Encoding Encoding a signal in the form of a string of 1s and 0s.

Digital Transmission Transmission of information encoded as 1s and 0s.

Internet A global public network based on the Internet protocol, connecting millions of hosts worldwide and for which users often pay a flat fee to access, with little or no charge for transmitting each packet of information. (Outside the United States, Internet access is often measured and charged on a usage basis, e.g., minutes or units of data.)

Internet Protocol (IP) A packet-switching protocol used for routing packets over and between and private networks that is "connectionless" (i.e., each packet making up the same message may take a different route to reach the ultimate destination).

Node A point of connection between transmission links, which may contain switches and/or converters to interconnect transmission links with differing modalities (e.g., for connecting wire links to wireless links, nondigitally encoded links to digitally encoded links, or fiber links to copper wire links).

Packet Router A type of packet-switching device that typically routes based on level 3 network address information (such as an IP address) and typically has the ability to choose optimal routing based on dynamically changing criteria and routing tables.

Packet Switch A type of packet-switching device that routes packets of data between links based on address information associated with each packet. A level 3 switch uses network addresses, such as IP addresses, to route packets of data. Level 2 switches uses data link layer addresses (which are typically local and/or hard-coded) for routing.

Public Switched Telephone Network (PSTN) A circuit-switched network that is provided by regulated common carriers who offer their voice telephone services to the general public.

Quality of Service (QoS) A set of performance parameters or criteria, such as bandwidth, jitter, packet loss, and delay, prespecified for a service.

Transducer A device actuated by signal power from one system and supplying signal power in another form to a second system; for example, a telephone receiver earpiece actuated by electric power of a received transmission signal and supplying acoustic signal power to the surrounding air, which the telephone user can hear, or a telephone microphone that has a quartz crystal that produces electrical signal power for transmission over wires from the mechanical acoustic power originating from the telephone user's voice.

Transmission The movement of information (whether or not digitally encoded) from one point to another via a signal carried over a physical medium, such as wires, fiber, radio, or light.

Transmission Link A transmission path connecting two nodes.

Voice Communication The transmission of information contained in a voice signal.

INTRODUCTION TO SECURITY AND WEB QoS

The Web has become the preferred interface for a growing number of distributed applications with various demands for reliability, availability, security, privacy, timeliness, and network bandwidth, as shown in Figure 1. These properties are often called Web *quality of service* (Web QoS) dimensions. The new demands call for both network and end-system architectures for performance guarantees to satisfy quality of service. Deployment of QoS architectures has been much more successful at the application layer than at the network layer. The failure of network layer architectures such as int-serv, RSVP, and diff-serv is attributed in part to the lack of a good pricing model for network QoS, the lack of appropriate enforcement, and the lack of an end-to-end solution that spans multiple administrative domains and is upheld by all Internet service providers (ISPs) on the path of a client's packet. In the absence of an agreed-upon end-to-end solution, incremental deployment of QoS mechanisms by a subset of ISPs is not enough to guarantee QoS and does not encourage client buy-in. In contrast, end-system solutions can be implemented and priced entirely within a single administrative domain, which explains their recent success. In this chapter, we first review the main components of the Web architecture and describe the protocols that govern their interaction. We then discuss how this architecture and these protocols are affected by QoS considerations, and explore the different security considerations that emerge specifically in QoS-aware end systems.

WEB QoS ARCHITECTURE AND SECURITY IMPLICATIONS

The questions this chapter addresses are why did Web QoS emerge as a new challenge area, what makes this challenge important, and what implications does QoS have on security. Today, the World Wide Web is by far the largest source of Internet flows. The great majority of Internet connections use hypertext transfer protocol (HTTP), which is the protocol that governs Web access. Improving

its performance, therefore, has dramatic global effects. Efforts to improve performance come in two flavors. First, infrastructure improvements, such as realizing higher bandwidth, faster servers, and better last-mile technologies, are pursued. This is largely a cost and capacity provisioning problem that motivates development of lower cost facilities and higher capacity switches and routers. Concurrently, a substantial amount of research is done to make Web performance more *predictable*. Performance is said to be predictable when its quality can be *guaranteed* in advance. Many societal and commercial forces contribute to this need. In particular, the commercialization of the Internet and the pricing of many Internet services play a significant role in elevating the idea of performance guarantees from a value-added option to a primary concern driven by contractual obligations. The need for guarantees gives rise to new concerns on balancing performance and additional processing needed for security. In particular, a new class of security breaches in which a malicious user or set of users attempts to cause the system to violate its guaranteed performance to others emerges. We call this class *denial-of-QoS attacks*. The simplest form of such an attack is one that attempts to overload the server.

Mechanisms for thwarting denial-of-QoS attacks are of growing importance. In traditional commercial products, commercial users of the Internet have grown to take quality guarantees for granted. Vendors have contractual obligations to accept returns of defective products or products that do not perform as advertised. Similarly, paying consumers of Internet-based services expect a performance guarantee or a money-back statement. Much as with other services, it will be important that clients and service providers be able to negotiate mutually acceptable quality levels in the service contract for a corresponding price. Denial-of-QoS attacks can therefore result in monetary losses to online business.

This relation between performance guarantees and revenue is manifested today in several domains. For example, ISPs often sign mutual service level agreements (SLAs), which among other things describe the performance that the traffic of one ISP should receive in the network of the other and the corresponding fee. Closer to the end user,

Figure 1: Web architectures and application.

online trading services sometimes tie their commission fees to performance in executing the trades. The fee is waived for trades delayed by more than a certain amount of time. In view of this emphasis on performance as a contractual obligation, a significant amount of research has been spent on architectures that enforce quality of service guarantees on the Web, even in the presence of malicious users. In the rest of this chapter, mechanisms and policies for QoS provisioning, QoS negotiation, and utility optimization, as well as means for protection against the corresponding denial-of-QoS attacks, will be discussed.

THE CHALLENGE OF QoS GUARANTEES

The most popular QoS attributes of importance in the Web infrastructure revolve around some notion of time. For example, guarantees may be needed on delay, or on the number of requests served per unit of time. We call such metrics *temporal*. A significant body of literature has addressed the issue of guaranteeing temporal QoS attributes in the absence of adequate prior knowledge of operating service conditions such as load and resource capacity. Until recently, the current state of the art in providing acceptable temporal performance to the users has been overdesign. Throwing money and hardware at a performance problem eventually ensures that there are enough resources to service incoming requests sufficiently fast. This approach, however, is inadequate for several reasons. First, it is rather expensive, because more resources are expended than is strictly necessary. Second, it provides the same service to all clients. In many cases, however, a service provider might want to use performance differentiation as a tool to entice clients to subscribe to a “better” (and more expensive) service. Third, the server provides only a best-effort service in that there are no bounds on worst-case performance. It is sometimes advantageous to be able to quantitatively state a performance guarantee for which users can be commensurately charged.

In the following sections, we describe several approaches for QoS guarantees in more detail. We then describe related security concerns and approaches for mitigating them. We begin by a brief review of the current Web architecture and the underlying principles of Web server operation (Figure 1). We then survey the modifications suggested to this architecture to provide security and performance guarantees to Web clients.

CURRENT WEB ARCHITECTURE

From an architectural standpoint, the World Wide Web is a distributed client-server system glued together by the

hypertext transfer protocol (HTTP), which is simply a request-reply interface that allows clients (browsers) to download files from servers by (URL) name and allows one page to reference another, creating a logical mesh of links. The architecture is completely decentralized. By creating links from existing content, new content is seamlessly integrated with the rest of the Web.

HTTP

The main exchange between clients and servers occurs using HTTP. When a client requests a page from a server, only the text (hypertext markup language, HTML) portion is initially downloaded. If the page contains images or other embedded objects, the browser downloads them separately. At present, two important versions of HTTP are popular; namely HTTP/1.0 and HTTP/1.1. The most quoted difference of HTTP/1.1, and the primary motivation for its existence (Mogul, 1995), is its support for persistent connections. In HTTP/1.0, each browser request creates a new TCP connection. Because most Web pages are short, these connections are short-lived and are closed once the requested page is downloaded. Unfortunately, TCP is optimized for long data transfers. Each new TCP connection begins its life cycle with a connection setup phase, followed by a slow-start phase in which connection bandwidth gradually ramps up from a low initial value to the maximum bandwidth the network can support. Unfortunately, short-lived connections, such as those of HTTP/1.0, are closed before reaching the maximum bandwidth. Hence, transfers are slower than they need to be.

Persistent connections in HTTP/1.1 avoid the above problem by sending all browser requests on the same TCP connection. The connection is reused as long as the browser is downloading additional objects from the same server. This allows TCP to reach a higher connection bandwidth. Additionally, the cost of setting up and tearing down the TCP connection is amortized across multiple transfers. The debate over which protocol is actually better is still going on. For example, a disadvantage of HTTP/1.1 is its reduced concurrency, because only one TCP connection is used for all objects downloaded from the same server, instead of multiple concurrent ones. Another problem with HTTP/1.1 is that the server, having received and served a request from a client, does not know when to terminate the underlying TCP connection. Ideally, the connection must be kept alive in anticipation of subsequent future requests. However, if the client does not intend to send more requests, keeping the connection open only wastes server resources. The present default is to wait for a short period of time (around 30 s)

Figure 2: Web proxy caching.

after serving the last request on a connection. If no additional requests arrive during that period, the connection is closed. The problem with this policy is that significant server resources can be blocked waiting for future requests that may never arrive. It is therefore not obvious that the bandwidth increase of HTTP/1.1 outweighs its limitations.

Caching and Content Distribution

To improve Web access delays and reduce backbone Web traffic, caching and Web content distribution services have gradually emerged. These services attempt to redistribute content around the network backbone so that it is closer to the clients who access it. The difference between caching and content distribution lies in a data-pull versus a data-push model. Whereas caches store content locally in response to user requests, content distribution proxies proactively get copies of the content in advance.

There are generally three types of caches, namely proxy caches, client caches, and server caches. Proxy caches, shown in Figure 2, are typically installed by the ISPs at the interface to the network backbone. They intercept all Web requests originating from the ISP's clients and save copies of the requested pages when replies are received from the contacted servers. This process is called page caching. A request to a page already cached can be served directly from the proxy, thereby improving client-side latency, reducing server load, and minimizing backbone traffic for which the ISP is responsible to the backbone provider. An important question is what to do when the cache becomes full. To optimize its impact, a full cache retains only the most recently requested URLs, replacing those that have not been used the longest. This is known as the least recently used replacement policy. Several variations and generalizations of this policy have been proposed, e.g., to account for page size, cost of a page miss, and the importance of the client.

To improve performance further, client browsers locally cache the most recently requested pages. This cache is consulted when the page is revisited (e.g., when the client pushes the "back" button), hence obviating an extra access to the server. Finally, some server installations use server-side caches (also known as reverse proxies) to reduce the load on the server. The caching infrastructure significantly affects the user-perceived performance of the Web. Arlitt, Friedrich, and Jin (2000) compare the effects of different replacement policies on cache performance.

Recent research efforts have addressed developing caches that provide some form of performance differentiation or QoS guarantees. A proxy cache, for example, can offer preferential treatment to content requested by a certain subset of clients or content belonging to a certain subset of providers. This mechanism will be described in later sections.

Recently, content distribution networks (CDN) have emerged as a technology that enables scalable content delivery from content providers to clients. Compared to Web caches, CDNs have the advantage that content can be prepopulated to their proxies based on the business relationships between CDN providers and content providers. CDNs also improved the ability of hosting content not cacheable by regular Web caches such as secure content and dynamic content.

PERFORMANCE GUARANTEES AND DENIAL-OF-QoS IN WEB SERVERS

In this section, we describe performance guarantee mechanisms for Web server end systems with an emphasis on enforcement considerations that prevent QoS violations in the presence of malicious clients and security attacks. As a running application example, consider a Web server farm that hosts multiple Web sites on behalf of different content providers. Web hosting is a growing business in which major investments are made by companies such as Intel, IBM, and Hewlett-Packard. We discuss the type of performance guarantees required, the parties to whom the guarantees are made, and the mechanisms used to enforce these guarantees in the face of denial-of-QoS attacks. The server farm example provides a context for describing the general classes of server performance challenges and helps illustrate solutions needed when resources are shared among multiple parties with different QoS requirements.

A Web hosting service interacts with at least three different parties:

- (i) End users who access the hosted content;
- (ii) Content providers who own the Web sites exported for hosting; and
- (iii) Network providers who provide Internet connectivity to the Web hosting farm.

End users are typically interested in a fast response time; content providers care more about throughput, which translates into total capacity dedicated to their Web sites; and network providers care primarily about network bandwidth consumed by the hosting installation.

In general, the mechanisms to provide these guarantees lie either on servers (i.e., on the end system) or inside the network. Many QoS mechanisms inside networks such as int-serv and diff-serv have been proposed over the past 15 years. These technologies usually involve network users to make "reservations" so that different types of network service (traffic) will receive different qualities in terms of delay, packet drop ratio, and so forth. Although these QoS mechanisms on the network layer are vital for successful end-to-end QoS guarantees, their widespread

deployment has yet to be realized. Because of their status quo of limited deployment, network layer QoS mechanisms have not suffered significant security attack yet. On the other hand, QoS guarantee mechanisms on the end system have been widely adopted by various operating system kernels and commercial application server products. Therefore, most malicious attacks are trying to exploit security holes or vulnerabilities of operating systems. In the following, we focus on mechanisms on the end system.

Performance Isolation

The most basic guarantee needed among multiple traffic classes is that of performance isolation. Informally, the guarantee states that the performance seen by any particular class of clients should be independent of the load imposed by any other class. For example, consider a Web server that hosts two Web sites, A and B. Unless proper action is taken, an attack on B may overload the entire server, preventing the clients of A from accessing the server as well. Performance isolation contains the problem by imposing limits that prevent any one site such as B from monopolizing the server. Hence, performance isolation localizes the effects of denial-of-QoS attacks. It acts as a fault-containment mechanism in fault-tolerant architectures. There are several different ways performance isolation may be implemented. They typically rely on some form of resource allocation and admission control. In the following subsections, we discuss some of the most important mechanisms for performance isolation in the operating system, middleware, and application layer.

Operating System Solutions

The core mechanism for performance isolation is resource reservation. Each Web site must be allocated its own resource quota on the Web server. Requests for that Web site are allowed to consume only those computing resources within the site's quota. Excess load on one site should not be allowed to divert resources dedicated to other sites. Traditionally, resource allocation and management is the responsibility of operating systems. Hence, the most fundamental solutions to performance isolation are operating system solutions.

Generally speaking, in a shared computing system, such as a server farm shared by multiple cohosted Web sites, common resources can be categorized into two different types: those shared in time and those shared in space. Space-shared resources include, for example, memory and disk space. Different processes may own different subsets of the resource concurrently and be denied access to resources owned by others. Space-sharing implies that the resource can be partitioned. Some resources, however, are indivisible. The prime example is the CPU. Indivisible resources can only be time-shared. In other words, they can only be allocated in their entirety to one process at a time. Clients are queued up on the time-shared resource. The queuing order and duration of resource access allowed by each client decide how the resource is shared.

Traditional operating systems such as UNIX implement a time-sharing scheduling policy, which allocates the

processor one quantum at a time in a round-robin fashion among the waiting processes. This policy is inadequate for performance isolation in that it does not prevent any one class of clients from monopolizing the CPU. Consider our server farm example, where it is desired to isolate requests for different sites cohosted on the same platform. The CPU capacity available to one site under the UNIX time-sharing scheduling policy is roughly proportional to the number of processes serving that site at a given time. This number is in turn proportional to the client request rate. A Web site under attack with a large (malicious) request rate generates a large number of processes to serve these requests. It can therefore monopolize the CPU.

To ensure performance isolation, many researchers have addressed the problem of reservation of time-shared resources. The first effort on this subject came from the Real-Time Mach project at Carnegie-Mellon University and is called *processor capacity reserves*. The idea of processor capacity reserves is to implement separate accounting entities (the reserves), which keep track of the processing budgets allocated to abstract CPU activities. For example, a programmer can associate a budget with each separate Web site on the hosting server. The budget specifies the percentage of time that the CPU is allowed to spend on the corresponding site (e.g., 4 ms every 30 ms). The budget is replenished periodically. To enforce performance isolation, when a Web server reads a request, the request is classified and the corresponding budget is charged for the time it takes to serve the request. If the reserve is exhausted before the end of the period, the budget is said to have expired. When a budget expires, processes charged to that budget are blocked until the next replenishment period. Hence, these processes cannot jointly exceed the CPU allocation specified for their Web site.

One limitation of the aforementioned technique is the way accounting is done in the operating system. The party that the CPU is working for at any given time is identified in the operating system as either the kernel or a particular user process. Hence, only total kernel execution time and the total execution time of any single process can be measured. In particular, kernel execution time is not properly broken into independent activities. For example, the kernel-processing time of incoming requests is not properly attributed to the site for which the requests are destined and is thus not charged properly to the correct reserve. The problem is exacerbated by the inability to differentiate connections until they have been processed by the TCP/IP stack. To address the aforementioned accounting problem, resource containers (Banga, Druschel, & Mogul, 1999) have been proposed as a new operating system abstraction for resource reservation and performance isolation in monolithic kernels running server end systems. The authors of this approach make the observation that the accounting problem arises from the fact that in traditional operating systems the resource principal (i.e., the system entity capable of owning resources) is generally associated with a protection domain (such as a process). In server end systems, this association is not appropriate. The logical resource principal could be a user or a content provider. Depending on the server architecture, multiple processes can serve the same principal, or a single process can serve multiple principals. The resource

principals should be charged for processing that occurs both on the kernel level and in user space. Banga et al. (1999) propose the abstraction of resource containers to resolve the dichotomy. In this approach, packet filters are placed at the lowest level of the protocol stack. These filters demultiplex incoming traffic into distinct categories (e.g., by IP address). All kernel and user-level processing of traffic in each category is charged to the corresponding resource container. As before, when the container is exhausted, the operating system stops processing the corresponding traffic type until the container is replenished. The approach has been shown to provide excellent isolation. In particular, it is very efficient in isolating denial-of-QoS attacks. For example, if the identity of the attackers is known, all traffic from them can be isolated and associated with a separate resource container of zero capacity. This traffic will thus be dropped, causing no negative effects on the rest of the system.

The need for early demultiplexing presents several challenges of its own. Such demultiplexing is typically performed based on fields in the TCP or IP header. Unfortunately, in many Web applications, client classification is a little more complex (Menasce, Almeida, Fonseca, & Mendes, 2000). Designing general purpose mechanisms to express such classification constraints at the operating system level is a challenging task, unless one is willing to sacrifice the application-independent nature of general purpose operating systems.

Another complication is that packets arriving at the bottom of the protocol stack (e.g., IP fragments) may not always have an application-layer header, which contains the information necessary for classification. These headers would be reconstructed higher in the communication protocol stack, which makes early classification more challenging. Construction of efficient packet filters for early classification based on application-specific information is therefore an important research challenge.

Middleware Approaches

When client classes are defined in an application-specific manner, a different solution to performance isolation is to develop middleware that augments generic operating system support with application-specific middleware policies. The operating system approach, described in the previous section, is perhaps the most efficient approach for fine-grained performance isolation. However, it suffers from the lack of generality and the lack of portability. The former refers to the difficulty of incorporating application-specific classification policies into the kernel. The latter (i.e., portability) stems from the fact that support for time-multiplexed resource reservation described earlier is still far from being a standard operating system feature. Thus, performance isolation solutions that do not *require* this support in the operating system are often preferred. These considerations lead to middleware solutions.

Middleware refers to any software layer that runs below the application and above the operating system. Generally, there are two types of middleware; that which is transparent to the application and that which requires application modification to adhere to a new interface. The former is more general in that it does not require access

to application source code. Hence, a hosting service, for example, can develop in-house middleware components even when the source code for the Web server and the operating system is not available. Similarly, a middleware vendor can develop its software independently to interoperate with multiple Web server and operating system products without the need to modify their code.

An important challenge in designing transparent middleware services is to architect their (transparent) interaction with the server software. Such interaction is usually implemented by instrumenting standard dynamic shared libraries used by the server. Dynamic shared libraries are those loaded by the server at run time, as opposed to being precompiled together with server code. This feature is made possible because of late binding, supported by most operating systems today. In late binding, references to called library functions are not resolved until the call is made at run time and the corresponding library is dynamically loaded into the server's memory. It is therefore possible to make changes to the shared library without having to recompile or relink the server software. Once the server makes the standard library call, the new (modified) library gets invoked. In the case of middleware for performance isolation, the modified shared library may implement accounting functions that approximate resource containers.

One of the most obvious libraries to instrument is the socket library. Hewlett-Packard Labs researchers (Bhatti & Friedrich, 1999) were the first to suggest architectures where the socket library is replaced with a QoS-sensitive version, which implements performance isolation. In the context of regular socket calls, the QoS-sensitive library dequeues service requests from the server's well-known port and classifies them into per-class queues. The `accept()` or `read()` socket calls are modified so that no connections are accepted from a given per-class queue unless the budget of the corresponding class (maintained by the modified library) is nonzero. The scheme, shown in Figure 3, implements approximate performance isolation. It has been successfully integrated into a server platform sold by Hewlett-Packard, called Web QoS.

Figure 3: A middleware architecture for Web QoS.

A general problem with middleware approaches to performance isolation is their larger overhead. All requests (including malicious ones) must be processed by the operating system before reaching the middleware layer where they are classified and handled in accordance with their class. Hence, an attacker can overload the server by sending a large number of requests such that their operating system processing overhead alone is sufficient to saturate server resources. In view of this, middleware approaches for performance isolation can only elevate the threshold of overload, but not eliminate it completely. These mechanisms simply make it harder for an attacker to achieve denial of QoS. They do not address the operating system overhead spent on malicious requests.

Application-Layer Mechanisms

Current state-of-the-art Web servers, such as Apache (the most widespread Web server today), maintain a single process pool for all incoming requests. The single-pool architecture significantly complicates QoS provisioning because all requests are treated alike in the server. Hence, a group of attackers can send a large number of requests to the server until the entire process pool is consumed thereby denying QoS guarantees to other clients. In a multiclass server, attainment of performance isolation can be significantly simplified if the server is designed with QoS guarantees in mind. The single main feature that provides the most impact is to maintain a separate pool of processes for each traffic class. Once the server identifies an incoming request as belonging to a particular class, it is queued up for the corresponding process pool. Hence, attacker requests can be queued up in a separate queue from the rest of the clients, making it possible for these clients to continue to use their quota of server processes while an attack is underway. Several examples of this architecture have been proposed in the literature. QoS provisioning reduces to controlling the resource allocation of each separate pool.

Service Differentiation

An important second category of QoS guarantees is service differentiation. The goal of performance isolation, discussed previously, is to logically *partition* the resource so that each class of clients would get its own independent portion. Competition among classes is *eliminated* by giving each exclusive ownership over a subset of resources. Faults (such as overload due to an ongoing attack) are localized to individual resource partitions and hence are conveniently contained. In contrast, service differentiation policies do not attempt to partition the resource. The resource is *shared*. When the resource is in demand by multiple classes, the differentiation policy *resolves* the competition in a way that favors some class over others. Service differentiation policies are classified depending on what it means to “favor” a particular class. Regardless of the nature of differentiation, the system becomes susceptible to a different type of denial-of-QoS attack. Namely, an attacker can impersonate an important client and send enough requests to degrade service to others. Hence, *authentication* becomes important. Authentication refers to the act of verifying client identity to

prevent identity theft. A server should not treat a client preferentially until the server has determined that this client is entitled to the preferential service. Authentication itself requires some processing time. Hence, an attacker can overload the server by continuously sending bogus requests that fail the authentication test but consume enough resources in the process such that the server becomes overloaded. One method to alleviate this attack is to delegate the authentication function to a separate dedicated machine. In the following, we describe the most common examples of service differentiation and their enforcement mechanisms.

Prioritization

The simplest method for providing differentiation is prioritization. Consider a situation where a Web service is accessed by two classes of clients: paying customers and nonmembers. The server offers two types of service: premium and basic. Assume that a dedicated authentication server that ensures that only authorized (i.e., paying) clients can get premium service exists. In contemporary Web services, paying customers are usually allowed access to protected parts of the Web site inaccessible to nonpaying users. This type of differentiation, however, fails to achieve its goal when the Web site is overloaded. In such a situation, a large group of nonpaying malicious users can increase load on the server to the extent that all users (including the paying ones) have difficulty accessing the site content. Performance isolation can be applied between paying and nonpaying users, but it suffers the problem of having to decide on the relative sizes of the respective resource partitions, which typically depend on the current load. One approach to circumventing this problem is to serve clients in absolute priority order. In this scheme all client requests are queued up in a single priority queue for server access. Under overload, the queue overflows. Clients at the tail of the queue are dropped. These clients, by construction of the queuing policy, are the lower priority ones. The mechanism ensures that denial-of-QoS attackers (who are presumably unauthenticated clients—hence are given a low priority) cannot degrade the performance of paying clients.

The problem with prioritization alone is that it fails to provide meaningful performance guarantees to the low-priority clients. The top priority class receives the best service, but very little can be predicted about the performance received by other classes. Prioritization, however, becomes an extremely useful analyzable tool once combined with admission control techniques discussed in the following.

Absolute Delay Guarantees

Prioritization, in conjunction with admission control, allows customizable absolute delay guarantees to an arbitrary number of client classes. Consider a case where there are N classes of paying clients. To recover a fee, the server is contractually obligated to serve each class within a maximum time delay specified in the corresponding QoS contract signed with that class. For example, in an online trading server, first-class clients may be guaranteed a maximum response time of 2 s, whereas economy clients are guaranteed a maximum response time of 10 s.

Failure to execute the trade within the guaranteed response time results in a commission waiver. Alternatively, in a Web hosting service, the content provider of each hosted site might have a QoS contract with the host that specifies a target service time and a fee paid to the host per request served within the agreed-upon delay. Hence, an overloaded hosting server, which consistently fails to meet the delay constraints, will recover no revenue from the content providers.

Because, in these examples, a host does not derive revenue from requests that miss their deadlines, admission control may be used against clients who are unlikely to meet their timing constraints. The rationale for such admission control is that scarce server capacity should not be wasted on clients who are unable to make revenue. Although theoretically admission control refers to a choice between acceptance and rejection, it is more realistic to choose between acceptance and *background service*. In other words, for the purposes of the following discussion, a rejected client is put in a separate lowest-priority queue to be served if resources permit.

Admission control has received much attention in Web QoS literature. Admission control algorithms may be classified into optimistic and pessimistic. The former type may admit clients optimistically even when they may miss their deadlines. The latter may reject them unnecessarily. Note that absence of admission control can be thought of as the extreme of optimistic admission control tests. Recent results (Abdelzaher & Lu, 2001) have shown that in a server with randomly arriving requests it is possible to use a constant-time admission control test to distinguish clients who will meet their deadlines from those who may not. The test is based on a running counter, which maintains a utilization-like metric. The counter is updated by a constant-time operation upon request arrivals and departures. If a request arrives while the counter is below a certain high-water mark, it is guaranteed to meet its deadline. Otherwise, the deadline may be missed and the request is served at the lowest priority level. Recent evaluation results of this admission control algorithm show that it rarely errs in the sense of unnecessarily rejecting requests. The test is shown to improve revenue at overload not only by eliminating resource consumption wasted on requests that miss their deadlines but also by favoring smaller requests (all other factors being equal) and hence improving server throughput. The derivation of the high-water mark representing the client admission threshold assumes that clients are served in a priority order such that more urgent requests are served first. A generalization of this test has later been proposed for first-in-first-out (FIFO) scheduling.

When priority-driven scheduling is used to meet deadlines, priority should be set proportional to urgency. There are two ways urgency can be defined. In the first, clients with shorter per-class response times are considered more urgent. The resulting priority assignment is called deadline-monotonic. In the second, urgency is defined by absolute deadline. The resulting priority assignment is called earliest-deadline-first (EDF). For example, consider a request arriving at time 0 with a maximum response time constraint of 10 s. At time $t = 9$, a second request of a different class with a maximum

response time constraints of 2 s arrives. According to the deadline-monotonic priority assignment, the second request should receive higher priority because its maximum response time constraint, 2, is tighter than 10. According to EDF the first request should receive higher priority because its absolute deadline is $0 + 10 = 10$, which is before the absolute deadline of the second request, $9 + 2 = 11$.

EDF has been proved to be the optimal priority-driven scheduling policy. Deadline-monotonic scheduling is optimal among time-independent scheduling policies, i.e., those where priorities are assigned independent of absolute request arrival times. Optimality, here, is defined in terms of the ability to meet a larger number of deadlines. EDF can meet deadlines when deadline-monotonic scheduling fails because it takes arrival times into account. For instance, in the above example, if the first request has an execution time of 9.5 s, and the second request has an execution time of 1.5 s, both requests meet their deadlines under EDF, but not under deadline-monotonic scheduling. A problem with EDF is that it is less commonly implemented on standard operating systems, with the exception of embedded real-time operating systems where application timing is of prime importance. Deadline-monotonic scheduling is therefore a good compromise.

As previously, a separate authentication server would typically be required to determine the class of the incoming request. In this model, authorized paying clients can be served at a priority higher than that of nonpaying clients to mitigate denial-of-QoS attacks by the latter.

Statistical Delay Guarantees

An entirely different line of reasoning is to provide statistical guarantees on delays and deadline misses. Statistical guarantees require queuing analysis of the Web server. This analysis makes two types of assumptions. First, it must make assumptions regarding the queuing structure of the Web server. Second, it must make assumptions regarding the request arrival process. In the following, we outline the most important challenges underlying the statistical approach to QoS guarantees.

Consider the first challenge, namely, deriving the queuing structure of the Web server. This queuing structure depends on the protocol used. We describe HTTP 1.0 for illustration. Consider a typical multithreaded (or multiprocess) Web server. Packets arrive from the network, causing hardware and software interrupts that, respectively, read the packets from network interface cards and deposit them into a kernel-level input queue called the *IP queue*. In between interrupts, packets in the IP queue are processed by the kernel and queued for the particular application ports for which they are destined. These ports are often called sockets. Each socket is associated with an input queue, called the *listen queue*, where incoming connection requests are queued. Independently schedulable entities in the Web server, called *worker threads*, are blocked for data to be deposited at the listen queue. These threads are unblocked by request arrivals to execute the arriving requests. Each thread implements a loop that processes each incoming request and generates a response. Worker threads that have been unblocked by request arrival become runnable.

Multiple runnable threads may exist at a given time. The order in which such threads get the CPU to execute a request is determined by the CPU scheduling policy. This policy maintains a priority queue called the *ready queue*. The thread at the top of this queue executes for a particular time quantum or until it is blocked. Request processing by a worker thread typically entails access to one or more auxiliary server resources, the most notable being disk I/O. For example, in a Web server, disk I/O is usually needed to read the requested Web page from disk. Access to auxiliary resources blocks the calling thread, at which time it is queued for I/O until the awaited resource becomes available. Each resource usually has a queue, which determines the order in which accesses are served. We call it the *I/O queue*. The resource is made available to the thread at the top of the queue, at which time the corresponding thread becomes runnable again and re-enters the CPU ready queue. When request processing is done, the worker thread sends a response back to the client. Sending the response entails queuing data into the *outgoing packet queue* for transmission on the network.

The above discussion identifies five different queues involved in the Web server's queuing structure: namely the IP queue, the listen queue, the ready queue, the I/O queue (assuming a single I/O resource, e.g., disk), and the outgoing packet queue. The interconnection of these queues creates a queuing network with loops and other dependencies. For example, threads that repeatedly read and process disk data essentially loop between the ready queue and the I/O queue. Moreover, when the number of threads is fixed, dequeuing from the listen queue is synchronized with progress in the ready queue in that new requests are dequeued from the former only when some runnable thread has finished serving a request or has blocked. These factors make accurate analysis of the server's queuing structure difficult. Instead, many approximations are possible. For example, it is possible to consider only the queue for the bottleneck resource. The general idea is that a Web request is likely to spend most of its time waiting in the bottleneck queue.

The second challenge in providing statistical guarantees in Web servers is to identify the stochastic nature of the arrival process. Many queuing theory results assume a continuous Poisson arrival process. This process is characterized by an exponential distribution of interarrival times. This assumption does not hold for Web traffic. Research on Web characterization has identified that arrival of Web requests is generally modeled by a heavy-tailed distribution (Crovella & Bestavros, 1997). One distribution commonly used to model request interarrival times and request execution times is the Pareto distribution. Breslau, Cao, Fan, Phillips, and Shenker (1999) also determined that URL popularity follows a Zipf-like distribution. This information is important for studies of Web performance because it helps quantify the effects of caching. To experiment with Web performance in laboratory testbeds, Barford and Crovella (1998) developed a synthetic Web workload generator that faithfully reproduces the characteristics of realistic Web traffic, including its heavy-tailed distribution, URL popularity, and reference locality characteristics. The problem of providing

queuing-theoretic performance predictions for such Web traffic arriving at a server modeled by the queuing structure outlined earlier is still an open research topic.

Statistical delay guarantees should only be provided to authenticated clients. Other QoS management mechanisms such as prioritizations or performance isolation should be used to defend against attacks launched by nonauthorized users.

Relative Guarantees

From queuing theory we know that delay experienced by a request is a function of server load. Ultimately, the only way one can reduce delay to meet deadline guarantees is to keep the load low enough. This implies denying service to some requests under high load to improve performance. In many cases, however, it is preferred that *all* clients receive service when capacity permits. One QoS-provisioning paradigm that subscribes to this model is *proportional relative differentiated services*.

Proportional relative differentiation was first proposed in the networking community in the context of delay differentiation in routers. It has since been extended to server end systems. In the relative differentiated services model, it is desired that the ratio between the performance levels of different classes of traffic be fixed; e.g., it may be that the delays of two traffic classes in a network router should be fixed at a ratio of 3:1. In general, if there are multiple traffic classes in the system, and if H_i is the measured performance of class i , the relative guarantee specifies that $H_1 : H_2 : \dots : H_n = C_1 : C_2 : \dots : C_n$, where C_i is the weight of class i . Hence, only relative delay between any pair of classes is specified. The absolute delay can take any value. When the system approaches overload, the delay of all classes increases, although some classes see a larger delay increase than others do in accordance with the relative delay guarantee. At present, mechanisms for providing relative delay differentiation are well understood, but not yet deployed.

Relative delay guarantees make the most sense under moderate server load. When the load is light, all classes see identically good service (no delay). When the load is very high, all classes suffer unacceptable delays and timeouts. In particular, in the presence of a denial-of-QoS attack, all classes will be affected, which is undesirable. Hence, from a security standpoint, it is useful to combine relative delay guarantees with absolute delay guarantees in a single framework. The combined architecture bounds the maximum delay of authenticated classes in addition to providing the correct delay ratio when the bound has not been reached. The architecture allows specifying a partial order on absolute and relative time constraints that determines which constraints should be relaxed first when network conditions make the combination unrealizable. Typically, in the presence of an attack, the relative constraints should be relaxed first, hence breaking the performance dependency among authenticated and unauthenticated classes. The performance of authenticated classes (bound by absolute delay constraints) is then enforced.

Convergence Guarantees

In an environment where unpredictable traffic conditions make it impossible to satisfy absolute constraints, an

alternative type of performance guarantee has recently been defined. This guarantee views QoS provisioning as a convergence problem and employs control theory to ensure stability and timeliness of convergence of system performance to the right specification (Abdelzaher, Shin, & Bhatti, 2002). The statement of the guarantee is that a performance metric, R , will converge within a specified exponentially decaying envelope to a fixed value, called the *set point*, and that the maximum deviation from the set point will be bounded at all times.

The absolute convergence guarantee is translated into a control loop such as those used in industrial control plants. The loop samples the measured performance metric (e.g., delay), compares it to the set point, and uses the difference to induce changes in resource allocation and load. Typically, it performs admission control to reduce load, and reallocates resources to alleviate the bottlenecks.

The use of control theory to control the performance of software processes has gained much popularity in recent years. Traditionally, control theory was used to model and control industrial processes described by difference equations. The intuitive reason that such a theory would be applicable to server performance control is that input load on a server resembles input flow into a water tank. The fill level of the server queue resembles the tank fill level. Admission control resembles a valve on the input flow pipe. Hence, the delay dynamics of a Web server are similar to flow and level control dynamics in a physical plant. The latter are well understood and can be described by difference equations. The second reason that control theory is becoming popular for server control is that feedback control loops are very robust to modeling errors. Hence, accurate models of software dynamics are not needed.

In the context of time-related performance metrics, it is interesting to classify the convergence guarantee loops, depending on the performance variable being controlled. As is the case with physical plants, the controlled output of interest affects the model of the system and whether the control loop is linear. Because most of control theory was developed for linear processes, the ability to satisfy the convergence guarantee is often contingent on the ability to approximate the server well by a linear model.

To a first approximation, rate metrics and queue length are easiest to control because they result in linear feedback loops. Rate can be controlled in much the same way physical flow is controlled in pipes. Queue length is simply the integral of rate, and therefore is also linear. Delay guarantees are more difficult to provide. This is because delay is inversely proportional to flow. If a request arrives at a queue of length Q , with a constant dequeuing rate of r , the queuing delay, d , of the request is $d = Q/r$. The inverse relation between the manipulated variable (rate) and the delay makes the control loop nonlinear. At present, providing convergence guarantees on delay remains an active research topic.

The effect of denial-of-QoS attacks on systems that provide convergence guarantees has not yet been investigated. In particular, it may be possible for an attacker to destabilize the system with sufficient knowledge of the

feedback control loop, causing violations of convergence guarantees.

Challenges

In the previous section we outlined the semantics of the most important types of performance guarantees and corresponding security concerns. Next we summarize the challenges common to achieving these guarantees in Web servers in the presence of denial-of-QoS attacks.

Admission Control

A common enforcement mechanism of many QoS guarantee types in Web servers is client admission control. An important decision in the design of an admission controller is to choose the entity being admitted or rejected. In a Web server, admission control can operate on individual requests, individual TCP connections, or individual client sessions.

Per-request admission control is the simplest to implement, but has serious limitations. Consider an overloaded server operating at 300% capacity. Statistically, this means that two out of three requests must be rejected on average. For simplicity assume that all clients belong to the same class. Because client browsers typically issue multiple requests over the duration of the client's interaction with the server (even when downloading a single page), per-request admission control will uniformly cause each client to encounter failures in two-thirds of the accesses. Such service is virtually unusable. Per-request admission control discriminates against longer sessions. This has very negative implications, especially from an e-commerce perspective. For example, it has been shown in many studies that those e-shoppers who eventually complete a purchase from an online server typically have longer sessions with the server than occasional visitors who do not buy. Hence, discriminating against longer sessions gives a lower QoS precisely to those users who are more likely to generate revenue.

A better admission control scheme is to select a consistent subset of clients to admit. Those clients are admitted as long as they continue to send requests to the server within a specified time interval. The rest are consistently rejected. This scheme succeeds in making the service usable by at least some consistent subset of clients. It is also more meaningful in the context of addressing attacks on the server, as malicious clients may be tagged for rejection. This scheme is commonly called *session-based admission control*. It was first analyzed at length for Web servers by Cherkasova and Phaal (1999) and continues to be an important research topic (Chen & Mohapatra, 2002). Session-based admission control is more difficult than per-request admission control because at the time a session is admitted the server has no knowledge of the future load that it may impose, and whether the client is indeed malicious. Hence, it is difficult to decide how many and which sessions can be admitted. Different clients can impose substantially different load demands. For example, if the admitted client is a Web crawler, it may impose a much larger load than a human user. A mechanism for identifying malicious clients is needed. The admission controller must continuously refine the subset of clients

to be admitted based on measurements of resulting load and outcomes of authentication.

Rejection Cost

Another issue tightly related to admission control is the cost of rejecting an incoming request. If admission control is based on the client identity obtained from browser-supplied cookies, a connection cannot be classified early inside the kernel. Instead, all requests must reach the application layer, where the server process can interpret the cookies and identify them as belonging to a particular class. Now imagine an overloaded server, which decides to admit all requests of class A and reject all requests of class B. Because the kernel cannot tell the two classes apart, all requests are forwarded to the application layer after being processed in the kernel. Kernel processing, as mentioned earlier, takes a nonnegligible overhead. This overhead is incurred whether the request is accepted or not. In particular, it is incurred for each rejected request. It is therefore called *rejection cost*. The rejection cost of a request can be more than half the cost of processing the request successfully. Hence, at overload, a significant portion of server capacity is wasted on request rejection. Rejection cost is therefore one of the primary challenges in mitigating denial-of-QoS attacks.

Consistent Prioritization

Many guarantee types, such as absolute delay guarantees, usually rely on priority-driven scheduling. Prioritization imposes a significant challenge in most mainstream operating systems. To be effective, all resource queues should be *identically* prioritized. Unfortunately, CPU priorities, which can be set explicitly in many operating systems, control only the order of the ready queue. It has been shown in recent studies that this queue is often not the bottleneck. In a previous section, we have identified at least five resource queues involved in a Web server. In many cases, the largest queue in the server is the listen queue on the server's well-known port. This queue is maintained in the TCP layer and is handled in FIFO order. Correct prioritization would imply prioritizing the socket listen queues as well. In I/O-intensive servers, such as those serving dynamically generated content, the I/O queue may be the bottleneck. Hence, disk access should be prioritized. Moreover, in a server implementing data structures protected by semaphores, it must be ensured that processes queued on a semaphore are awakened in consistent priority order. Unless all queues are consistently prioritized, an attacker can generate workload that overloads a nonprioritized resource, making that resource the performance bottleneck. Such an attack will circumvent any priority differentiation mechanisms employed by other resources to protect high-priority clients, because prioritizing access to nonbottleneck resources has only a marginal effect on performance. For example, if access to disk is not prioritized, an attacker can generate a disk-intensive workload, causing high-priority threads to block on disk I/O in a FIFO manner behind a large number of malicious low-priority ones.

Communicating priority information among multiple resources is a nontrivial undertaking. Proper operating

system support must exist for priority inheritance across different resources. This support is complicated by the fact that blocking over nonpreemptive resources may cause involuntary priority inversion. The classical example of that is the case of two requests, A and B, where A is of higher priority. Let request B arrive first at some server and be blocked on a nonpreemptive resource such as a shared data structure protected by a semaphore. Request A arrives later and is blocked waiting for B to release the lock. Meanwhile, the progress of B may be interrupted by an arbitrary number of requests of intermediate priority. In this scenario, A is forced to wait for an arbitrary number of lower priority requests, even when all resource queues (including the semaphore queue) are correctly prioritized. The problem may be solved by the *priority ceiling protocol* developed at CMU, which bounds priority inversion. Unfortunately, current mainstream operating systems neither enforce resource priorities nor implement mechanisms for bounding priority inversion, such as the priority ceiling protocol. Thus, the current state of deployment is far from adequate for the purposes of implementing priority-based QoS support on Web server platforms that protects against denial-of-QoS attacks.

QoS Adaptation

The forgoing discussion focused on controlling load to provide time-related guarantees. The underlying assumption is that service must be provided by the deadline. There are no intermediate compromises. In the following, we present a case for QoS adaptation algorithms, which can negotiate intermediate performance levels within a predefined range deemed acceptable by the user. We describe mechanisms that implement adaptation in Web servers.

The Case for QoS Adaptation

Most QoS-sensitive applications have a certain degree of flexibility in terms of resource requirements. For example, JPEG images can be adapted to bandwidth limitations by lossy compression or resolution reduction. Dynamically generated pages can be replaced by approximate static versions to save execution time. Thus, when the server is overloaded, an alternative to rejection of further requests would be to adapt a quality of responses such that the load on the server is reduced. Many leading news and sports Web sites adopt this policy. For example, the appearance of the Cable News Network Web site (<http://www.cnn.com>) is often significantly simplified upon important breaking news to absorb the higher request rate. An instance of that was the great reduction in CNN site content during the first hours after the attack on the World Trade Center on September 11, 2001.

Content degradation is preferred to service outage for obvious reasons. One is that it maintains service to all clients, albeit at a degraded quality, which is preferred to interruption of service. Another is that it does not incur rejection cost because service is not denied. As mentioned previously, rejection cost can be considerable when user-level admission control is used.

To express the flexibility of adaptive Web applications, an expanded QoS-contract model is proposed. It assumes

that the service exports multiple QoS levels with different resource requirements and utility to the user. The lowest level, by default, corresponds to request rejection. Its resource requirements are equal to the rejection cost, and it has no utility to the user. The objective is to choose a QoS level delivered to each user class such that utility is maximized under resource constraints. QoS adaptation should be used with great care as malicious clients can take advantage of it to artificially degrade server performance to a lower QoS level. Several content adaptation architectures have been proposed in Web QoS literature. They can be roughly classified into two general types, depending on the reason for adaptation, namely adaptation to network/client limitations and adaptation to server load. These two types are described in the following.

Adaptation to Network and Client Limitations

In the first type, adaptation is performed online and is sometimes called dynamic distillation or online transcoding. For example, see the work of Chandra, Ellis, and Vahdat (2000). The reason for such adaptation is to cope with reduced network bandwidth, or client-side limitations. Note that the dynamic distillation algorithm itself will in fact increase the load on the server. In effect, the algorithm implements a trade-off where extra computing capacity on the server is used to compress content on the fly to conform to reduced network bandwidth. Alternatively, transcoding or distillation proxies may be introduced into the network. For example, a transcoding proxy can identify a client as a wireless personal digital assistant device and convert a requested HTML page into wireless markup language for display on the client's limited screen. In the absence of additional protection mechanisms, an attacker can launch a denial-of-QoS attack on the transcoding proxy by requesting large volumes of content that require high-overhead transcoding operations. This is an inherent problem with all transcoding schemes.

Adaptation to client-side limitations can also be done using layered services. In this paradigm, content delivery is broken into multiple layers. The first has very limited bandwidth requirements and produces a rough version of the content. Subsequent layers refine the content iteratively, each requiring progressively more resources. JPEG images, for example, can be delivered in this manner. An adaptive service could control the number of layers delivered to a client, depending on the client's available bandwidth. A client with a limited bandwidth may receive a fraction of the layers only. The determination of the number of layers to send to the client can be done either by the server or by the client itself. For example, consider an online video presentation being multicast to the participants of a conference call. The server encodes the transmitted video into multiple layers and creates a multicast group for each layer. Each client then subscribes to receive a fraction of the layers as permitted by its resource capacity and network connectivity. Such adaptation architectures have initially been proposed in the context of streaming media. This technique has better security properties since slow clients cannot impose a large overhead on the server (unlike the case with transcoding).

Adaptation to Server Load

In the second type of adaptation, content is adapted to reduce server load. In this case, dynamic distillation or compression cannot be used because the server itself is the bottleneck. Instead, content must be preprocessed a priori. At run time, the server merely chooses which version to send out to which client. The server in such an architecture has multiple content trees, each of a different quality. For example, it can have a full content tree, a reduced content tree where some decorative icons, backgrounds, and long images have been stripped, and a low-quality text-only tree. A transparent middleware solution that features a software layer interposed between the server processes and the communication subsystem has been described. The layer has access to the HTTP requests received by the server and the responses sent. It intercepts each request and prepends the requested URL name with the name of the "right" content tree from which it should be served in accordance with load conditions. To decide on the "right" content tree for each client the interposed content adaptation layer measures the current degree of server utilization and decides on the extent of adaptation that will prevent underutilization or overload. This type of adaptation should be used with care. Otherwise, malicious clients may cause the server to downgrade its service to others.

An interesting question is whether load can be adapted in a continuous range when only a finite small number of different content versions (trees) are available. Such continuous adaptation is possible when the number of clients is large. To illustrate this point, consider a server with M discrete service levels (e.g., content trees), where M is a small integer. These levels are numbered $1, \dots, M$ from lowest to highest quality. The level 0 is added to denote the special case of request rejection. The admission control algorithm is generalized, so that instead of making a binary decision, it determines a continuous value m , in the range $[0, M]$, which we call the degree of degradation. This value modulates server load in a continuous range. In this case, $m = 0$ means rejecting all requests (minimum load), and $m = M$ means serving all requests at the highest quality (maximum load). In general, when m happens to be an integer, it uniquely determines the service level (i.e., tree) to be offered to all clients. If m is a fractional number, composed of an integral part I and a fraction F (such that $m = I + F$), the two integers nearest to m (namely, I and $I + 1$) determine the two most appropriate service levels at which clients must be served. The fractional part F determines the fraction of clients served at each of the two levels. In effect, m is interpreted to mean that a fraction $1 - F$ of clients must be served at level I , and a fraction F at level $I + 1$. The policy can be accurately implemented when the number of clients is large. It ensures that load can be controlled in a continuous range by fractional degradation and offers fine-grained control of delay and server utilization. Figure 4 shows an example of content (an image) with two service levels; regular (Figure 4a) and degraded (Figure 4b). In this example, the storage requirements of the degraded image are roughly an order of magnitude less than the requirements of the regular image.

Figure 4: Example of content degradation: (a) regular and (b) degraded content.

PERFORMANCE AND SECURITY CONSIDERATIONS IN WEB PROXY SERVERS

Before this chapter concludes, a word on performance and security considerations in proxy servers is in order. Proxy servers are intermediaries between the clients and the accessed Web servers. They are the main performance acceleration mechanism on the Web, which makes their study very important. QoS architectures should consider the effects proxy servers have on user-perceived Web performance and make use of them to satisfy client QoS requirements. Proxies may be used for caching, transcoding, or content distribution. A proxy intercepts incoming requests and attempts to serve them locally. If the requested content is not locally available the proxy may forward the request to another server (e.g., content distribution proxies), contact the origin server and save the response (Web proxy caches), or contact the origin server, transcode the response, and forward it to the client (transcoding proxy). Although current proxy servers typically treat all clients alike, there has been much talk on making them QoS-aware. For example, the server may offer preferential treatment to some classes of clients or classes of content.

Several research efforts have looked at biased replacement policies in proxy caches (Kelly, Chan, Jamin, & Mackie-Mason, 1999). Such policies attempt to maximize a weighted hit ratio, where weights are set in accordance with content importance. For example, content fetched from the preferred providers can have a higher weight and therefore a lower likelihood of being replaced. Another research direction is to determine dynamically the disk space allocation of a cache or a content distribution proxy such that content of preferred providers receives a higher hit ratio. In this approach, the “performance distance” between different content types can be controlled (Lu, Saxena, & Abdelzaher, 2001). For example, one can specify that preferred content is to receive twice the hit ratio of regular content. The underlying adaptive disk allocation policy uses feedback control to translate this

specification into a dynamic disk space allocation that satisfies the specified requirement in the presence of dynamically changing load patterns.

Content distribution networks composed of multiple proxy servers situated around the Internet backbone bring another degree of freedom in Web QoS provisioning. The distribution provider may make agreements with content providers to distribute their content preferentially for a corresponding fee. Alternatively, the distribution provider may make agreements with certain ISPs to improve the quality of service to their clients by virtue of the content distribution network. An example of such a network is that introduced by Akamai. When a content provider authorizes a CDN provider to host its content, the CDN could create more than one replica of the content provider’s Web objects on the CDN’s servers. Obviously, the more replicas there are, the better average client access latency can be achieved because chances are clients’ requests can be redirected to a replica closer than the origin server. The actual number of CDN servers hosting a Web content object is decided by its popularity, workload conditions of the CDN, and the QoS SLA between the CDN provider and the content provider. Supporting secure content distribution is an attractive feature of CDNs. It is envisioned that in the near future not only content but also “computation” of content providers will be distributed to CDNs. Security concerns must be carefully addressed before content providers are willing to authorize CDN providers to distribute their sensitive information, such as private data and Web applications.

Different from the scenario of clients directly communicating with servers, adding CDNs to the Web infrastructure makes each request from a client be intercepted by CDN servers. Hence, for those secure content requests, both the connection between clients and CDN servers and the connection between CDN servers and origin servers must be on top of secure channels. The level of protection used by the CDN servers should match those of the origin servers because stronger security protection means higher performance overhead and yet security is always as weak as the weakest link. For example, if the origin server uses 1024-bit keys for its content objects, then the CDN

servers should also use 1024-bit keys to communicate with clients; if the origin server uses 128-bit keys, then there is no point incurring more overhead by using 1024-bit keys.

A security-related performance issue in CDNs is brought by the redirection mechanisms. CDNs use request redirection mechanisms such as DNS-based redirection and URL rewriting to offload content providers' origin servers and achieve a load balance. Note that redirection mechanisms do not necessarily guarantee that requests for some server's content from a client will always be directed to the same CDN server. Establishing SSL sessions has a very high overhead. If multiple requests of a single session happen to be redirected to different CDN servers, the overhead of initiating SSL sessions is amplified. Consider a scenario where a client established a SSL session with a CDN server and requested a Web page, which contains n embedded objects. The requests to download these objects, however, are redirected to n different CDN servers. This will incur n SSL sessions in total. This brings much higher workload to both the client and the CDN system. This problem requires the redirection mechanisms of CDN providers to be more intelligent. For example, if URL rewriting is used for request redirection, then the rewriting rule should make sure Web objects that are likely to be accessed together within a secure session will be rewritten to reside on the same CDN server. For DNS-based redirection, the DNS servers must maintain state information such that future queries from the same client are resolved to the same CDN server.

OTHER SECURITY ISSUES

The discussion on Web QoS so far has focused on denial-of-QoS attacks, raising the need for other security mechanisms such as authentication, secure sockets, and low-cost solutions to client request filtering. These issues are discussed next.

Client Authentication

As mentioned earlier, one fundamental problem of QoS performance isolation and differentiation is client identification. Different classes of clients need to be securely authenticated by robust and efficient methods. The simplest scheme is to identify the clients by their IP addresses. For example, the library of a university can configure its Web server to serve only those requests that originate from IP addresses within a certain range. This identification, however, is not accurate. In several cases, the IP address of the client is unavailable to the server. For example, it is possible that the client is behind a firewall or a proxy. In this case, it is the proxy's IP address that is seen by the server, not the client's. Besides, the granularity of authentication based on IP address can only be very coarse. Just because two different users used the same IP address does not mean they necessarily should be granted the same permissions or receive the same level of QoS. Moreover, the ease of IP address masquerading makes this mechanism inherently vulnerable.

To identify clients, Web servers may use "cookies," which work similarly to passwords. The server sends a cookie, which basically is a piece of state information, to a client upon the first access. The client's browser automati-

cally presents the server with this cookie when subsequent accesses are made. The server is therefore able to identify accesses that belong to the same client and separate them from those of another. Usually an expiration time is associated with a cookie. This capability may be used to implement session-based admission control. In general, cookies have several security flaws. For example, it is possible for cookies to be copied, allowing a third party to impersonate the client. Moreover, cookies are sent in plaintext.

The HTTP specifications (RFC 2617) provide two Web-specific authentication mechanisms, namely basic access authentication and digest access authentication. In basic authentication, clients are required to send a username/password pair to the server, in clear text, as part of their HTTP requests. The advantage of basic authentication is its simplicity. It requires no additional software support on the client side. However, basic access authentication is vulnerable to eavesdroppers. To avoid transmitting clear text, digest access authentication is added to HTTP/1.1. A server using the digest authentication mechanism first challenges the client using a nonce value. The client is then supposed to send the hash checksum of the username, the password, the given nonce value provided by the server, the HTTP request method, and the requested URI using some one-way hash function (e.g., MD5, SHA-1). This mechanism is more robust to eavesdropping because the most important feature of one-way functions is that it is *extremely* hard to figure out the original message from its hashed digest. Even if a sniffer gains access to the traffic between a client and the server, it is virtually impossible for him or her to decipher the client's username and password. Although it is supported by the Apache Web server, HTTP digest authentication still enjoys very little client support, causing it to remain in obscurity after having been proposed a few years ago.

It is worth mentioning that stronger authentication protocols generally cost more computation on both server and client sides. High computation overhead can be a deployability hurdle for authentication schemes.

Performance Implications of SSL/TLS

In recent years, the secure sockets layer has been widely accepted on the Web as a very strong authentication system that can provide server/client mutual authentication (assuming both parties have a public key) and encrypted communication. Originally designed by Netscape, SSL has been standardized by IETF and called transport layer security (TLS). HTTP over SSL/TLS, also known as HTTPS, has received support from popular Web server systems such as Apache and Microsoft ISS and is now playing a very important role in e-commerce. SSL/TLS authentication is based on the public key infrastructure (PKI) and is typically used to authenticate the server to the client. In contrast, client authentication is usually done by supplying a password (shared secret). When an SSL-capable client communicates with a Web server, the identity of the server is first confirmed using digital certificates, which are issued by a trusted third party called the certificate authority (CA). When the initial authentication is complete, the client sends the server a "master secret" encrypted with the server's public key. The Web server then

decrypts the “master secret” with its own private key. After that, a symmetric key is generated, which will be used to encrypt data sent between the client and the server during the session.

Secure communication over SSL/TLS, however, imposes significant performance penalties on Web systems. A previous study (Coarfa, Druschel, & Wallach, 2002) has shown that a standard Web server can handle only 10 to 30% of its normal load when processing secure SSL sessions. It is known that the largest performance cost of SSL is the handshake process of an SSL session, specifically the RSA operations to generate session keys. It is also shown that SSL/TLS is purely CPU intensive. Measures like reducing network traffic have very little effect on server performance.

The performance overhead of SSL/TLS has important implications on Web QoS service provisioning. Since an individual Web request/session is usually small, the overhead of establishing an SSL/TLS session can dominate the total cost of processing the Web request. This could diminish the effect of QoS differentiation mechanisms we discussed because the SSL/TLS overhead is equal for different client QoS classes. Imagine that establishing a SSL/TLS session takes 20 ms and that a QoS adaptation service makes the processing time for the requests in a session for two different client classes 5 and 10 ms, respectively, targeting for a QoS contract specifying a 1:2 service differentiation. The real response times experienced by the two classes of clients are actually 25 and 30 ms. This ratio is far from the 1:2 target.

Many solutions for alleviating the SSL/TLS performance penalty have been proposed. Since the task of SSL/TLS is purely CPU bound, one natural idea is using some dedicated components to offload this CPU workload. Today, hardware accelerators that perform operations of RSA are available from industrial vendors such as iVea, nCipher, and ArrayNetworks. These accelerators reduce load on the server CPU. Another approach that proved to be very effective in reducing SSL/TLS overhead is caching SSL session keys. The idea is that establishing an SSL session first attempts to reuse a cached session key, which was generated previously. Since session key generation is where the highest cost lies, reusing a session key greatly saves overhead. Only if the reuse attempt fails will a new session key generated. Experimental studies (Coarfa et al., 2002) showed that session key caching improves server throughput by two- to three-fold.

DoS/DDoS Attack

Denial of service (DoS) is known to be “an explicit attempt by attackers to prevent legitimate users of a service from using that service” (CERT, 1999). For example, attackers may send a huge volume of requests to saturate a server’s operating system resources such as bandwidth and CPU capacity. Consequently, the server may no longer serve requests from legitimate users. All denial-of-QoS attacks discussed in this chapter are special cases of this category. DoS and its variant distributed DoS (DDoS) are becoming more and more frequent in today’s Internet. In a recent measurement study (Moore, Voelker, & Savage, 2001), more than 12,000 attacks against more than 5,000 distinct targets were observed during a 3-week period.

The target servers include famous e-commerce Web sites and small ISPs. DoS/DDoS attacks have a very significant impact on server’s performance and sometimes cause service downtime, let alone QoS violations.

Although efficient means for preventing DoS attacks are still an open question, there are many defense mechanisms. One common practice for counteracting a DoS attack that is underway is to identify sources of the attackers and set up filters to drop packets from them. This kind of filters should be placed at the very early stage of packet processing (e.g., kernel TCP/IP stack or even border routers) so that the cost of dropping the packet is minimized. The drawback of this simple strategy is that oftentimes it is difficult to distinguish attackers from real requests because attackers can forge their source IP addresses since they do not expect meaningful responses from the target server. Besides, if the attacker identifying process gives false positives, packets from legitimate users will be dropped by mistake.

Many more intelligent solutions for defending specific DoS attacks have been devised. Take synchronization packet (SYN) flooding, the most common DoS/DDoS attack, for example. SYN flooding happens when attackers send a large number of TCP SYN packets but discard the SYN/ACK packets from the servers. Hence, the resources allocated for initiating the connections will not be released for a long time until TCP times out. A trivial solution for SYN flooding is for the operating system to randomly drop some SYN packets when a server detects that there are too many incomplete TCP connections lingering in the system. However, this is obviously not a desirable strategy because it may affect legitimate users. To alleviate the problem, we need mechanisms for reducing or even eliminating the resources consumed upon receiving a SYN packet. Two known approaches are SYN caching and SYN cookies. A SYN cache simply reduces the resource demand by allocating a much smaller structure to hold the initiation of TCP connection request. More resources will be taken on when the TCP handshake is completed. However, when there are too many incomplete connections in the system, the queue to hold SYN packets can overflow, causing packets to be indiscriminately dropped.

The SYN cookie goes one step further. It stores absolutely no state information. When a SYN is received, the server takes the hashing digest of the incoming information (IP address, port number, and sequence number) along with a secret key and makes the sequence number of the SYN/ACK sent back the digest. When the final handshake packet comes back from the client, the server uses the same hash function to get the digest of the incoming information of this packet. Note that the IP address and port number of this packet should be the same as those of the SYN packet and the sequence number of the SYN packet can be inferred from that of this packet. Also note that the digest the server just sent to the client will be included in this final handshake packet replied from the client. The server can compare the two digests. If they match, the state information structure will be allocated and the connection will be established. Otherwise, the packet will simply be discarded. Since SYN flooding attackers use forged IP addresses to send SYN packets, they will not be able to reply with a valid handshake packet.

Hence, the resource consumed on these packets is virtually zero. Actually, a server using a SYN cookie does not have to drop SYN packets even if the queue to hold SYN packet is full. The server simply sends back the SYN/ACK to the client, as if it has a queue of infinite length. The SYN cookie method is now included in FreeBSD kernel.

CONCLUSIONS AND FUTURE TRENDS

In this chapter, we briefly introduced the most important issues and mechanisms for providing quality of service in the modern Web architecture, as well as the implications of these mechanisms on security. The topic of providing secure quality of service guarantees is becoming increasingly important with the pricing of Internet services, and with the tendency to include performance requirements within the contractual obligations of service providers. The need for performance guarantees makes computing systems more vulnerable to attack, since impairing a system's ability to meet its performance requirements now constitutes a violation of its "proper" functionality. This performance-requirement-induced vulnerability gives rise to a multitude of denial-of-QoS attacks. In this chapter, the authors reviewed some of the most common attack methods, as well as mechanisms that can be used to mitigate their impact. The chapter also touched on security and performance considerations that arise in content distribution networks, as well as mechanisms for improving the performance of some essential components of any secure infrastructure. A particularly good reference for further readings on Web architecture, performance, QoS, and security issues is the recent book by Krishnamurthy and Rexford (2001).

GLOSSARY

Authentication The act of verifying client identity.

Backbone Provider A party that owns the communication fabric of an Internet backbone. Examples of backbone providers include AT&T, Sprint, MCI, and UUNET.

Cache Server A network server that acts as a cache of popular Web content and is able to serve it on behalf of the original servers.

Content Distribution Network A network of server platforms whose sole purpose is efficient content dissemination around the Internet backbone.

Cookies Small text files that servers put on the client's hard drive to save client and session information needed for future access.

Data-Pull Model A data communication model in which the client explicitly asks the server for data each time the data are needed.

Data-Push Model A data communication model in which servers unilaterally push data to the client without being asked. The model is a good optimization when future client requests can be accurately predicted.

Demultiplexing The separation of an incoming packet flow into multiple segregated flows. For example,

demultiplexing must occur upon the arrival of a packet at a server, in order to queue the packet for the right recipient.

Differentiated Services A framework for classifying network traffic and defining different policies for handling each traffic class, such that some classes receive better service than others.

EDF (Earliest-Deadline-First) A scheduling policy that schedules the task with the earliest deadline first.

HTML (Hypertext Markup Language) A language for defining the content and appearance of Web pages.

HTTP (Hypertext Transfer Protocol) The protocol used for Web access in the current Internet; there are currently two popular versions, HTTP 1.0 and HTTP 1.1.

IP (Internet Protocol) The glue that connects the computer subnetworks of which the Internet is composed and is responsible for packet addressing and routing between Internet senders and receivers.

IP Fragment Part of an IP-layer message after fragmentation.

Kernel The core part of the operating system, typically responsible for scheduling and basic interprocess communication.

Microkernel An operating system architecture where most operating system functions are delegated to user-level processes, keeping the kernel small.

Packet A unit of data transfer across a network.

Persistent Connections Communication abstraction implemented by HTTP 1.1. It allows the same TCP connection to be reused by multiple Web requests to the same server. This is a main departure from the traditional "one request per connection" model of HTTP 1.0.

Proxy Server A specialized server that performs an auxiliary Web content management function such as content replication, caching, or transcoding.

QoS (Quality of Service) The quantifying of different performance aspects of Web access such as timeliness and throughput.

Semaphore An operating system construct used for synchronization.

Sockets The main interprocess communication abstraction, originally introduced in UNIX. A socket represents a connection endpoint. The connection is between two processes on the same or different machines.

TCP (Transmission Control Protocol) The transport protocol used for reliable data communication on the Internet.

Threads The smallest schedulable entities in multi-threaded operating systems.

Transcoding The process of converting content on the fly from the server's format to a format more suitable to the client, or more appropriate for network load conditions.

Web hosting The business of providing resources (servers, disk space, etc.) to serving customers' Web pages. Typically, Web-hosting companies build large server installations of hundreds of machines for serving the Web sites. These installations are called server farms.

INTRODUCTION

Mobile devices are used for information generation, delivery, storage, and management; they can be carried and moved with ease. The mobile device market has extremely heterogeneous brands. They range from simple cellular phones to powerful laptop PCs. Generally speaking, however, they share similar physical characteristics, such as small screen size, short battery lifetime, limited input/output capability, limited computing power, and low network bandwidth. Nevertheless, mobile devices have become one of the fastest growing segments of the computer industry and will become the predominant medium for Internet access. There are two primary reasons for this trend. First, people want to communicate anytime and anywhere; and second, the rapid growth of wireless local area networks (WLAN) and new wireless transmission technologies have enabled higher connectivity.

This chapter provides an overview of two mobile device families. Each family is introduced from the following perspectives:

- Main functionality
- System resources (e.g., memory, computing power, and networking bandwidth)
- Input and output facilities
- Potential applications
- Embedded components (e.g., digital cameras, modems, and keyboards)
- Operating systems and software support

To better understand these devices, this chapter also outlines mobile communication protocols, security issues and measures, and mobile device management. In summary, we provide a conclusion and future trends. It should be noted that this chapter intends to present an overall picture of mobile devices and protocols as well as mobile device management. Many technologies and protocols cited in this chapter can be easily found elsewhere in this encyclopedia.

MOBILE DEVICE FAMILIES

Based on the main functionalities and the form factors, we classify mobile devices into two families as listed in Table 1. The first family includes mobile handsets, such as Web-enabled phones, personal digital assistants (PDAs), pagers, and portable storage devices. The second family includes mobile PCs, such as laptop PCs and tablet PCs. For a quick comparison among these mobile devices, Table 1 also provides the distinguished features of each device. It should be noted, however, that this list is not exhaustive: there are many other mobile devices available on the market. Next, we describe each family in detail.

Mobile Handsets

Web-Enabled Phone

For many years, the primary function of cellular phones was voice communication. However, starting in the year 2000, cellular phones have begun to incorporate basic data services, such as messaging and Web access. A Web-enabled phone is a cellular phone with features including Web access, messaging, e-mail, entertainment, address book, and customized applications. To access the Web or the Internet, a wireless application protocol (WAP) microbrowser is installed on each Web phone. The microbrowser allows users to access simplified versions of Web sites and to retrieve information such as stock quotes, weather forecasts, or news briefs. Messaging allows Web-enabled phones to send and receive short messages, which could include text, audio, and video. Most Web-enabled phones let users send and receive a short e-mail by running Microsoft Outlook or Web-based e-mail programs. The majority of Web-enabled phones also allow users to play games, listen to music, and take pictures. Most Web-enabled phones employ various digital transmission technologies, such as time division multiple access (TDMA) and code division multiple access (CDMA).

Web-enabled phones form a broad category, including Smartphones, WAP, i-Mode, Internet, Java, and GPS phones. Although the functionalities and features of these

Table 1 Mobile Devices Families

Mobile handsets	Web-enabled phone		Voice communication Web access Messaging E-mail Entertainment
	Personal digital assistant		Personal Information Management Word processing Web access Touch screen interface Handwriting recognition
	Pager		One- and two-way paging Address book E-mail Messaging
	Portable storage device		Large storage capacity Digital audio player Digital photo display Address book
Mobile PCs	Laptop PC		Most powerful mobile device High-speed networking connection Office applications Standard keyboard
	Tablet PC		Office applications Web access Digital ink input Handwriting recognition

mobile phones vary, essentially they share the same characteristics: small screen size, simple input and output facility, limited computing power, and low network bandwidth. A Web-enabled phone typically provides a small screen with between 6 and 12 lines of text, a standard 12-button keypad, and a few special keys (such as joysticks) for data entry. The typical phone battery life is from 3 days to a week depending on how often it is used.

Traditionally, Web-enabled phones create the wireless networking connection through a built-in wireless modem. Once connected, the user can perform voice calls or data communications or both at the same time. The rapid growth of wireless local area networks (WLANs) in the recent past provides an opportunity for large-scale WLAN integration into public phone networks. With the newly produced WLAN enabled handsets, users have immediate and convenient access to a wide variety of cost-effective high-bandwidth WLAN applications and services. One example is Nokia's 9500 Communicator. It provides extensive network access flexibility through WLAN, EDGE (enhanced data GSM environment), and Bluetooth.

Spurred by the ever-growing demands of business professionals, Web-enabled phones are expected to have more features in data processing and communications. Recently developed Web-enabled phones incorporate PDA features and have a larger screen to allow execution of data based tasks. One such phone is Samsung's SGH-D415. It can be easily converted into a full-size phone by

sliding up the cover, exposing a wide display and large keypad. The 262,144-color display offers higher quality and richer images than conventional PDA displays. Users can receive and send multimedia messages of 100 kB each and store up to 1 MB of data. They may also download Java applets to broaden their mobile phone usage. When these phones also incorporated a global positioning system (GPS) receiver, the users can tell their exact location and send their position to a map on a friend's cell phone. The phone can even suggest a route to a user's friends.

Personal Digital Assistant

A PDA is a handheld mobile computer that assists users with its information management capabilities. The main operating systems used on PDAs are Windows CE, Palm OS, and Linux. Data are entered through either a small keyboard or a touchscreen with handwriting recognition. The output is a medium-sized color screen. Originally, PDAs were designed for personal information management (PIM). These tasks include, for example, address books, calendars, schedulers, calculators, to-do lists, and notes. More advanced PDAs have a preinstalled micro-browser for Web viewing, a built-in camera for video capture, still imaging and multimedia messaging. Some of them run word processing applications, spreadsheets, e-mail programs, and electronic book reading programs. Certain PDA models can even play music and record voice memos. Most PDAs can exchange information with

a desktop or laptop PC by using synchronization utilities, such as Microsoft ActiveSync. Just like Web-enabled phones, the wireless networking connection is made through a built-in wireless modem, WLAN, EDGE, or Bluetooth.

PDA's are usually palm sized and typically have a touch screen and a stylus. The user must tap on an on-screen keyboard or enter data by writing on the screen with built-in character recognition support. Because PDA's are typically designed for handling basic PIM tasks, they generally have less memory (usually 2 MB), slower processors, and gray scale displays. Advanced PDA's usually have up to 256 MB RAM, processors at clock speeds of up to 1 GHz, and color displays. Therefore, they are able to handle other applications, including short message service (SMS), e-mail, and Web browsing.

Although PDA's are basically data-centric mobile devices, the convergence of voice and data functionalities in one device has added new features to PDA's. Recently developed PDA's, such as the RIM's BlackBerry 7780, the Nokia's 9210 Communicator, and the Ericsson's R380, are effectively PDA equipped phones. They integrate phone functionality, e-mail, SMS, Web browser, customized applications, and the Java development platform into a single wireless handheld device. Larger screens and easier data input make them more appealing devices for browsing wireless data than Web-enabled phones. More intelligent PDA's, such as Garmin's iQue 3200/3600, are designed for business users who want a device that can manage their personal information and deliver personal navigation in a single unit. They offer a fully integrated GPS that lets a user see an electronic map and get turn-by-turn directions.

Pagers

A pager is a small wireless device that uses a paging network to send and receive text messages (Beaulieu, 2002). To page someone, a person dials the service number, enters the number of the person to be paged, and sends out a short message. Immediately after a short transmission delay, the paged person will receive the message. For this reason, pagers are considered alerting devices. Originally, pagers were designed for one-way paging; the pager beeps and displays a short text message, and the paged person can take action accordingly. But the two-way pager enables the *paged* pager to automatically respond upon receiving a message. More recent paging devices, such as Motorola's Talkabout T900 2-Way, offer more features in addition to the basic paging services. These include the following:

- Wireless e-mail
- Calendar, address book, and memo pad
- Short message service (SMS)
- Information services (e.g., weather)
- Custom applications (e.g., Java)
- Preprogrammed reply capability
- Confirmed message delivery
- Automatic signature capability

These paging devices are essentially an e-mail pager with built-in Web phone functions. This indicates the

convergence between two-way paging devices and Web phones. Pagers, however, have the unique features of low-cost and time sensitive messaging capability. A Web phone may act as a pager in terms of messaging and e-mail. The main difference is the network connection. Web-enabled phone users need to establish a dedicated network connection for messaging and sending e-mail, whereas in paging systems, the network connection is always there. Pager devices are specifically targeted at mobile professionals who depend on e-mail as a mission critical business tool.

Portable Storage Devices

Portable storage devices are the devices that are portable, lightweight, and durable and that allow users to permanently store their information. These devices include DVDs, CDs, memory sticks, Zip disks, SuperDisks, USB flash drives, hard drive MP3 players, and iPods. As an example, iPod will be detailed as follows.

iPod (<http://www.apple.com/ipod/>) features a combination of huge hard drive capacity and a digital audio player. The hard drives range from 20 GB to 80 GB, letting you easily slip up to 10,000 songs or 25,000 digital photos in your pocket and enjoy them wherever you go. With the click wheel, users can select playlists and scroll through a long list of albums or artists to choose their favorite song. The digital audio player is platform dependent. For Windows, it is called Musicmatch Jukebox Plus, whereas for Mac, it is called iTunes.

Popular iPod features include a calendar, address book, to-do list, alarm clock, games, and text reader. The iPod's Notes Reader lets users take text-based information such as news downloaded off the Web, stock tips, restaurant reviews, directions, and shopping lists anywhere. The iPod has a LCD display for viewing 6 to 10 lines of text at a time. Its battery life could be as long as 15 h. The newest member of the iPod family, the iPod Photo, displays 25 full-color thumbnails at a time. You can scroll through them the same way you scroll through song titles.

The iPod can be connected to a computer through either a FireWire (Mac or Windows) or USB (Windows only) port. Simply plug the iPod into the Mac or Windows computer to transfer music libraries and playlists. It is possible to load an entire CD onto an iPod in as little as 5 s. Users may also use the iPod to capture voice memos. The 40 GB iPod allows up to 28 days of continuous recording. The files automatically synchronize with the music library when it is connected to the computer.

Mobile PCs

Laptop PC

A laptop PC is a portable desktop PC. Like other mobile devices, laptop PCs can be carried and moved with ease. The main operating systems used on laptop PCs are Windows XP, Linux, and Mac OS X. A laptop PC typically has all the functions that a desktop PC has. These include the following:

- Office applications (e.g., word processing and spreadsheet processing)
- Web access
- E-mail
- Information services (e.g., weather and quotes)

- Multimedia (e.g., digital video and audio)
- Custom application (e.g., Java)
- Publishing
- Games

Laptop PCs are considered a special type of mobile device because of the following unique features:

- Powerful computing resource—most laptop PCs have the equivalent capabilities as desktop PCs. One configuration of a laptop would be as follows: Pentium Mobile Processor, Microsoft Windows XP Professional or Home Edition, video card with 64 MB or more of DDR video memory, 1 GB DDR SDRAM, and 40 GB internal hard drive. Thus laptop PCs can run the same operating systems and applications customized for desktop PCs.
- High-speed networking connection—most laptop PCs support both wired network connection (Ethernet 10/100/1000) and wireless network connection (802.11x and Bluetooth).
- Convenient input and output format—laptop PCs have screen sizes of up to 17 in. and the same keyboard as for desktop PCs. All laptop PCs also provide an embedded mouse as well as an external mouse.

Despite all these attractive features, the size and weight of laptop PCs limit their mobility. Because they run comprehensive operating systems and have complex hardware, it may take a few minutes to boot up the system; instead of a few seconds for other mobile devices. Laptop PCs that were produced prior to 2000 do not support wireless communications. These laptop PCs have to rely on the wired network connection, which is not convenient if a user is traveling.

Tablet PC

A tablet PC is a general purpose mobile computer with a large, integrated, interactive screen (Lee, Schnider, & Schell, 2004). Tablet PCs include many innovations, including handwriting recognition, longer battery life, a low-heat processor and an operating system that is a specialized version of Windows XP Professional. Users may write with a *digital pen* directly on the screen of the tablet PC, create handwritten documents, store, search, and review handwritten notes, and convert handwritten notes into text to use in other applications. A tablet PC typically has all the functions that a laptop PC has. However, a tablet PC is a perfect choice if you often need to be away from your desk or in an area where a laptop PC is not practical. Some tablet PCs, such as Acer's TravelMate 100, are able to morph between laptop and tablet layouts.

Tablet PCs are very similar to PDAs in terms of handwriting-enabled features. However, a tablet PC runs a more powerful and fully featured operating system. It also has a hard disk drive. Unfortunately, these features also mean that you cannot boot up a tablet PC nearly as rapidly as a PDA. Nevertheless, the tablet PC's large touch screen, digital pen, QWERTY keyboard, and sophisticated handwriting recognition and drawing capability have raised hopes that it might become the mobile device of choice for enterprise workers. These workers not only have to be mobile but also have to read, write, and type a great deal.

MOBILE PROTOCOLS

While there are two families of mobile devices, they generally employ the same communication protocols for messaging, e-mail, and Web access. Mobile protocols can be generally classified as peer-to-peer protocols and client-server protocols based on the communications model. In the peer-to-peer communication model, two mobile users send and receive messages instantly or by a store-and-forward manner. In the client/server communication model, a mobile user typically requests services or retrieve information from a more powerful server, which is typically a stand-alone unit. Next we introduce protocols deployed in each communication model.

Peer-to-Peer Protocols

Peer-to-peer protocols refer to protocols that enable one mobile user to send and receive messages to and from another mobile user. The operation can proceed instantly or in the store-and-forward manner. In the instant mode, the sender and receiver need to be well synchronized. The communication happens only if both peers are ready. Three well-known protocols are short message service (SMS), multimedia message service (MMS), and instant messaging (IM). In the store-and-forward mode, the sender starts the communication without synchronization with the receiver. Messages are temporarily stored on a server and retrieved later by the receiver. Whether or not the receiver is ready does not affect the operation of the sender. E-mail protocols work in the store-and-forward mode.

Short Message Service

This is a globally accepted wireless service protocol that provides a connectionless transfer of short text messages to and from mobile devices. It was first introduced in 1991 in Europe as part of the GSM standard. In North America, SMS was made available initially on digital wireless networks based on GSM, CDMA, and TDMA standards.

Figure 1 demonstrates the message delivery processes using the SMS protocol. Once a message is constructed at the source mobile device, it is sent over a wireless connection to the SMS center (SMSC) for that particular wireless carrier network. The SMSC then gets the message to the destination mobile device through the wireless carrier. To do this, the SMSC sends a SMS *request* to the home location register (HLR) to find the destination mobile device. Once the HLR receives the request, it responds to the SMSC with the destination mobile's status, which includes (1) inactive or active and (2) where the mobile is

Figure 1: SMS architecture.

roaming. If the response is *inactive*, then the SMSC will act as a store-and-forward system and hold the message for a period of time. When the destination mobile device becomes active, the HLR sends a SMS *notification* to the SMSC, and the SMSC will attempt delivery. The SMSC transfers the message in a short message delivery point-to-point format to the serving system. The system pages the destination mobile, and if it responds, the message gets delivered. The SMSC receives verification that the message was received by the end user and then categorizes the message as *sent* and will not attempt to send again.

A distinguishing characteristic of SMS is that an active mobile handset is able to receive or submit a short message anytime and anywhere, independent of whether a voice or data call is in progress. SMS also guarantees delivery of the short message by the network. Temporary failures because of unavailable receiving mobiles are identified, and the short message is stored in the SMSC until the destination mobile becomes available. Initial applications of SMS focused on eliminating alphanumeric pagers by permitting two-way general purpose messaging and notification services, primarily for voice mail. As technology and networks evolved, a variety of services have been introduced, including e-mail, fax, and paging integration, interactive banking, information services, and integration with Internet-based applications.

With the advent of more mobile applications, some significant limitations of SMS have become apparent. The most serious of these is that messages must be no longer than 160 alphanumeric characters and contain no images or graphics. Another one is the lack of interoperability between network operators (Mallick, 2003). For these reasons, enhanced message service (EMS) was introduced to enable mobile devices to send and receive messages that have special text formatting (such as bold or italic), animations, pictures, icons, sound effects, and special ring tones. To help overcome the message size limitation, EMS allows for message concatenation. Because EMS is based on SMS, it can use SMSC the same way that SMS does. EMS messages that are sent to devices that do not support it will be displayed as SMS transmissions. The standard is considered an intermediate technology between SMS and multimedia message service (MMS), with more capabilities than SMS but fewer than MMS.

Multimedia Message Service

Multimedia message service (MMS) is a new standard in mobile messaging. Like SMS, MMS is a way to send a message from one mobile to another. The difference is that MMS can include not just text, but also images (JPEG, GIF format), audio (MP3, MIDI), and video (MPEG), or any combinations of the above. In addition, MMS also allows users to send MMS messages from a mobile phone to an e-mail address. This feature dramatically increases the scope of mobile communications. In addition, users can create, edit, preview, and send MMS multimedia messages, either via mobile handsets or via the Web. Each multimedia message contains a number of *pages*; each page may include content in different files associated with different media types. These files are incorporated into the slide show using the synchronized multimedia integration language (SMIL) (Bulterman & Rutledge, 2004). SMIL is

an XML-based language specified by the World Wide Web Consortium (W3C) that is used to control the presentation of multimedia elements. Within the SMIL specification is a set of tags that can be used for defining the layout of each page and the time that each page is displayed.

MMS is an important emerging service that allows sending multiple media in a single message and sending a message to multiple recipients. The originator can easily create a multimedia message, using either a built-in or accessory camera, or can use images and sounds stored previously in the mobile. The message is first sent to the MMS Center (MMSC)—a similar concept to SMSC for SMS messages. Once the receiving mobile is located and is ready to receive messages, the MMSC immediately forwards the message to the receiving mobile and deletes the message from its memory. On a compatible mobile, the MMS message will appear with a new message alert. The picture message will open on the screen; the text will appear below the image and the sound will begin to play automatically. If the message is sent to a non-compatible MMS mobile the user will receive a SMS message. The user may then be given a Web site address to view the message. One of the main practical differences between MMS and SMS is that although SMS messages are limited to 160 bytes, an MMS message has no size limit and could be hundreds of kilobytes in size. MMS requires a 3G network to enable such large messages to be delivered, although smaller messages can be sent even with 2G networks using general packet radio services (GPRS).

Instant Messaging

Instant messaging is a type of real-time communications service that enables you to create a kind of private chat room with another individual over the Internet. IM allows you to maintain a list of people that you wish to contact, often called a contact list. You can send messages to any of the people on the contact list as long as that person is online. Typically, the IM system alerts you whenever somebody on your contact list is online. You can then initiate a chat session with that particular individual by opening up a small window where you and your contact can type in messages that both of you can see. Indeed, IM provides similar capabilities to other two-way messaging technologies, such as SMS, paging, and e-mail, with an addition of one significant feature: *presence* (Mallick, 2003). Presence lets you know the current status of the people with whom you are communicating.

Most of the popular IM programs provide a variety of features allowing your contacts to share your favorite Web links, music, images, and files stored on your device. ICQ is an example of IM program. The ICQ client that resides on your computer connects to an ICQ server and through the server communicates to your contacts, provided they are also ICQ members. AOL Instant Messenger (AIM), another IM program, supersedes ICQ by allowing AOL members to communicate with nonmembers.

Although AIM and ICQ are the leaders in the IM race, there are several other worthy entrants. Microsoft's MSN Messenger, like other IM programs, allows users to talk with other MSN Messenger users just like they would talk over the telephone. Another IM utility is Yahoo

Messenger. The interesting thing about Yahoo Messenger is how well it integrates with other Yahoo content and services. There are several utilities, such as Odigo and Omni, that combine various services. Odigo allows users to combine AIM, ICQ, and Yahoo Messenger contact lists. Omni lets users combine the functionality of AIM, ICQ, MSN Messenger and Yahoo Messenger, plus file-sharing utilities, all in one program.

E-mail Protocols

Three widely used e-mail protocols for mobile users are simple mail transfer protocol (SMTP), post office protocol version 3 (POP3), and Internet message access protocol (IMAP). SMTP is a protocol for sending e-mail messages from the e-mail client to e-mail server. When a mobile user wants to send an e-mail, his client application first establishes a TCP connection to port 25 of his e-mail server. The e-mail server will then look at the address to which this message is being sent and set up another TCP connection to the e-mail server at the destination address domain. When the destination e-mail server receives the message, it puts the message into the recipient's mailbox if such a recipient exists. Otherwise, an error report is returned to the message originator. Either case, the TCP connection will be released after the transmission is finished.

POP3 is a protocol used by e-mail client to retrieve the e-mail messages from the destination mail server. When mobile users check their e-mail, the client application establishes a TCP connection to port 110 of their e-mail server. Once the connection is set up, the POP3 protocol authorizes the user by checking the user's name and password. Once authorized, the user is allowed to access his stored messages and download the messages onto his local machine. Once the messages are delivered to the client they are deleted from the e-mail server.

IMAP is a protocol that allows e-mail clients *online* to process their e-mail. In this design, e-mail is still delivered to an e-mail server and the remote client reads the messages from the server using IMAP e-mail software. The messages are not all downloaded to the client machine. The client can ask for specific messages or search the server for messages meeting certain criteria. The user also has the option to save the messages locally. The mobile user receives the biggest advantage of the IMAP protocol because he or she simply needs a machine that is connected to the Internet to read his or her messages.

Client/Server Protocols

Client/server protocols refer to protocols that enable a mobile client to access a Web server or receive information from a Web server at anytime and anywhere. In this section, we outline hypertext transfer protocol (HTTP), handheld device markup language (HDML) notifications, wireless application protocol (WAP), WAP push protocol, and Web services.

HTTP

HTTP is a transfer protocol employed by mobile clients to access Web servers. It specifies what information mobile clients may send to servers and what responses they receive from servers. The original language to specify

the information is hypertext markup language (HTML). HTML is a set of markup symbols or tags inserted in a file to tell a browser how to present output on a screen. HTML 4.1 is the latest version preceding the introduction of the extensible markup language (XML). Both HTML and XML contain markup symbols to describe the contents of a page or file. XML, however, describes content without style. More specifically, XML describes the content in terms of *what* data are being described. One of the most powerful features of XML is that it allows a user to construct other languages, including new markup symbols and attributes. However, both HTML and XML were designed for stand-alone Web servers and desktop PCs with a default window width of about 80 characters. This makes it unsuitable for handheld mobile devices. Three widely used markup languages for mobile devices are HDML, wireless markup language (WML), and compatible HTML (cHTML) (Lu, 2002).

A microbrowser on a mobile client typically connects to a Web server by establishing a TCP connection to port 80 on the server. After the connection is established, the mobile client sends request *methods* to the server. After the server receives the request, it retrieves the specified content and responds to the mobile client by sending the requested information in HDML, WML, or cHTML format. The microbrowser on a mobile client then interprets the information and displays it on the mobile device. With the current HTTP 1.1, it is possible to have multiple requests and responses take place under one TCP connection. The connection will be released on demand or after a given amount of time.

HDML Notifications

HDML notifications are the first form of push messaging available to mobile users (Mallick, 2003). They allow the server to send information to clients in a timely fashion—a process similar to SMS text messaging. But they differ from SMS in that they interact with the mobile device's microbrowser through the HDML gateway. One way to interact is to send an alert message, which typically contains a uniform resource locator (URL), to the device's microbrowser that will beep or display a visual signal to notify the user that new information is available. Another interaction method is to send notifications to mobile devices instructing them to remove certain URLs from the microbrowser's cache or preload contents into the microbrowser's cache. These kinds of operations are transparent to the users.

HDML notifications provide a powerful way to push contents to mobile users. However, because HDML notifications are a proprietary messaging technology developed by Openwave, they are only supported in Openwave microbrowsers.

WAP and WAP Push

WAP is a communication protocol between server applications and mobile clients (WAP 2.0, 2002). When a mobile client with a WAP browser accesses a Web server, it generates an encoded request in WML format and sends the request to a WAP gateway. The WAP gateway then forwards the request to the Web server. The Web server parses the request and responds to the WAP gateway with either

Figure 2: WAP communication model.

WML or HTML content (depending on whether the Web server provides WML content). If the server does not provide WML content, the Web server responds to the WAP gateway with HTML content. The WAP gateway needs to encode the HTTP response and return it to the WAP browser on the mobile client in WML format. Figure 2 illustrates this process, where mobile client could either retrieve a static document from the Web server or request the Web server to launch an application and return the results. In either case, the content is sent back to the mobile client for viewing or further processing. More information about WAP can be found in Chapter 68 (which is dedicated to WAP).

In the WAP communication model described above, a mobile client requests a service or information from a Web server, which then responds by transmitting information to the mobile client. This is known as *pull* technology. In contrast to this, there is a *push* technology, in which there is no explicit request from the client before the server transmits its content. WAP Push, first introduced in the WAP 1.2 specification, is the successor to HDML notifications. It is the delivery of content to the mobile device without previous user interaction (Openwave, 2002). Figure 3 depicts the WAP push structure. The push initiator (PI) is an application that pushes content and delivery instructions to the push proxy gateway (PPG) using the push access protocol (PAP). The PPG uses the push over-the-air (OTA) protocol to actually push the content to the WAP client over a wireless network. The PPG may also store the content temporarily if it cannot deliver the content immediately. It also maintains the status of each message, allowing the PI to cancel, replace, and request the current status of a message. The WAP client is a mobile device equipped with a WAP microbrowser to view the pushed content.

Web Service

“A Web service is a software system identified by a URI, whose public interfaces and bindings are defined and described using XML. Its definition can be discovered by other software systems. These systems may then interact with the Web service in a manner prescribed by its definition, using XML based messages conveyed by Internet protocols (W3C Web service, 2004).” Based on this

Figure 3: WAP push structure.

definition, a Web service application is built from three major components:

1. A Web service registry, which stores information about Web service providers and Web services.
2. A Web service client, which makes use of a service offered on the Web. Web service clients can discover available Web services and get detailed information by searching the registry.
3. A Web service, which offers a service and is accessible via a standard messaging and transport protocol. Web services publish information about themselves in a Web service registry.

Accordingly, the following three technologies are the forefront for implementing a Web service:

1. Universal discovery, description and integration (UDDI) is a standard for Web service registries (UDDI Version 3.0.1, 2003). UDDI defines a set of services supporting the description and discovery of Web service providers, the available Web services, and the technical interfaces that may be used to access those services. Based on a common set of industry standards, including SOAP and XML, UDDI provides an interoperable, foundational infrastructure for a Web services-based software environment.
2. Simple object access protocol (SOAP) is a protocol for a program on client to call a Web service on server by sending XML data over HTTP (SOAP Version 1.2, 2003). It also specifies how the called program can return a response. Unlike other similar technologies (CORBA, Java RMI, and DCOM), SOAP is an open standards protocol; this provides interoperability among machines running different operating systems.
3. Web services description language (WSDL) is an XML-based specification that provides a standard format for describing Web services (WSDL Version 2.0, 2004). It contains the information about how to invoke the service and what, if any, response to expect. WSDL enables one to separate the description of the abstract functionality offered by a service from concrete details of a service description such as *how* and *where* that functionality is offered.

To deploy the Web services technology for mobile devices, mobile Web services were designed to enable mobile users to take advantage of wireless applications, such as mobile messaging and location-based services, and delivering integrated services across wired and wireless networks. Microsoft and Vodafone achieve this by using an XML-based Web services architecture, allowing developers to build new, innovative services across both fixed and wireless networks. IBM provides the Web services tool kit for mobile devices (WSTKMD) and the run-time environments that allow development of applications that use Web services on small mobile devices, gateway devices, and intelligent controllers. The Mobile SOAP server uses the WSTKMD run-time environment in conjunction with a mobile gateway server to receive SOAP requests from any SOAP client and to return a response. Other mobile

Web service initiatives include Sun's Javafirst project, Symbian's Action Engine mobile Web services platform, QUALCOMM's Binary Runtime Environment for Wireless (BREW), and GSM Association's M-Services.

MOBILE DEVICES SECURITY AND MEASURES

We start this section by first introducing the common security issues in computer networks. Then we clarify how these issues apply specifically to mobile devices and protocols. Network security issues can be divided into six closely interrelated areas:

1. **Authentication:** This deals with determining the identity of the communication partner.
2. **Authorization:** This determines whether an authenticated user has the permission to access the system resource or to receive services.
3. **Confidentiality:** This keeps the data encrypted so that the data are out of the hands of the third party.
4. **Integrity:** This ensures that the data has not been altered or corrupted in any way during the transmission or storage.
5. **Availability:** This prevents malicious users from blocking legitimate access to network resources or services.
6. **Nonrepudiation:** This guarantees that no communicating party can deny the fact that it once sent a message and deny the contents included in the message.

Many security issues in mobile networks are essentially the same as those described above. However, security protocols developed for desktop PCs do not work well on mobile devices. The mobility and wireless natures of mobile networks make the security more challenging. Indeed, special design attention is needed to provide an acceptable security level for mobile devices. In this section, we first introduce security attacks on mobile devices; then we examine mobile security measures at three levels: (1) the mobile-user level, (2) the mobile data and applications level, and (3) the network communications level.

Security Attacks on Mobile Devices

Security attacks on mobile devices can be in either passive mode or active mode. A passive attack does not attempt to damage the target mobile system. It performs the attack mainly by spoofing, eavesdropping, and installing malicious code. Information collected can be used to analyze the target mobile system and thus steal the confidential information. An active attack tries to damage the target mobile system completely and instantly. The main approaches for active attacks include, for example, denial of service (DOS), man-in-the-middle, and theft. Because of their natures, passive attacks are more difficult to detect and active attacks are more detrimental. Following are the typical attacks on mobile devices:

- **Spoofing:** This is an attempt to obtain unauthorized access to a mobile system by pretending to be a legitimate

user. If the attacker succeeds, he or she can then create fake responses to the mobile system in an attempt to acquire further knowledge and access to the associated wireless network. It is possible to prevent spoofing by a strong combination of user authentication and authorization.

- **Eavesdropping:** This is a technique to monitor data flow on a mobile network. By listening to network data, unauthorized parties can obtain sensitive information that allows them to further damage mobile users. It is possible to prevent eavesdropping by deploying a strong confidentiality mechanism.
- **Malicious code:** This is a technique to install a small piece of code on mobile devices to perform damaging activities by stealing private information, modifying data, deleting data, and blacking screens. These codes could be in the format of spyware or viruses and can be triggered by certain events, such as network transmissions or event time. Even worse, they can easily be spread to other mobile devices or networks by a simple call. It is possible to combat this attack by embedding a strong authorization algorithm and to install on-device built-in security checks to ensure that only authorized code is allowed to execute.
- **Denial of service:** This is a technique to block legitimate access to the mobile devices. A wireless network is even more vulnerable to DOS attacks, because the attacker is not tied to a wired connection. In the case of mobile phones an attack can be mounted from anywhere in the world. Even worse, an authorized device could also become infected and consequently be used to mount a DOS attack. It is possible to reduce DOS attacks by limiting the devices authorized to connect to a mobile thus ensuring the availability.
- **Man-in-the-middle (Zhang & Chen, 2004):** In this technique an attacker intercepts the messages transmitted between the communicating parties. The intercepted messages can then be modified, delayed, relayed to another party, and replayed to the legitimate communicating party. Under this attack, an attacker could pretend to be an authorized user, to access a network or information, even when the captured information was strongly encrypted. It is possible to alleviate this attack by implementing a strong integrity system.
- **Theft:** Modern mobile devices are increasingly lightweight in design. Because of this, mobile devices tend to be easily lost or stolen and thus the data stored on devices and the network resources accessible through the devices are exposed to serious attack.

Except the theft attack, whose prevention depends primarily on device owners, other attacks occur at different communications levels, which are detailed next.

User-Mobile Level Security Measures

The main security issue at this level is user authentication (i.e., verifying that a person attempting to access a mobile device is a legitimate user). Security measures at this level help mitigate the attacks of spoofing, man-in-the-middle, and theft.

There are several mechanisms to perform authentication. The most common one is a strong username/password combination. Many mobile devices have built-in username/password functionality. This requires the user to authenticate before they are granted access to the device. When a user attempts to access the device with an incorrect username/password combination, the system imposes a time delay before allowing access again—a delay that increases exponentially with each attempt. A failure after a limited number of tries indicates an unauthorized usage. More rigorous authentication methods include (Dedo, 2004)

- Signature authentication
- Picture-based passwords
- Fingerprint authentication
- Smart card security
- Secure ID card authentication
- Certificate authentication on a storage card

By doing one or more of the aforementioned authentication processes, a user is required to authenticate every time he or she accesses the device and the associated network. Although this might be considered a usability drawback, it is an essential measure to combat attacks such as spoofing, man-in-the-middle, and theft.

Mobile Data and Applications Level Security Measures

The main security issue at this level is user authorization (i.e., verifying the person has the appropriate authority to access the data and run the applications stored on the device and the associated network). Security measures at this level help mitigate spoofing and theft attacks.

Mobile users often store important documents on the mobile device itself—either in the memory or a storage card that can store hundreds of megabytes to tens of gigabytes. To protect these documents as well as other sensitive data such as username/password and personal information, effective encryption algorithms are designed and implemented on the device itself and on external storage cards. There are a number of ways to encrypt the stored data to protect it from unauthorized access. For mobile PCs, Microsoft offers a mechanism for storing encrypted data in a relational database, protected with both 128-bit encryption and a password.

Recently, as more computing power and local storage become available on mobile devices, many more applications can be implemented on mobile devices. Such applications are also called smart client applications. In this case, the application may have a login page that authenticates against a local database. A user must log in to use a particular application regardless of whether the mobile device is connected to a network.

Network Communications Level Security Measures

The main security issues at this level are confidentiality, integrity, and nonrepudiation. Security measures at this

level help mitigate the attacks of eavesdropping, DOS, and man-in-the-middle.

To protect data transmitted over the Internet and wireless networks, there are three steps needed before a user can transmit data (Brown, 1995; Zhang & Chen, 2004):

- Security provisioning: This is to generate and distribute credentials to both users and the network.
- Local registration: With the provisioned security information, a user can perform registration with the network to gain permission to use the network.
- Authentication and key agreement (AKA): The AKA provides a methodology to authenticate a user and to generate two keys, an encryption key and an integrity check key. In addition, there is also a secret key shared by the user and the network that is available only to the authentication center. Thus, the mobile and network mutual authentication allows mobile users and networks to authenticate each other (3GPP, 2002).

A broad range of security algorithms have been developed and deployed in the above three steps. The main measures are data encryption, digital certificates, Internet protocol security (IPSec), transport layer security (TLS), and WAP security.

Encryption algorithms (more details can be found in Chapters 108–117 of Volume II) encode information in such a manner that only the persons or applications with the correct key can decode it. Digital certificates (more details can be found in Chapter 56) provide a way to guarantee that a public key belongs to the party it represents (Mallick, 2003). For this to be successful, the certificate itself also has to be verified to ensure that it represents the claimed party. This is accomplished using a trusted third party called a *certificate authority*. IPSec (more details can be found in Chapters 64 and 65) is a set of protocols in the network layer to provide cryptographic security services that will flexibly support combinations of authentication, authorization, confidentiality, and integrity. TLS (more details can be found in Chapter 66) is a protocol in the transport layer to ensure confidentiality between communicating applications and their users on the Internet. When a server and client communicate, TLS ensures that no third party may eavesdrop any message.

WAP (more details can be found in Chapter 69) is a standardized protocol that allows a mobile device to retrieve information from a server. There are several components used by the WAP specifications to provide security. A WAP identity module (WIM) stores certificates and is used by the wireless transport layer security (WTLS) to provide a TLS-like secure connection between the mobile device and a WAP gateway. There are also functions defined that allow data to be signed. Earlier versions of the WAP specifications defined a WAP gateway that mapped the WAP protocols onto Internet protocols to allow WAP devices to connect to servers on an IP network. This allowed the transmission to become vulnerable at the WAP gateway. WAP 2.0 addresses the lack of end-to-end security by introducing support and services for Internet protocols into the WAP environment. Internet protocols can, therefore, be used directly between the client and wireless network

and this eliminates the need for protocol translation at the WAP gateway. This provides secure end-to-end communications.

MOBILE DEVICE MOBILITY MANAGEMENT

Mobility is the ability for mobile devices to remain connected to the network continuously when they move. Mobility management consists of three components: (1) handoff management, (2) location management, and (3) roaming management. Handoff is a process in which a mobile device changes its network attachment point within the same administration domain. Location management is a process in which an association between the mobile device and its home network as the mobile device moves from one network to another. Roaming is a process where a mobile device changes its network attachment point between different administration domains.

Handoff Management

In an attempt to increase the system capacity, modern mobile networks are organized as a set of radio cells. Users tend to move in and out of cells frequently without notice. The system therefore needs to maintain the continuity of an ongoing connection whenever a user crosses the cell boundary. A typical example is that a mobile device moves from one cell to another and thus its radio channels will be changed from one base station to another base station. Because of the dynamic nature of the mobile networks, a changing of one radio channel to another within the same base station is also considered handoff. It should be noticed that handoff management is one of fundamental features of mobile networks. Essentially, all connections are established after a successful admission process. That means once the system admits a connection request, it is totally the network's responsibility to maintain the connection until the user tears it down. In an effort to reduce the handoff overhead, a cluster of neighboring cells can be grouped together and controlled by a mobile switching center (MSC). The MSC has much more computing power and functionalities than base stations. When a mobile device moves among cells within the same cluster, the handoff is mainly handled by the serving MSC. This is called *intraswitch handoff*. When a mobile device moves crossing the cluster boundary, the handoff must be handled at least by the two MSCs involved. This is called *interswitch handoff*. Because of the state information exchange between two MSCs, interswitch handoff takes longer than intraswitch handoff.

There are three methods for initiating handoffs. They are (1) mobile controlled handoff (MCHO), (2) network controlled handoff (NCHO), and (3) mobile assisted handoff (MAHO). In MCHO, the mobile device continuously monitors the quality of signals received from nearby base stations. When the signal level from a new base station exceeds that from the current base station, the mobile device realizes that it is leaving the current cell and entering a new cell. Thus the mobile device initiates the handoff and requests a new radio channel from the new base station. Because the mobile device controls the entire handoff

process, a fast handoff is expected. However, this increases the complexity of the mobile devices.

In NCHO, the base stations continuously monitor the signal quality from individual mobile devices and report the measurements to the MSC. The MSC, which has a whole picture of the entire system, chooses the new base station and starts the handoff process. The mobile device operates in passive mode and thus a simple design is needed. However, this increases the burden of the network. A more desirable method is MAHO, in which the mobile device continuously measures the signal quality from nearby base stations and feeds this information back to the MSC via the current base station. The current base station also provides the distance information to the MSC. The MSC then makes a decision for handoff. MAHO achieves the balance between mobile device complexity and network burden; therefore it is widely used in today's mobile networks.

The handoff process can be in one of the four modes: hard, soft, backward, or forward handoff (Mark & Zhuang, 2004). During a hard handoff, a mobile device can receive user data from only one base station at any time. Thus, the old connection is terminated before a new connection is established. This mode of operation is called *break-before-make*. In the soft handoff, a mobile device receives copies of the same user data from two or more base stations simultaneously. The mobile is supposed to have the capability to recognize that the multiple copies actually represent the same data. Then the mobile uses signal processing techniques to determine the most likely correct value of the data from its multiple copies. Thus, soft handoff provides better reliability. This mode of operation is called *make-before-break*.

In backward handoff, the handoff is predicted ahead of time and initiated through the existing radio link. A sudden loss or rapid deterioration of the old link imposes a major problem in backward handoff. In forward handoff, the handoff is initiated via the new radio link associated with the new base station. Because of a late availability of the new radio link, forward handoff may cause a long delay. The general requirements when designing a handoff algorithm are low handoff delay and cell loss, scalable with network size, and reliability of recovering from link failures.

Handoff management is handled differently in mobile IP and cellular IP networks. In mobile IP, a mobile terminal needs to change its IP address when it moves into a new IP subnet and registers the new IP address with its home agent. This could lead to long handoff delay when the mobile is far away from its home agent. Cellular IP is designed to support fast handoff in a wireless network of limited size, for example, a network within the same administrative domain. Cellular IP reduces handoff latency by eliminating the need for a mobile to change its IP address while moving inside a Cellular IP network, hence reducing the delays caused by acquiring and registering new IP addresses.

Location Management

The term location in the context of mobile networks means which network the mobile is visiting, more specifically, which network attachment the mobile is using.

Location management typically includes the following three steps:

- Location discovery—a process to determine the mobile's current location
- Location update—a process to notify the mobile's home network of its current location
- Packet delivery—a process to deliver packets to the destination mobile

Location Discovery

To provide a wide geographical coverage and to support more users, a wireless mobile network is normally configured as an interconnection of many regional subnetworks. Each subnetwork may consist of multiple cells. These subnetworks are interconnected via intelligent routers such as MSCs or a backbone network such as the Internet or a satellite network. For message delivery purposes, a mobile device is identified with a home network where the mobile subscribes. Messages sent from other mobiles or fixed terminals are always delivered to its home network first. The association between the mobile and its home network is made through a registration process. The location register that belongs to the mobile's home network is called the home location register (HLR). When the mobile moves into a new subnetwork, it has to register its current location with a visitor location register (VLR) in the visiting network. The registration request sent by the mobile device should include its mobile identification number (MIN) among others. The base station in each subnetwork periodically broadcast beacon signals. A mobile listens to the pilot signals from the base stations in the subnetwork and uses these to identify its current subnetwork.

Location discovery can be initiated by either the mobile's home network or the mobile itself. In the former case, the home network does not maintain mobiles' precise locations at all times. It only needs to locate the mobile when there are messages destined to the mobile. Typically, the home network sends a message to the VLR through its association with the HLR. The VLR then locates the called mobile by broadcasting a polling message that contains the MIN of the called mobile. Upon receiving the polling message, the called mobile responds to the VLR through its current serving base station. The called MSC then knows where to forward the call. A communication channel between the message originator and the mobile can be established thereafter. If the location discovery is initiated by the mobile itself, the home network must know the current location of the mobile at all times. Therefore, the mobile must inform its home network whenever it enters a new subnetwork.

Location Update

A location update strategy determines when a mobile should perform location updates and what location-related information the mobile should send to its home network. One strategy is to update the mobile's precise location whenever it leaves its home network. This strategy makes the location discovery unnecessary. However, this strategy is not desirable if mobiles change their network attachment points frequently and there are no traffic destined to them. A number of strategies are designed to

save scarce network and mobile resources. They can be classified into the following categories:

- Traffic-on-demand update: the home network does not maintain mobiles' precise locations at all times. The network only requests the mobile to update its location when it needs to deliver user traffic to it.
- Location-area-based update: A network can group a set of network attachments points into one location area. When the mobile and network have no traffic to send to each other, the network only needs to keep track of which location area a mobile is likely to be in.
- Movement-based update (Dutta et al., 2001; Noy, Kessler, & Sisi, 1995): A mobile performs a location update whenever it traverses a predetermined number of location areas.
- Distance-based update (Noy, Kessler, & Sisi, 1995; Wong & Leung, 2000): A mobile performs a location update whenever it has traversed a predetermined distance since its last update. Here the distance could be measured in many ways, such as physical distance or cell distance.

Each location update strategy has unique advantages and limitations. A potential drawback of the traffic-on-demand strategy is an unacceptable long end-to-end message delay. For location-area-based, movement-based, and distance-based strategies, location discovery is required to locate the precise location of a mobile when the network needs to deliver user traffic to it. Therefore, a proper trade-off is needed to achieve reduced overhead, high performance, and low complexity.

Packet Delivery

Packet delivery to mobiles is the process whereby a packet originator and the network use location information to deliver packets to a mobile. Packet delivery strategies can be classified into two basic categories:

1. Direct delivery: a packet originator first obtains the destination mobile's current location and then sends the packets directly to the current location of the destination mobile. In this case, the packet originator needs to maintain the mobile's location by itself or obtain location information from a location server.
2. Relayed delivery: a packet will be first sent to a mobility anchor point, which then relays the packet toward its final destination. In this case, the packet originator does not need to know the precise location of the destination mobile. What the originator needs to know is the address of the mobility anchor point, which typically is fixed.

Direct delivery could reduce the packet end-to-end delay by using the most direct path to the destination. However, the originator needs to have the ability to find the proper location server for the destination mobile. Relay delivery has fewer requirements on the packet originator. However, the packet end-to-end may be longer in relay delivery than that in direct delivery, because the mobility anchor point could become the performance bottleneck.

Roaming Management

Roaming is a process whereby a mobile user moves into a visited domain. Before proceeding to the discussion of roaming, we first define *home domains* and *visited domains* for a mobile user. A user's home domain is the domain where the mobile maintains a service subscription account, which contains information regarding the subscriber's identity, billing address, service plan, and security information needed to authenticate the user. Among other information, the service plan includes which networks the user is allowed to use (i.e., which networks the user can roam into and communicate with). When a mobile moves into a domain with which it does not have an account, this domain is called the mobile's visited domain.

Roaming is similar to handoff in the sense that a mobile changes its network attachment point in both cases. However, supporting roaming requires more network capabilities, such as roaming agreement between the mobile's home domain and the visited domains. A roaming agreement contains enough information for a visited domain to authenticate, authorize, and bill the roaming user. When a user enters a visited domain, the visited domain needs to determine if this user is allowed to use its networks. To make this decision, the visited domain needs to know who this user is, who the user's home domain is, and if there is an agreement between them.

CONCLUSIONS AND FUTURE TRENDS

We have introduced the basic concepts and general features of mobile devices. Particularly, we presented the specific features of Web-enabled phones, personal digital assistants, pagers, portable storage devices, laptop PCs, and tablet PCs. To better understand these mobile devices, we also outlined the protocols widely deployed by mobile devices and several mobile security issues and measures. It should be noted that this chapter provided only a framework of the mobile protocols and security. Readers are suggested to refer other chapters in volumes I and II that contain the details of individual topics, such as WAP, SMTP, HTTP, Mobile IP, 802.11x, Bluetooth, and the foundations of network security. Finally, this chapter reviewed mobile device management, which includes handoff management, location management, and roaming management.

We make two predictions for the next generation mobile devices. The first prediction regards the mobile domain itself. Specifically, various mobile devices within each family will converge to one unit. For example, we expect that a single mobile device will combine all the functions of Web-enabled phones, PDAs, pagers, and iPods. The second prediction pertains to both mobile and wireless domains. New mobile devices must be able to access any public wireless local area network services and connect to the wireless Internet through any available Internet connection services. However, there are a number of barriers preventing this. First, for the new mobile devices to run intensive computing applications, new technologies for processors, hard disks, and memories must be available. Second, for them to be truly

portable, the size and weight must be significantly reduced. Third, new technologies to increase the network bandwidth for mobile devices must be developed. And finally, the battery lifetime must allow days of continuous usage.

GLOSSARY

Code Division Multiple Access A spread spectrum approach for the digital transmission of data/voice over radio frequencies.

Enhanced Data GSM Environment A faster version of the GSM wireless service.

Enhanced Message Service Enables mobile devices to exchange messages with formatted text, animations, pictures, icons, sound effects, and special ring tones.

Global System for Mobile Communications A digital cellular phone technology based on TDMA.

Handheld Devices Markup Language Specifications that allow Internet access from wireless devices such as handheld personal computers and smart phones.

Home location register A database containing subscriber information files about the subscriber and the current location of a subscriber's mobile station.

Hypertext transfer protocol It is the protocol used for Web access in the current Internet. Currently, it has two popular versions, HTTP 1.0 and HTTP 1.1.

Internet Message Access Protocol A protocol for e-mail clients to retrieve e-mail messages from a mail server while the mailboxes are on.

Internet Protocol Security A security protocol from the Internet Engineering Task Force (IETF) that provides authentication and encryption over the Internet.

Multimedia Message Service A messaging service for the mobile environment very similar to SMS or text messaging.

Simple Mail Transfer Protocol A protocol used to send e-mail on the Internet.

Simple Object Access Protocol A lightweight protocol for exchange of information in a decentralized, distributed environment.

Synchronized Media Integration Language A markup language designed to present multiple media files together.

Time Division Multiple Access A digital wireless telephony transmission technique

Uniform Resource Identifier The most common form of URI is the Web page address.

Universal Discovery Description and Integration An XML- and SOAP-based lookup service for Web service consumers to locate Web services and programmable resources available on a network.

Visitor Location Register A local database function that maintains temporary records associated with individual subscribers.

Voice eXtensible Markup Language A proposed specification for accessing voice recognition software via the Internet.

Wireless Identity Module It identifies and authenticates a wireless device on a wireless network.

Wireless Markup Language It allows the display of Web pages on mobile phones and PDAs.

INTRODUCTION

Launched in May 1998, Bluetooth wireless technology rapidly has become one of the most well-known means of communication in the information technology industry. The unusual name *Bluetooth* itself has garnered much attention (I discuss the origins of this name later), but the main reason for the focus that the technology receives from so many companies and individuals is the new capabilities that it brings to mobile computing and communication.

This chapter discusses many facets of Bluetooth wireless technology—its origins; the associated Bluetooth Special Interest Group; its applications, especially in personal area networks; how it works; and how it addresses security issues. I also present numerous references where more information can be found about this exciting new way to form wireless personal area networks (WPANs) that allow mobile devices to communicate with each other.

BLUETOOTH WIRELESS TECHNOLOGY

Bluetooth wireless technology uses radio frequency (RF) to accomplish wireless communication. It operates in the 2.4-GHz frequency spectrum; the use of this frequency range allows Bluetooth devices to be used virtually worldwide without requiring a license for operation. Bluetooth communication is intended to operate over short distances (up to approximately 100 m, although the nominal range used by most Bluetooth devices is about 10 m). Restricting communication to short ranges allows for low-power operation, so Bluetooth technology is particularly well suited for use with battery-powered personal devices that can be used to form a WPAN. Both voice and data can be carried over Bluetooth communication links, making the technology suitable for connecting both computing and communication devices, such as mobile phones, personal digital assistants (PDAs), pagers, and notebook computers. Table 1 summarizes these key attributes of Bluetooth wireless technology.

Bluetooth wireless technology originally was designed for cable replacement applications, intended to remove the need for a cable between any two devices to allow them to communicate. For example, a cable might be used to connect two computers to transfer files, to connect a PDA

cradle to a computer to synchronize data, or to connect a headset to a telephone for hands-free voice calls. This sort of wired operation can often be cumbersome, because the cables used are frequently special-purpose wires intended to connect two specific devices; hence, they are likely to have special connectors that make them unsuitable for general-purpose use. This can lead to “cable clutter”—the need for many cables to interconnect various devices. Mobile users may find this especially burdensome because they need to carry their device cables with them to connect the devices when they are away from home, and even with a large collection of cables, it is unlikely that all of the devices can be plugged together. Nonmobile environments, too, can suffer from cable clutter. In a home or office, wires used to connect, say, computer peripherals or stereo speakers limit the placement of these items, and the cables themselves become obstacles.

Bluetooth technology attempts to solve the problem of cable clutter by defining a standard communication mechanism that can allow many devices to communicate with each other without wires. The next section explores the genesis and evolution of Bluetooth wireless communication.

Origins

The genesis of Bluetooth wireless technology generally is credited to Ericsson, where engineers were searching for a method to enable wireless headsets for mobile telephones. Realizing that such a short-range RF technology could have wider applications, and further realizing that its likelihood for success would be greater as an industry standard rather than a proprietary technology, Ericsson approached other major telephone, mobile computer, and electronics companies about forming an industry group to specify and standardize a general-purpose, short-range, low-power form of wireless communication. This small group became the Bluetooth Special Interest Group (SIG), discussed later.

Of special interest to many is the name “Bluetooth.” Such a name for an industry initiative is unusual. A two-part newsletter article (Kardach, 2001) offers a full explanation of the name’s origin; the salient points follow here. Some of the first technologists involved in early discussions about a short-range wireless technology were

Table 1 Key Bluetooth Technology Characteristics

Characteristic	Bluetooth Technology Attributes
Medium	Radio frequency (RF) in the 2.4-GHz globally unlicensed spectrum
Range	Nominally 10 m; optionally up to 100 m
Power	Low-power operation, suitable for battery-powered portable devices
Packet types	Voice and data
Types of applications	Cable replacement, wireless personal area networks
Example applications	Network access, wireless headsets, wireless data transfer, cordless telephony, retail and m-commerce, travel and mobility, and many other applications

history buffs, and the discussion at some point turned to Scandinavian history. A key figure in Scandinavian history is 10th-century Danish king Harald Blåtand, who is credited with uniting parts of Scandinavia. It is said that a loose translation of his surname to English produces “blue tooth.” Those involved in early discussions of this technology recognized that it could unite the telecommunications and information technology (IT) industries, and hence they referred to it as “Bluetooth,” after King Harald. At that time, Bluetooth was considered a temporary “code name” for the project. When the time came to develop an official name for the technology and its associated special interest group, the name Bluetooth was chosen after considering several alternatives. Today, this is the trademarked name of the technology and the incorporated entity (the Bluetooth SIG, discussed next) that manages it. In fact, the SIG publishes rules and guidelines (Bluetooth SIG, 2005a) for using the term.

The Bluetooth Special Interest Group

Formed in early 1998 and announced in May of that year, the Bluetooth SIG originally was a rather loosely knit group of five companies: Ericsson, Intel, IBM, Nokia, and Toshiba. These companies established themselves as Bluetooth SIG promoter members and formed the core of the SIG. Other companies were invited to join as adopter members, and the SIG’s membership grew rapidly. The promoter companies, along with a few invited experts, developed the original versions of the Bluetooth specification (detailed later).

In December 1999, four additional companies—3Com, Lucent, Microsoft, and Motorola—were invited to join the group of promoter companies (later Lucent’s promoter membership was transferred to its spin-off company, Agere Systems). By this time, the SIG’s membership had grown to more than 2,000 companies. In addition to promoters and adopters, a third membership tier, called associate member, also was defined. Companies may apply to become associate members and must pay membership fees. Adopter membership is free and open to anyone. In general, promoter and associate members develop and

maintain the Bluetooth specification; adopter members may review specification updates before their public availability.

The SIG’s original purpose was to develop the Bluetooth specification, but it has taken on additional responsibilities over time. In 2001, the SIG incorporated and instituted a more formal structure for the organization, including a board of directors that oversees all operations, a technical organization led by the Bluetooth Architecture Review Board (BARB), a marketing arm, and a legal group. The SIG continues to develop and maintain the specification and promote the technology, including sponsoring developers’ conferences and other events. One important function of the SIG is to manage the Bluetooth qualification program, in which products are tested for conformance to the specification. All Bluetooth products must undergo qualification testing. The SIG’s official Web site (Bluetooth SIG, 2005b) offers more details about the organization and the qualification program.

Wireless Personal Area Networks

A *personal area network* (PAN) generally is considered to be a set of communicating devices that someone carries with him or her. A wireless PAN (WPAN), of course, is such a set of devices that communicate without cables, such as through the use of Bluetooth technology. One can imagine a “sphere” of connectivity that surrounds a person and moves with her or him, so that all of the devices in the WPAN remain in communication with one another.

WPANs need only short-range communication capability to cover the personal area, in contrast with local area (LAN) or wide area networks (WAN), which need to communicate across greater distances using established infrastructure. One source (Miller, 2001) contrasts PANs, LANs, and WANs, particularly Bluetooth technology, as a WPAN solution versus Institute of Electrical and Electronics Engineers (IEEE; 1999) 802.11 WLAN technology.

The usefulness of a WPAN derives primarily from the ability of individual devices to communicate with each other in an ad hoc manner. Each device still can specialize in certain capabilities but can “borrow” the capabilities of other devices to accomplish certain tasks. For example, a PDA is useful for quickly accessing personal information, such as appointments and contacts. A mobile telephone can be used to contact people whose information is stored in the PDA. Hence, a user might look up the telephone number of an associate and then dial that number on the mobile phone. With a WPAN, however, this process can be automated: once the telephone number is accessed, the PDA software could include an option to dial the specified phone number automatically on the mobile telephone within the WPAN, using wireless communication links to transmit the dialing instructions to the phone. When combined with a wireless headset in the same WPAN, this could enable a more convenient device usage model for the user, who might never need to handle the mobile telephone at all (it could remain stored in a briefcase). Moreover, the user interface of the PDA is likely to be easier to use than a telephone keypad for retrieving contact information. This allows each of the devices (PDA, mobile phone, and wireless headset in this example) to

Figure 1: Dial-up networking illustration.

be optimized to perform the specific tasks that they do best. The capabilities of each device are accessed from other devices via the WPAN. This often is preferred over an alternative usage model, the “all-in-one” device (imagine a PDA that also functions as a mobile telephone). Such multifunction devices might tend to be cumbersome and are more difficult to optimize for specific functions.

Because it was developed primarily to replace cables that connect mobile devices, Bluetooth wireless communication is an ideal WPAN technology. Indeed, most of the popular usage scenarios for Bluetooth technology originate in a WPAN of some sort, connecting personal devices to each other or to other networks in proximity. The use of Bluetooth communication links in WPANs is illustrated next, in an examination of various Bluetooth applications.

Bluetooth Applications

Because Bluetooth technology primarily is about replacing cables, many of its applications involve well-known usage scenarios. The value that Bluetooth communication adds to these types of applications derives from the ability to accomplish them without wires, enhancing mobility and convenience. For example, dial-up networking is a task commonly performed by many individuals, especially mobile professionals. One of the original usage scenarios used to illustrate the value of Bluetooth technology involves performing dial-up networking wirelessly—with the use of a mobile computer and a mobile phone, both equipped with Bluetooth communication, dial-up networking no longer is constrained by cables. This application and others are detailed next.

Basic Cable Replacement Applications

These applications comprise the original set of usage models envisioned for Bluetooth wireless technology. When the SIG was formed and the technology began to be popularized, these applications were touted as the most common ways in which Bluetooth wireless communication would be used. Although many other, perhaps more sophisticated, applications for Bluetooth technology have been discovered and envisioned, these original usage models remain as the primary application set. Nearly all of these early applications involve a mobile

computer or a mobile telephone and, for the most part, they involve performing typical existing tasks wirelessly.

One such application, already mentioned, is dial-up networking. In this application, a Bluetooth communication link replaces the wire (typically a serial cable) between a computer and a telephone. When the telephone is also a mobile device, the network connection can be entirely wireless; a Bluetooth wireless link exists between the computer and the telephone and a wide-area communications link (using typical cellular technology, such as the global system for mobile communication [GSM], time division/demand multiple access [TDMA], or others) carries the network traffic, using the mobile telephone as a wireless modem. Figure 1 depicts this usage model.

A variant of this application uses direct (rather than dial-up) connection to a network such as the Internet. In this case, the Bluetooth link allows a computer to connect to a network such as a LAN without using a cable. Together, these two applications (wireless dial-up networking and wireless LAN access) form a usage model that the SIG calls the *Internet bridge*. Both applications involve access to a network, using existing protocols, with the main benefit being the ability to access the network without the cables that typically are required to connect the network client computer.

Another type of cable replacement application involves data transfer from one device to another. One of the most common such usage models is transferring files from one computer to another. This can be accomplished with removable media (diskettes, CDs), with cables (via a network or a direct connection) or wirelessly (using infrared or Bluetooth communication, to name two ways). Infrared file transfer is not uncommon, but it requires the two devices to have a line of sight between them. Bluetooth file transfer operates similarly to that of IrDA infrared file transfer (in fact, the Bluetooth protocol stack, discussed later, is designed such that the same application can be used over either transport medium). Bluetooth communication, being RF-based, does not require a line of sight between the two devices, however. Moreover, through the use of standard data formats, such as *vCard* (Internet Mail Consortium, 1996a), *vCal* (Internet Mail Consortium, 1996b), and others, objects other than files can be exchanged between devices using Bluetooth links

in a manner similar to that used with IrDA. So, for example, electronic business cards, calendar appointments, and contact information can be shared wirelessly among devices.

Building on this capability to exchange data objects is the application that allows these same objects to be synchronized. This means that data sets on two devices reflect the same information at the point in time when they are synchronized. Hence, in addition to simply sending a copy of contact information or a calendar appointment from one device to another, the full address book or calendar can be synchronized between the two devices so that they have the same set of contacts or appointments. This allows a user to enter information on any convenient device and then have that information reflected on other devices by synchronizing with those devices. In addition to the benefit of performing these tasks wirelessly, by using standard protocols and data formats, information can be exchanged easily among many kinds of devices. Specialized cables to connect two computers, or custom cradles to connect a PDA to a computer, are not needed once Bluetooth technology enters the picture. Instead, the same data can be exchanged and synchronized to and from notebook computers, PDAs, mobile phones, pagers, and other devices. This illustrates a hallmark of the value of Bluetooth technology: a single standard wireless link can replace many cables of various types, allowing devices that otherwise might not be able to be connected to communicate easily.

Another data transfer application is related to those just described, but it has a distinguished usage model because of the kind of data it transfers, namely, image data. The SIG calls this usage model the *instant postcard*, and it involves transferring pictures from one device to another. One reason that this application is separately described is because it involves the use of a digital camera. Today, when a camera captures new images, they typically are loaded onto a computer of some sort (or perhaps a television or similar video device) to be displayed. Through the use of Bluetooth wireless technology, this image transfer can be accomplished more easily, but once again, this standard form of wireless link enables the same data to be transferred to other types of devices. For example, rather than uploading photos to a computer, the photos might be transferred to a mobile phone. Even if the phone's display is not suitable for viewing the photo, it still could be e-mailed to someone who could view it on his computer or other e-mail device.

Until now, this chapter has focused on applications involving data, but Bluetooth wireless technology is also designed to transport voice traffic (audio packets), and some of the cable replacement applications take advantage of this fact. The most notable of these is the wireless headset. Cabled headsets that connect to a mobile phone are widely used today to allow hands-free conversations. Bluetooth technology removes the cable from the headset to the telephone handset, enabling wireless operation that can allow the phone to be stowed away in a briefcase, pocket, or purse. In fact, as noted earlier, this particular application was the basis for the invention of Bluetooth technology. As with the previously discussed applications, however, once a standard wireless link is established, additional

ways to connect other kinds of devices present themselves. For example, the same Bluetooth headset used with a mobile phone might also be used with a stationary telephone (again to allow hands-free operation and increased mobility) and a computer (to carry audio traffic to and from the computer). Furthermore, although Bluetooth wireless communication was not originally designed to carry more complex audio traffic (such as digital music), advances are being made that will allow it to do so. With this capability, the same wireless headset also could be used with home entertainment systems, car audio systems, and personal music players. Hence, the Bluetooth SIG dubs this usage model the *ultimate headset*.

A variation on the wireless headset usage model is what the SIG calls the *speaking laptop*. In this application, Bluetooth links carry audio data in the same manner as for the headset application, but in this case the audio data is routed between a telephone and a notebook computer's speaker and microphone, rather than to a headset. One usage scenario enabled with this application is that of using the notebook computer as a speakerphone: A call made to or from a mobile telephone can be transformed into a conference call ("put on the speaker") by using the speaker and microphone built into nearly all portable (and desktop) computers.

Cordless telephony is another application for Bluetooth technology. With a Bluetooth voice access point, or cordless telephone base station, a standard cellular mobile telephone also can be used as a cordless phone in a home or office. The Bluetooth link carries the voice traffic from the handset to the base station, with the call then being carried over the normal wired telephone network. This allows mobile calls to be made without incurring cellular usage charges. In addition, two handsets can function as "walkie-talkies" or an intercom system, using direct Bluetooth links between them, allowing two parties to carry on voice conversations in a home, office, or public space without any telephone network at all. Because a single mobile telephone can be used as a standard cellular phone, a cordless phone, and an intercom, the SIG calls this cordless telephony application the *three-in-one phone* usage model.

Additional Applications

Although Bluetooth wireless technology was developed especially for cable-replacement applications such as those just cited, many observers quickly realized that Bluetooth communication could be used in other ways, too. Here I describe a few of the many potential applications of Bluetooth technology, beginning with those that the SIG already is in the process of specifying.

The Bluetooth SIG focused primarily on the cable-replacement applications already discussed in the version 1.x specifications that it released. The SIG is also developing additional profiles (detailed later) for other types of Bluetooth applications. Among these are more robust personal area proximity networking, human interface devices, printing, local positioning, multimedia, and automotive applications.

Bluetooth personal area networking takes advantage of the ability of Bluetooth devices to establish communication with each other based on their proximity to each other, so that ad hoc networks can be formed. The

Bluetooth network encapsulation protocol (BNEP) allows Ethernet packets to be transported via Bluetooth links, thus enabling many classic networking applications to operate in Bluetooth piconets (piconets are discussed at length in the section Bluetooth Operation). This capability extends the Bluetooth WPAN to encompass other devices. An example is the formation of an ad hoc Bluetooth network in a conference room with multiple meeting participants. Such a network could facilitate collaborative applications such as white-boarding, instant messaging, and group scheduling. Such applications could allow group editing of documents and scheduling of follow-up meetings, all in real time. Nonetheless, it should be noted that although this scenario resembles classic intranet- or Internet-style networking in some respects, Bluetooth personal area networking is not as robust a solution for true networking solutions as is a WLAN technology, such as IEEE 802.11.

Replacing desktop computer cables with Bluetooth communication links fundamentally is a cable-replacement application (dubbed the *cordless computer* by the SIG), and this was one of the originally envisioned Bluetooth usage scenarios, but the original specifications did not fully address it. The new *human interface device* (HID) specification describes how Bluetooth technology can be used in wireless computer peripherals such as keyboards, mice, joysticks, and so on. The Bluetooth printing profiles specify methods for wireless printing using Bluetooth communication, including “walk up and print” scenarios that allow immediate printing from any device, including mobile telephones and PDAs, as well as notebook computers, to any usable printer in the vicinity. This application of Bluetooth technology can obviate the need for specialized network print servers and their associated configuration and administration tasks.

Another application that can be realized with Bluetooth wireless technology is *local positioning*. Bluetooth technology can be used to augment other technologies, such as global positioning systems (GPS), especially inside buildings, where other technologies might not work well. Using two or more Bluetooth radios, local position information can be obtained in several ways. If one Bluetooth device is stationary (say, a kiosk), it could supply its position information to other devices within range. Any device that knows its own position can provide this information to other Bluetooth devices so that they can learn their current position. Sophisticated applications might even use signal strength information to derive more granular position information. Once position information is known, it could be used with other applications, such as maps of the area, directions to target locations, or perhaps even locating lost devices. *The Bluetooth local positioning profile* specifies standard data formats and interchange methods for local positioning information.

Multimedia applications have become standard on most desktop and notebook computers, and the Bluetooth SIG is pursuing ways by which streamed multimedia data, such as sound and motion video, could be used in Bluetooth environments. The 1 Mbps raw data rate of version 1 Bluetooth radios is not sufficient for many sorts of multimedia traffic, but the SIG is investigating methods for faster Bluetooth radios that could handle multimedia

applications. The SIG is also developing profiles for multimedia data via Bluetooth links.

Another emerging application area is that of automotive Bluetooth applications. Using Bluetooth communication, wireless networks could be formed in cars. Devices from the WPAN could join the automobile’s built-in Bluetooth network to accomplish scenarios such as the following:

- obtaining e-mail and other messages, using a mobile phone as a WAN access device, and transferring those messages to the car’s Bluetooth network, where they might be read over the car’s audio system using text-to-speech technology (and perhaps even composing responses using voice recognition technology);

- obtaining vehicle information remotely, perhaps for informational purposes (for example, querying the car’s current mileage from the office or home) or for diagnostic purposes (for example, a wireless engine diagnostic system for automobile mechanics that does not require probes and cables to be connected to the engine); and

- sending alerts and reminders from the car to a WPAN when service or maintenance is required (for example, e-mail reminders that an oil change is due or in-vehicle or remote alerts when tire pressure is low or other problems are diagnosed by the vehicle’s diagnostic systems).

The SIG, in conjunction with automotive industry representatives, is developing profiles for Bluetooth automotive applications. This area is likely to prove to be an exciting and rapidly growing domain for the use of Bluetooth wireless technology.

These new applications are only some of the potential uses for Bluetooth wireless technology. Many other domains are being explored or will be invented in the future. Other noteworthy applications for Bluetooth wireless communications include mobile e-commerce, medical, and travel technologies. Bluetooth devices such as mobile phones or PDAs might be used to purchase items in stores or from vending machines; wireless biometrics and even Bluetooth drug dispensers might appear in the future (the 2.4-GHz band in which Bluetooth operates is called the industrial, scientific, and medical band); and travelers could experience enhanced convenience by using Bluetooth devices for anytime, anywhere personal data access and airline and hotel automated check-in. In fact, this latter scenario, including the use of a Bluetooth PDA to unlock a hotel room door, has already been demonstrated (InnTechnology, 2000).

The Bluetooth Protocol Stack

A complete discussion of the Bluetooth protocol stack is outside the scope of this chapter. Numerous books, including Miller and Bisdikian (2000) and Bray and Sturman (2000) offer more in-depth discussions of Bluetooth protocols. Here, we present an overview of Bluetooth operation and how the various protocols may be used to accomplish the applications already discussed. A typical Bluetooth stack is illustrated in Figure 2. Each layer of the stack is detailed next.

Figure 2: Bluetooth protocol stack.

Radio, Baseband, and Link Manager

These three protocol layers constitute the *Bluetooth module*. Typically, this module is an electronics package containing hardware and firmware. Today, many manufacturers supply Bluetooth modules.

The *radio* consists of the signal-processing electronics for a transmitter and receiver (transceiver) to allow RF communication via an *air interface* between two Bluetooth devices. As noted earlier, the radio operates in the 2.4-GHz spectrum, specifically in the frequency range 2.400–2.4835 GHz. This frequency range is divided into 79 channels (along with upper and lower guard bands), with each channel having a 1-MHz separation from its neighbors. *Frequency hopping* is employed in Bluetooth wireless communication; each packet is transmitted on a different channel, with the channels being selected pseudorandomly, based on the clock of the master device (master and slave devices are described in more detail later). The receiving device knows the frequency-hopping pattern and follows the pattern of the transmitting device, hopping to the next channel in the pattern to receive the transmitted packets.

The Bluetooth specification defines three classes of radios, based on their maximum power output:

- 1 mW (0 dBm),
- 2.5 mW (4 dBm), and
- 100 mW (20 dBm).

Increased transmission power offers a corresponding increase in radio range; the nominal range for the 0-dBm radio is 10 m, whereas the nominal range for the 20-dBm radio is 100 m. Of course, increased transmission power also requires a corresponding increase in the energy

necessary to power the system, so higher power radios will draw more battery power. The basic cable replacement applications (indeed, most Bluetooth usage scenarios described here) envision the 0-dBm radio, which is considered the standard Bluetooth radio and is the most prevalent in devices. The 0-dBm radio is sufficient for most applications, and its low power consumption makes it suitable for use on small, portable devices.

Transmitter and receiver characteristics such as interference, tolerance, sensitivity, modulation, and spurious emissions are outside the scope of this chapter but are detailed in the Bluetooth specification (Bluetooth SIG, 2003).

The *baseband controller* controls the radio and typically is implemented as firmware in the Bluetooth module. The controller is responsible for all of the various timing and raw data handling aspects associated with RF communication, including the frequency hopping just mentioned, management of the time slots used for transmitting and receiving packets, generating air-interface packets (and causing the radio to transmit them), and parsing air-interface packets (when they are received by the radio). Packet generation and reception involves many considerations, including the following:

- generating and receiving packet payload,
- generating and receiving packet headers and trailers,
- dealing with the several packet formats defined for Bluetooth communication,
- error detection and correction,
- address generation and detection,
- data whitening (a process by which the actual data bits are rearranged so that the occurrence of zero and one bits

in a data stream is randomized, helping to overcome DC bias), and data encryption and decryption.

Not all of these operations are necessarily performed on every packet; there are various options available for whether a particular transformation is applied to the data, and in some cases (such as error detection and correction), there are several alternatives that may be employed by the baseband firmware.

The *link manager*, as its name implies, manages the link layer between two Bluetooth devices. Link managers in two devices communicate using the *link manager protocol* (LMP). LMP consists of a set of commands and responses to set up and manage a baseband link between two devices. A link manager on one device communicates with a link manager on another device. (Indeed, this is generally the case for all the Bluetooth protocols described here; a particular protocol layer communicates with its corresponding layer in the other device, using its own defined protocol. Each protocol is passed to the next successively lower layer, where it is transformed to that layer's protocol, until it reaches the baseband, where the baseband packets that encapsulate the higher layer packets are transmitted and received via the air interface.) LMP setup commands include those for authenticating the link with the other device; setting up encryption, if desired, between the two devices; retrieving information about the device at the other end of the link, such as its name and timing parameters; and swapping the master and slave roles (detailed later) of the two devices. LMP management commands include those for controlling the transmission power; setting special power-saving modes, called hold, park, and sniff; and managing quality-of-service (QoS) parameters for the link. Because LMP messages deal with fundamental characteristics of the communication link between devices, they are handled in an expedited manner, at a higher priority than the normal data that is transmitted and received.

Control and Audio

The *control* and *audio* blocks in Figure 2 are not actual protocols. Instead, they represent means by which the upper layers of the stack can access lower layers. The control functions can be characterized as methods for inter-protocol-layer communication. These could include requests and notifications from applications, end users, or protocol layers that require action by another protocol layer, such as setting desired QoS parameters, requests to enter or terminate power-saving modes, or requests to search for other Bluetooth devices or change the discoverability of the local device. Often, these take the form of a user-initiated action, via an application, that requires the link manager (and perhaps other layers) to take some action.

The audio block in Figure 2 represents the typical path for audio (voice) traffic. Recall that Bluetooth wireless technology supports both data and voice. Data packets traverse through the L2CAP layer (described later), but voice packets typically are routed directly to the baseband,

because audio traffic is isochronous and hence time critical. Audio traffic usually is associated with telephony applications, for which data traffic is used to set up and control the call and voice traffic serves as the content of the call. Audio data can be carried over Bluetooth links in two formats:

pulse code modulation (PCM), with either a-law or μ -law logarithmic compression, and continuous variable slope delta (CVSD) modulation, which works well for audio data with relatively smooth continuity, usually the case for typical voice conversations.

Host-Controller Interface (HCI)

The HCI is an optional interface between the two major components of the Bluetooth stack: the *host* and the *controller*. As shown in Figure 2 and described earlier, the radio, baseband controller, and link manager constitute the module, which is often, but not necessarily, implemented in a single electronics package. Such a module can be integrated easily into many devices, with the remaining layers of the stack residing on the main processor of the device (such as a notebook computer, mobile phone, or PDA). These remaining layers (described next) are referred to as the host portion of the stack.

Figure 2 illustrates a typical “two-chip” solution in which the first “chip” is the Bluetooth module and the second “chip” is the processor in the device on which the host software executes. (The module itself might have multiple chips or electronic subsystems for the radio, the firmware processor, and other external logic.) In such a system, the HCI allows different Bluetooth modules to be interchanged in a device, because it defines a standard method for the host software to communicate with the controller firmware that resides on the module. So, at least in theory, one vendor's Bluetooth module could be substituted for another, so long as both faithfully implement the HCI. Although this is not the only type of partitioning that can be used when implementing a Bluetooth system, the SIG felt it was common enough that a standard interface should be defined between the two major components of the system. A Bluetooth system could be implemented in an “all-in-one” single module, where the host and controller reside together in the same physical package (often called a “single-chip” solution), although in this case, the HCI might still be used as an internal interface. When the two-chip solution is used, the physical layer for the HCI (that is, the physical connection between the host and the controller) could be one of several types. The Bluetooth specification defines three particular physical layers for the HCI:

universal serial bus (USB),
universal asynchronous receiver/transmitter (UART), and
RS-232 serial port.

Other HCI transports could be implemented; the Bluetooth specification currently contains details and considerations for these three.

Logical Link Control and Adaptation Protocol (L2CAP)

The logical link control and adaptation protocol (L2CAP) layer serves as a “funnel” through which all data traffic flows. As discussed earlier, voice packets typically are routed directly to the baseband, whereas data packets flow to and from higher layers, such as applications, to the baseband via the L2CAP layer.

The L2CAP layer offers an abstraction of lower layers to higher layer protocols. This allows the higher layers to operate using more natural data packet formats and protocols, without being concerned about how their data is transferred over the air interface. For example, the Service Discovery Protocol layer (discussed next) defines its own data formats and protocol data units. At the SDP layer, only the service discovery protocol needs to be handled; the fact that SDP data must be separated into baseband packets for transmission and aggregated from baseband packets for reception is not a concern at the SDP layer, nor are any of the other operations that occur at the baseband (such as encryption, whitening, and so on). This is accomplished because the L2CAP layer performs operations on data packets. Among these operations are segmentation and reassembly, whereby the L2CAP layer breaks higher layer protocol data units into L2CAP packets, which in turn can be transformed into baseband packets; the L2CAP layer conversely can reassemble baseband packets into L2CAP packets that in turn can be transformed into the natural format of higher layers of the stack.

An L2CAP layer in one Bluetooth stack communicates with another, corresponding L2CAP layer in another Bluetooth stack. Each L2CAP layer can have many channels. L2CAP channels identify data streams between the L2CAP layers in two Bluetooth devices. (L2CAP channels should not be confused with baseband channels used for frequency hopping. L2CAP channels are logical identifiers between two L2CAP layers.) An L2CAP channel often is associated with a particular upper layer of the stack, handling data traffic for that layer, although there need not be a one-to-one correspondence between channels and upper-layer protocols. An L2CAP layer might use the same protocol on multiple L2CAP channels. This illustrates another data operation of the L2CAP layer: protocol multiplexing. Through the use of multiple channels and a protocol identifier (called a *protocol-specific multiplexer*, or PSM), L2CAP allows various protocols to be multiplexed (flow simultaneously) over the air interface. The L2CAP layer sorts out which packets are destined for which upper layers of the stack.

Service Discovery Protocol (SDP)

The SDP layer provides a means by which Bluetooth devices can learn, in an ad hoc manner, which services are offered by each device. Once a connection has been established, devices use the SDP to exchange information about services. An SDP client queries an SDP server to inquire about services that are available; the SDP server responds with information about services that it offers. Any Bluetooth device can be either an SDP client or an SDP server, acting in one role or the other at different times.

SDP allows a device to inquire about specific services in which it is interested (called *service searching*) or to perform a general inquiry about any services that happen to be available (called *service browsing*). A device can perform an SDP service search to look for, say, printing services in the vicinity. Any devices that offer a printing service that matches the query can respond with a “handle” for the service; the client then uses that handle to perform additional queries to obtain more details about the service. Once a service is discovered using SDP, other protocols are used to access and invoke the service; one of the items that can be discovered using SDP is the set of protocols that are necessary to access and invoke the service.

SDP is designed to be a lightweight discovery protocol that is optimized for the dynamic nature of Bluetooth piconets. SDP can coexist with other discovery and control protocols; for example, the Bluetooth SIG has published a specification for using the UPnPdiscovery and control technology over Bluetooth links.

RFCOMM

As its name suggests, the RFCOMM layer defines a standard communications protocol, specifically one that emulates serial port communication (the “RF” designates radio frequency wireless communication; the “COMM” portion suggests a serial port, commonly called a COM port in the personal computer realm). RFCOMM emulates a serial cable connection and provides the abstraction of a serial port to higher layers in the stack. This is particularly valuable for Bluetooth cable-replacement applications, because so many cable connections—modems, infrared ports, camera and mobile phone ports, printers, and others—use some form of a serial port to communicate.

RFCOMM is based on the European Telecommunications Standards Institute (ETSI) TS07.10 protocol (ETSI, 1999), which defines a multiplexed serial communications channel. The Bluetooth specification adopts much of the TS07.10 protocol and adds some Bluetooth adaptation features. The presence of RFCOMM in the Bluetooth protocol stack is intended to facilitate the migration of existing wired serial communication applications to wireless Bluetooth links. By presenting higher layers of the stack with a virtual serial port, many existing applications that already use a serial port can be used in Bluetooth environments without any changes. Indeed, many of the cable-replacement applications cited earlier, including dial-up networking, LAN access, headset, and file and object exchange, use RFCOMM to communicate. Because RFCOMM is a multiplexed serial channel, many serial data streams can flow over it simultaneously; each separate serial data stream is identified with a *server channel*, in a manner somewhat analogous to the channels used with L2CAP.

Telephony Control Specification-Binary (TCS-BIN)

The TCS-BIN is a protocol used for advanced telephony operations. Many of the Bluetooth usage scenarios involve a mobile telephone, and some of these use the TCS-BIN protocol. TCS-BIN is adopted from the ITU-T Q.931 standard (International Telecommunication Union,

1998), and it includes functions for call control and managing wireless user groups. Typically, TCS-BIN is used to set up and manage voice calls; the voice traffic that is the content of the call is carried as audio packets as described earlier. Applications such as the three-in-one phone usage model use TCS-BIN to enable functions such as using a mobile phone as a cordless phone or an intercom. In these cases, TCS-BIN is used to recognize the mobile phone so that it can be added to a wireless user group that consists of all the cordless telephone handsets used with a cordless telephone base station. TCS-BIN is also used to set up and control calls between the handset and the base station (cordless telephony) or between two handsets (intercom).

TCS-BIN offers several advanced telephony functions; devices that support TCS-BIN can obtain knowledge of and directly communicate with any other devices in the TCS-BIN wireless user group, essentially overcoming the master-slave relationship of the underlying Bluetooth piconet (detailed later). It should be noted that not all Bluetooth telephony applications require TCS-BIN; an alternative method for call control is the use of AT commands via the RFCOMM serial interface. This latter method is used for the headset, dial-up networking, and fax profiles.

Adopted Protocols

Although several layers of the Bluetooth protocol stack were developed specifically to support Bluetooth wireless communication, other layers are adopted from existing industry standards. I already have noted that RFCOMM and TCS-BIN are based on existing specifications. In addition to these, protocols for file and object exchange and synchronization are adopted from the Infrared Data Association (IrDA), and Internet networking protocols are used in some applications.

The IrDA's *object exchange* (OBEX) protocol is used for the file and object transfer, object push, and synchronization usage models. OBEX originally was developed for infrared wireless communication, and it maps well to Bluetooth wireless communication. OBEX is a relatively lightweight protocol for data exchange, and several well-defined data types—including electronic business cards, e-mail, short messages, and calendar items—can be carried within the protocol. Hence, the Bluetooth SIG adopted OBEX for use in its data exchange scenarios; by doing so, existing infrared applications can be used via Bluetooth links, often with no application changes. In addition, the *infrared mobile communications* (IrMC) protocol is used for the synchronization usage model. Typically, infrared communication occurs via a serial port, so the adopted IrDA protocols operate via RFCOMM in the Bluetooth protocol stack.

Networking applications such as dial-up networking and LAN access use standard Internet protocols, including point-to-point protocol (PPP), Internet protocol (IP), user datagram protocol (UDP), and transmission control protocol (TCP). As shown in Figure 2, these protocols operate via the RFCOMM protocol. Once a Bluetooth RFCOMM connection is established between two devices, PPP can be used as a basis for UDP-IP and TCP-IP networking packets. This enables typical networking applications, such as network dialers, e-mail programs, and

browsers, to operate via Bluetooth links, often with no changes to the applications.

Bluetooth Profiles

I have presented an overview of the Bluetooth protocols, which are described in (Bluetooth SIG 2003), the Bluetooth master specification. The Bluetooth SIG publishes multiple volumes of the specification, some of which define the Bluetooth *profiles*. Profiles offer additional guidance to developers beyond the specification of the protocols. Essentially, a profile is a formalized usage case that describes how to use the protocols (including which protocols to use, which options are available, and so on) for a given application. Profiles were developed to foster interoperability; they provide a standard basis for all implementations to increase the likelihood that implementations from different vendors will work together, so that end users can have confidence that Bluetooth devices will interoperate with each other. In addition to the profile specifications, the SIG offers other mechanisms intended to promote interoperability; among these are the *Bluetooth Qualification Program* (a definition of testing that a Bluetooth device must undergo) and *unplugfests* (informal sessions where many vendors can test their products with each other); detailed discussions of these programs are outside the scope of this chapter, but more information is available on the Bluetooth Web site (Bluetooth SIG, 2005b).

Our earlier discussion of Bluetooth applications presented several usage models for Bluetooth wireless communication. Many of these applications have associated profiles. For example, the dial-up networking profile defines implementation considerations for the dial-up networking application. Most of the applications cited here have associated profiles, and many new profiles are being developed and published by the SIG; the official Bluetooth Web site (Bluetooth SIG, 2005) has a current list of available specifications. In addition, there are some fundamental profiles that describe basic Bluetooth operations that are necessary for most any application. The version 1.1 profiles are illustrated in Figure 3. This figure shows the relationship among the various profiles, illustrating how certain profiles are derived from (and build upon) others.

The leaf nodes of the diagram consist of profiles that describe particular applications—file and object transfer, object push, synchronization, dial-up networking, fax, headset, LAN access, cordless telephony, and intercom. The telephony (TCS-BIN) profile includes elements that are common to cordless telephony and intercom applications; similarly, the generic object exchange profile describes the common elements for its children, and the serial port profile defines operations used by all applications that use the RFCOMM serial cable-replacement protocol. Note that the generic object exchange profile derives from the serial port profile; this is because OBEX operates via RFCOMM in the Bluetooth protocol stack.

The two remaining profiles describe fundamental operations for Bluetooth communication. The service discovery application profile describes how a service discovery application uses the service discovery protocol (described

Figure 3: Bluetooth profiles.

earlier). The generic access profile is common to all applications; it defines the basic operations that Bluetooth devices use to establish connections, including how devices become discoverable and connectable, security considerations for connections, and so on. The generic access profile also includes a common set of terminology used in other profiles; this is intended to reduce ambiguity in the specification. The generic access and service discovery application profiles are mandatory for all Bluetooth devices to implement, because they form the basis for interoperable devices. Other works, including Miller and Bisdikian (2000), delve more deeply into the Bluetooth profiles.

Bluetooth Operation

Having discussed WPANs, Bluetooth applications, protocols, and profiles, I now turn our attention to some of the fundamental concepts of Bluetooth operation, illustrating an example flow for a Bluetooth connection.

At the baseband layer, Bluetooth operates on a master-slave model. In general, the *master* device is the one that initiates communication with one or more other devices. *Slaves* are the devices that respond to the master's queries. In general, any Bluetooth device can operate as either a master or a slave at any given time. The master and slave roles are meaningful only at the baseband layer; upper layers are not concerned with these roles. The master device establishes the frequency-hopping pattern for communication with its slaves, using its internal clock values to generate the frequency-hopping pattern. Slaves follow the frequency-hopping pattern of the master(s) with which they communicate.

When a master establishes a connection with one or more slaves, a *piconet* is formed. To establish the connection, a master uses processes called *inquiry* and *paging*. A master can perform an inquiry operation, which transmits a well-defined data sequence across the full spectrum of frequency-hopping channels. An inquiry effectively asks, "Are there any devices listening?" Devices that are in *inquiry scan* mode (a mode in which the device periodically listens to all of the channels for inquiries) can respond to the master's inquiry with enough information for the master device to address the responding device directly.

The inquiring (master) device may then choose to page the responding (slave) device. The page is also transmitted across the full spectrum of frequency-hopping channels; the device that originally responded to the inquiry can enter a *page scan* state (a state in which it periodically listens to all of the channels for pages), and it can respond to the page with additional information that can be used to establish a baseband connection between the master and the slave. The master can repeat this process and establish connections with as many as seven slaves at a time. Hence, a piconet consists of one master and up to seven active slaves; additional slaves can be part of the piconet, but only seven slaves can be active at one time. Slaves can be "parked" (made inactive) so that other slaves can be activated. Figure 4 illustrates a typical Bluetooth piconet. Note that a device could be a slave in more than one piconet at a time, or it could be a master of one piconet and a slave in a second piconet. In these cases,

Figure 4: Example of a Bluetooth piconet.

the device participating in multiple piconets must use the appropriate frequency-hopping pattern in each piconet, so it effectively must split its time among all the piconets in which it participates. The Bluetooth specification calls such interconnected piconets *scatternets*.

Once a piconet is formed (a baseband connection exists between a master and one or more slave devices), higher layer connections can be formed, and link manager commands and responses may be used to manage the link. At some point, it is likely that an L2CAP connection will be formed for data packets (even if the main content for a link is voice traffic, an L2CAP data connection will be needed to set up and manage the voice links). A Bluetooth device can have one data (L2CAP) connection and up to three voice connections with any other Bluetooth device at a given time (recall, however, that L2CAP connections can be multiplexed, so many different data streams can flow over the single L2CAP connection). Once an L2CAP connection is established, additional higher layer connections can be established. If the devices are not familiar to each other already, it is likely that an SDP connection will be used to perform service discovery. RFCOMM and TCS-BIN connections also might be made, depending on the application. From here, applications can manage voice and data packets to accomplish their usage scenarios, which might be those defined by Bluetooth profiles or other ways to use Bluetooth wireless communication to accomplish a given task. Additional details about fundamental Bluetooth operations and connection establishment, including the various types of packets, master-slave communication protocols, and timing considerations, are outside the scope of this chapter but are detailed in works such as Miller and Bisdikian (2000) and Bray and Sturman (2000).

Bluetooth Security

A noteworthy aspect of Bluetooth operation is security. In the wireless world, security justifiably is a key concern for device manufacturers, device deployers, and end users. The Bluetooth specification includes security measures such as authentication and encryption, and the Bluetooth profiles discuss which security measures should be employed in various circumstances.

At the time that a link is established, Bluetooth devices may be required to authenticate themselves to each other. This is done using a shared-secret method (other methods such as those using public keys typically require some sort of central registry, which is not appropriate for WPANs that use ad hoc networking). The first device sends a randomly generated number to the second device, which performs some computation using a *link key* value and returns the result to the first device. If that value is the one expected by the first device, then it considers the second device authenticated. The second device might then, in turn, authenticate the first device so that the two devices are mutually authenticated with each other. Link keys are maintained by each device; a process called *pairing* can be used to generate a link key from an initialization key the very first time two devices are introduced to each other.

Once a link has been established, the data traffic over that link may be encrypted. The encryption key is derived

from the link key, so devices that exchange encrypted traffic must have been already authenticated with each other. Bluetooth links support up to 128-bit encryption; the devices mutually agree on the encryption key size.

The Bluetooth profiles provide guidance about how and when to use authentication and encryption in Bluetooth wireless communication. The Generic Access Profile (described earlier) defines three different security modes (non-secure, service-level enforced security, and link-level enforced security) and the procedures to follow to achieve those levels of security in Bluetooth communications. Other profiles specify the security measures that should be used for various applications or scenarios. For example, the file transfer profile requires that both authentication and encryption be supported, and it recommends that they be used; the dial-up networking profile requires that all data be encrypted, in addition to device authentication.

Applications are free to impose additional security restrictions beyond those that are provided in the specification. For example, applications might choose to expose data or services only to authorized users or to implement more robust user authentication schemes. Certain applications might include other security mechanisms beyond those built into the Bluetooth devices, such as the use of public key infrastructure, certificates, or other methods. More details about the operation of Bluetooth security features are included in works such as Miller and Bisdikian (2000) and Bray and Sturman (2000).

CONCLUSION

This introduction to Bluetooth wireless technology has touched on what can be done with the technology (Bluetooth applications), how it began, how it now is managed (the Bluetooth SIG), and how it works (Bluetooth protocols, profiles, and operation, including security). The chapter focused on the application of Bluetooth wireless communication as a WPAN technology for connecting personal portable devices. I have presented several references where this topic is explored in greater detail.

With tremendous industry backing, a design to work with both voice and data, the ability to replace cumbersome cables, and many new products being deployed on a regular basis, Bluetooth wireless technology is poised to become an important way for people to communicate for the foreseeable future. From its genesis as a method to provide a wireless headset for mobile phones, this technology named for a Danish king continues to spread across the planet.

GLOSSARY

Bluetooth SIG The Bluetooth Special Interest Group, an industry consortium that develops, promotes, and manages Bluetooth wireless technology, including the Bluetooth qualification program and the Bluetooth brand.

Bluetooth Wireless Technology Name given to a wireless communications technology used for short-range voice and data communication, especially for cable-replacement applications.

Frequency-Hopping Spread Spectrum A method of dividing packetized information across multiple channels of a frequency spectrum that is used in Bluetooth wireless communication.

IEEE 802.11 A wireless local area network standard developed by the Institute for Electrical and Electronics Engineers that is considered complementary to Bluetooth wireless technology.

IEEE 802.15.1 A wireless personal area network standard developed by the Institute for Electrical and Electronics Engineers that is based on Bluetooth wireless technology.

Infrared Data Association (IrDA) An industry consortium that specifies the IrDA infrared communication protocols, some of which are used in the Bluetooth protocol stack.

Piconet A Bluetooth wireless technology term for a set of interconnected devices with one master and up to seven active slave devices.

Profile In Bluetooth wireless technology, a specification for standard methods to use when implementing a particular application, with a goal of fostering interoperability among applications and devices.

Radio Frequency (RF) Used in the Bluetooth specification to describe the use of radio waves for physical layer communication.

Wireless Personal Area Network (WPAN) A small set of interconnected devices used by one person.

INTRODUCTION

Overview

In the past few years, we have seen wireless technology permeate every aspect of our lives. The fob on your key-chain (to open the car remotely), wireless mice and keyboards, and personal digital assistants (PDAs) that synchronize with your workstation are just a few examples. This proliferation of wireless devices was the result of the Federal Communications Commission (FCC) decision to open the ISM (industrial, scientific, and medical) band to the public. Wireless local area networks (WLANs) were among the domains that benefited from this release. This release from licensing motivated many companies and research laboratories to develop and implement wireless LAN solutions.

This disorganized and parallel effort resulted in the emergence of proprietary solutions that do not interoperate with each other. Lack of interoperability results in limited scope of acceptance because buyers of the technology from one vendor will either have to stick to that vendor or go through the pains of trying to work out a solution among different technologies. The IEEE 802.11 working group was formed to create a universal standard that can be followed by different vendors.

The first standard was released in 1997 and supported data rates up to 2 Mbps (IEEE, 1997). The specification defined both the physical and the media access control (MAC) layers. Other standards followed that addressed different requirements and provided higher data rates. These included the 802.11b, 802.11a, and 802.11g, which had higher data rates; the 802.11e, which had QoS support; the 802.11i, which had security; and others.

In parallel to the 802.11 effort, the European Telecommunications Standards Institute (ETSI) was working on

the high-performance radio LAN (HIPERLAN) project. Unlike the 802.11 project, which tried to use available technology, the HIPERLAN was built from scratch; the development of HIPERLAN was not driven by existing technologies and regulations. Instead, it was designed to meet a defined set of goals. The HIPERLAN Type 1 supports data rates of up to 25 Mbps. HIPERLAN Types 2, 3 and 4 specify standards for wireless asynchronous transfer mode (ATM)-supporting data and quality of service (QoS) applications.

Applications of WLANs

Similar to their wired counterparts, wireless LANs can be used to provide connectivity within a limited geographic area. Mobility, the ability to move around while still connected to a network, is a great feature of wireless LANs. In a working environment where staff members need to be mobile yet constantly connected to the network, WLANs are inevitable. Doctors and nurses accessing patients' data instantly, work coordination among members at different locations, and students' access to their accounts and class information around the campus are just a few examples of how easy and convenient life can be with support for mobility. An implication of mobility is outdoors connectivity. A wired network stops where your sockets and phone lines stop. A wireless LAN can provide you with connectivity while sipping a cup of coffee while sitting at a street corner.

A less obvious advantage of WLANs is has to do with the feasibility of running wires. Wireless LANs can be used to connect two wired LANs in different buildings. This might be the only way to provide connectivity, because accessing a public property (e.g., to cross a street) is not always possible. In this scenario, two bridges or switches can

Figure 1: BSS organization of a wireless LAN.

communicate wirelessly with each other to connect the two LAN segments. Even within the same building, a wired network may be unfeasible or impossible. Examples include museums and historical buildings. In addition, the lack of infrastructure and ad hoc topology of WLANs can be used in places where fast deployment is needed, such as relief-and-recovery teams in disaster areas. Ad hoc networks allow a group of nodes to communicate with each other in a distributed, peer-to-peer manner, without prior arrangement. They can also be used for settings where temporary connectivity is needed. A meeting where people need to exchange files and presentations is an example.

Yet another advantage of wireless LANs is their cost-effectiveness. It is known that a major part of a traditional wired LAN's installation is cabling and its implications of running conduits. Getting rid of cabling allows seamless additions, deletions, and modifications of the topology with no cost whatsoever. Also, the costs needed to run and maintain wires are all eliminated in a WLAN.

Chapter Organization

The remainder of this chapter is organized as follows: the second section discusses the possible topologies of 802.11 MAC and the MAC protocol description. The possible physical layers and the necessary background information are provided in the third section. The fourth section discusses HIPERLAN Types 1 and 2. Security and QoS support in 802.11 are described in the next two sections. We conclude the chapter by briefly describing some advanced topics in wireless networks.

802.11 MAC

Possible Topologies

Wireless LANs can be either infrastructure based or ad hoc. The latter LANs have no preexisting infrastructure or centralized management to support the mobile nodes. They consist of wireless nodes that can freely and dynamically self-organize into arbitrary and temporary network topologies. On the other hand, an infrastructure WLAN is based on central control, for example, by using an access point. In this section we discuss both schemes. The following classification of the different organizations of a wireless LAN is based on the concept of a service set. A service set is nothing more than a logical grouping of nodes. A node belongs to only one service set. By "belong," we mean it listens to transmissions from only one particular service set.

Basic Service Set (BSS)

The basic service set (BSS) resembles the basic building block in the 802.11 architecture. Nodes in a BSS communicate with each other through an access point (AP). An AP is responsible for coordinating communication among the nodes by receiving a node's transmission and forwarding it to the respective receiver. It is analogous to a base station in a cellular network. A BSS is analogous to a cell in a cellular network. The coverage area of a BSS is called a basic service area (BSA). Figure 1 illustrates the concept of a BSS (Crow, Widjaja, Kim, & Sakai, 1997a).

Extended Service Set (ESS)

Figure 2 shows how multiple BSSs can be connected to each other by connecting their APs to a distribution system (DS) and forming what is called an extended service set (ESS). Even though the APs can connect to the DS via either wired or wireless connections, usually the connection is wired. The DS resembles the backbone of the ESS and is responsible for communicating MAC segments from one BSS to another or from one BSS to an external wired network (Crow, Widjaja, Kim, & Sakai, 1997a).

Independent Basic Service Set (IBSS)

The BSS and its extension (through an ESS) both resemble an infrastructure-based organization. The independent basic service set (IBSS), on the other hand, resembles

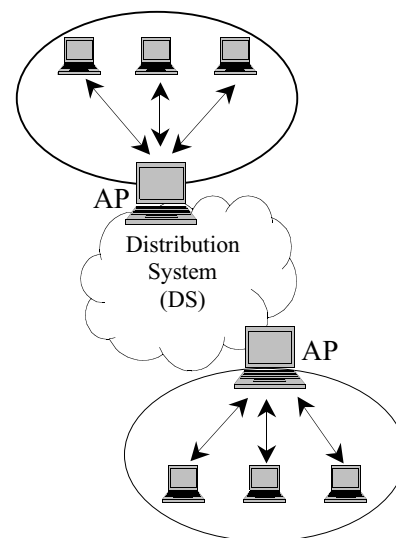

Figure 2: ESS organization of a wireless LAN.

Figure 3: IBSS (ad hoc) organization of a wireless LAN.

the infrastructureless ad hoc arrangement; see Figure 3. In an IBSS, stations communicate in a peer-to-peer fashion in which no AP or any other intermediary is needed. At least two stations are needed to form an IBSS.

Access Modes: DCF

The distributed coordination function (DCF) is the basic access mode of the 802.11 standard. It is based on the carrier sense multiple access with collision avoidance (CSMA/CA) scheme. The DCF is a contention-based protocol. Stations have to compete every time they want to access the channel. Before delving into the details of the protocol, an important question that comes to mind is why a specialized MAC is needed: why can't we simply adopt a wired MAC protocol? We start this section by answering this question and pointing out the issues that arise in a wireless communication context.

Why Wired Network Types of Channel Access Do Not Work

In the IEEE 802.3 Ethernet standard, carrier sense multiple access with collision detection (CSMA/CD) is used. The basic idea is that the sender senses the medium (a cable to which all the nodes in the Ethernet segment are attached) and if the medium is busy, the sender tries again later. If the channel is idle, on the other hand, the sender sends and keeps listening to the channel. If at any point during its transmission it hears a collision, it stops transmitting and sends a jamming signal.

The basic assumption in the CSMA/CD protocol is that a collision that takes place at the receiver can be detected

at the sender. This is true because the signal strength is basically more or less the same throughout the medium. This assumption is not true for the wireless medium because the signal strength decreases as the distance from the transmitter increases. Thus, an event may take place and not detected by the transmitter. The hidden and exposed terminal problems discussed next stem from this fact. In addition, a wireless node does not have the ability to transmit and receive at the same time because its own transmission would swamp any other signal in the vicinity (Nicolaitidis, Obaidat, Papadimitriou, & Pomportsis, 2003; Schiller, 2000).

Figure 4 shows three stations: A, B, and C. The transmission range of A reaches B but not C. Similarly, the transmission range of C reaches B but not A. As detection range (the range within which A can sense the medium) does not include C. C's detection range does not include A either.

Willing to transmit to B, A senses the channel and finds it idle. As a result, it starts transmitting. Meanwhile, C becomes interested in sending some data to B. C senses the channel but does not detect the ongoing transmission between A and B because it is out of its range. C also starts transmitting to B, which results in a collision at B that is not detected by either A or C. This problem, where two nodes are out of reach of each other but within the reach of a third node, is called the hidden terminal problem (or hidden node problem).

Another problem associated with the inability to detect collisions is the exposed terminal problem, which is illustrated in Figure 5. In this case, B is transmitting to A. C, willing to send to D, senses the channel and finds it busy. If C transmits, its transmission would not interfere with the ongoing transmission between B and A, because A is outside its range. C's transmission, even though it would collide with B, would not collide with A because the signal would be too weak to cause collision. Thus, C mistakenly postpones its transmission, even though it should not. In this case, we say that C is exposed to B.

Consider the situation where node A is closer to node C than node B, as shown in Figure 6. In this case even though both A and B can reach C, the signal power of A's transmission is much higher than that of B's transmission. As a result, C cannot hear B's transmission. To go around this problem, B has to compensate for the difference in distance by transmitting at a higher signal strength. This

Figure 4: The hidden terminal problem: C is outside the transmission and detection range of A. Similarly, A is outside the transmission and detection range of C.

Figure 5: The exposed terminal problem: C, even though is out of A's range, is within B's range. Hence, it postpones transmitting to D even though it should not, because its transmission would not collide with A, even though it would collide with B.

is the near–far effect, and it contrasts to wired networks, where nodes receive more or less the same signal strength.

CSMA/CA

As discussed in the previous section, the wireless medium imposes its own requirements on a MAC protocol. The main issue to be dealt with is the inability of nodes to detect collisions, and therefore the necessity to eliminate or minimize collisions. That is exactly why CSMA/CA was proposed. In CSMA/CA, nodes perform two types of carrier sensing: physical carrier sensing and virtual carrier sensing, which refer to sensing at the physical and the MAC layers, respectively. A channel is considered busy if either the physical or the virtual carrier senses a busy channel indication. The physical carrier monitors the medium for any ongoing transmissions by looking at the strength of any received signal. Let us examine the case of the hidden terminal problem.

Figure 7 shows the same scenario as that in Figure 4. When node A decides to send to node B, it first sends a request-to-send (RTS) control packet. All nodes within the range of A overhear the RTS packet and postpone their attempt to transmit. When B receives the RTS packet, it sends back a clear-to-send (CTS) packet. All nodes in the range of B will defer any attempt to transmit. As we can see, C now is not going to transmit to B because it heard the CTS packet. This procedure is also known as the four-way handshake.

Although the RTS–CTS exchange mitigates the hidden terminal problem, it does not solve it entirely. For example, A and C may both transmit an RTS packet at the same time. Another possibility is that B sends a CTS at the same

time as C sends an RTS, which results in a collision of both control packets at C. Node C does not hear the CTS sent to A nor a CTS for its own RTS and thus retransmits the RTS, which would collide with A's packet.

Collisions involving the RTS and CTS control packets carry a small penalty when compared with collisions of data packets. This is readily apparent from the sizes of the RTS and CTS packets (20 bytes and 16 bytes, respectively), in contrast to the maximum data packet size, which is 2346 bytes. Thus, the RTS–CTS exchange gives better overall performance.

The basic idea of virtual carrier sensing involves an announcement of the amount of time a node will be occupying the channel, so that all nodes hearing the announcement will defer their transmissions. To achieve this, every packet (be it a data packet, an RTS, or a CTS) carries a duration field, which indicates the amount of time the channel will be needed after the current packet transmission is done. This period includes the time to transmit the RTS, CTS, the data packet, and the returning ACK (acknowledgment). Every node maintains what is called a network allocation vector (NAV). Nodes adjust the values of their vectors as they overhear packet transmissions. A node attempts to check the channel status (whether idle or not) only when the duration in the NAV elapses.

Access priority to the wireless channel is provided through the use of inter-frame spacing (IFS), which is the duration of time that has to pass before trying to access the channel. Three IFSs are defined in the protocol; these are, in increasing order of importance, distributed coordination function IFS (DIFS), point coordination function IFS (PIFS), and short IFS (SIFS). The SIFS is the shortest

Figure 6: Near–far effect.

Figure 7: RTS-CTS control packet exchange.

amount of time and hence the highest priority, followed by the PIFS used by the PCF, and the DIFS, which is the time delay used by DCF frames.

Figure 8 shows how a frame transmission takes place along with the NAV table's adjustments at other nodes (those that are not involved in the current transmission). Prior to sensing the channel, a node has to wait the duration of a DIFS. After that, if the channel is idle, the node sends an RTS. The duration field is set to include the time for the CTS, the data packet, the ACK, and the SIFS durations that separate each one of these. When the receiver gets the RTS, it waits the duration of a SIFS and sends back a CTS. Upon receiving the CTS, the sender waits another SIFS and transmits the data packet, which is followed by another SIFS and an ACK. The success of these steps marks a successful packet transmission. Nodes wait the duration of a DIFS and contend for the channel again.

After a channel has been busy, the probability of more than one node trying to access the channel is large. The idle period following a DIFS interval is referred to as the contention window. To prevent collisions and enhance performance, nodes enter into a back-off period so that channel access demands are spread over time. Nodes calculate a random back-off interval. A station calculates the amount of back-off to be between 0 and the minimum

size of the contention window (CW_{min}). A station transmits only when its back-off reaches 0 and the channel is idle. In case the transmission results in a collision, the station calculates a new contention window size equal to $2^{2+i} - 1$ time slots, where i is the number of consecutive collisions the station experienced. For every transmission failure, the station calculates a contention window until it reaches a maximum window size (CW_{max}). When the retry counter, i , exceeds a specific (user-defined) value, the packet is dropped. It must be mentioned that the countdown timer freezes when the channel is sensed to be busy and it is resumed once the wireless medium is detected to be subsequently idle for the DIFS time.

Access Modes: PCF

Unlike the DCF, which is a contention-based protocol used for data traffic, the point coordination function provides a contention-free protocol that can be used for connection-oriented real-time traffic such as voice. This is done by polling the stations one at a time. PCF needs an element called the point coordinator (PC), which decides when and which node can transmit according to a polling list (normally in round-robin fashion). We recommend the PC to be integrated with the AP. Given the centralized

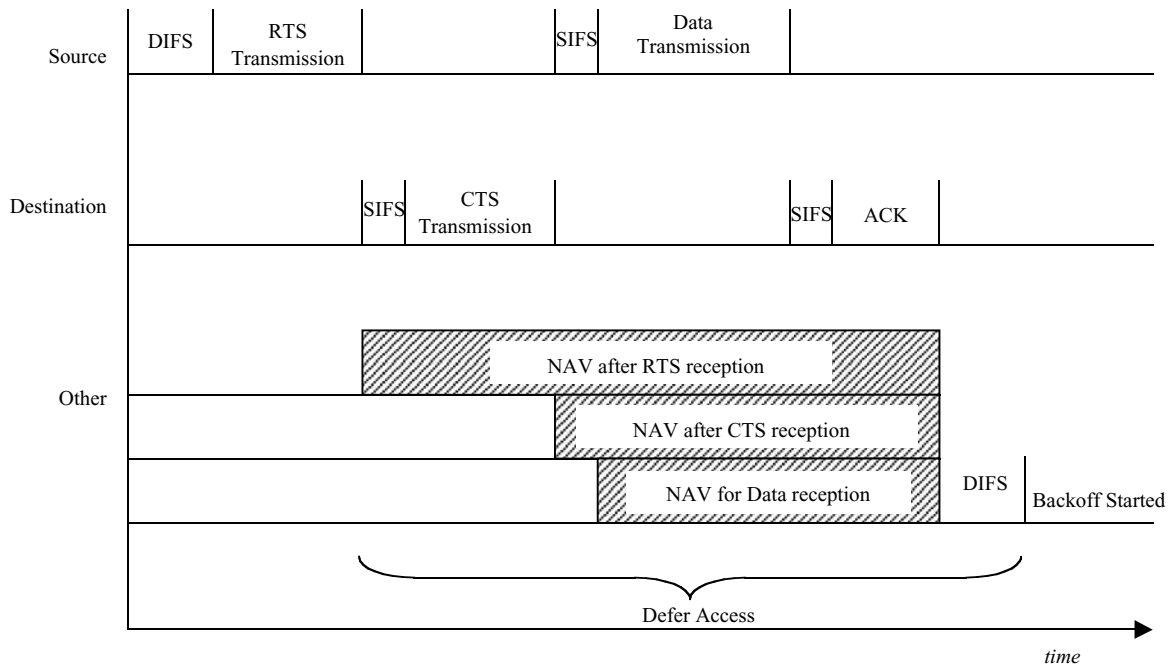

Figure 8: Frame transmission along with the changes in the NAV as time progresses.

approach of PCF, which depends on the AP for polling, PCF works only for the infrastructure-based topology and not for the ad hoc topology. It must be mentioned that PCF has not yet been implemented and of course is not available in any WLAN card. The protocol works by dividing time into contention-free periods (CFPs). The length of the CFP is manageable and determines how often the PCF runs. Each CFP consists of a contention-free portion followed by contention-based period (i.e., for DCF traffic). Each CFP must allow at least one DCF packet to be transmitted (so that DCF traffic does not starve). The portion allotted to PCF traffic is dynamic and the AP can change it as the traffic requirements change. For example, if a small number of nodes are interested in the PCF service, more time is allotted to the DCF function. The AP announces the beginning of a CFP by sending a beacon frame. Stations update their NAV to the maximum length of CFP, which is a defined parameter, *CFP_Max_Duration*. Periodically, the AP sends a beacon frame, which contains the remaining time of the CFP, *CFPDurationRemaining*.

To initiate the beginning of a CFP, the AP waits a PCF inter-frame space (PIFS), which is shorter than a DIFS. Thus, the AP gains access to the channel before any DCF station. It then sends a beacon frame, which is used for synchronization and a parameter-information announcement. At this point, all stations have updated their NAV, and no one will access the channel unless requested by the AP. The AP can send a poll frame, a data frame (i.e., forwarding from one station to another), a combination of data and poll, or a CFP end frame.

802.11 PHYSICAL LAYER

In this section, we discuss basic concepts related to the physical layer, followed by a discussion of the main problems associated with wireless channels. Afterward, we explain the different radio layers of the 802.11 standard. Finally, we close with a discussion of some of the physical-layer standards.

Concepts

Channel Coding and Modulation

Modulation is the process of changing the data stream to a form suitable for transmission via a physical medium. Two categories of modulation exist: analog modulation and digital modulation. Analog modulation works by impressing the analog signal containing the data onto a carrier wave, thereby changing a property of the carrier wave. Digital modulation refers to the mapping of one or more bits to a symbol where a symbol is the basic unit communicated between a transmitter and a receiver. This works by converting a bit string (digital data) to a suitable continuous time waveform. This conversion involves modifying one of the signal characteristics, such as the amplitude, frequency, or the phase, which gives rise to amplitude modulation, frequency modulation, or phase modulation; see Figure 9. Amplitude refers to the signal strength, frequency refers to the number of times per second the signal repeats its pattern (measured in Hz or cycles/sec), and phase refers to the relative position in time.

In digital modulation, the higher the number of bits mapped to a symbol, the denser the modulation scheme is said to be. The denser the modulation scheme, the more spectrally efficient it is. The number of bits per symbol depends on the modulation scheme used. For example, if the channel bandwidth is 1 MHz, the wave frequency is fixed and equal to the frequency of the carrier wave, and if every bit is mapped into a symbol, then the channel capacity is 1 Mbps. This holds because 1 million wave transitions per second are supported. On the other hand, if every two bits are mapped into one symbol, the channel capacity will be doubled to become 2 Mbps. Nonetheless, the increase in the number of bits per symbol is not arbitrary. The higher the number of bits per symbol, the higher the chances of error in recovering the bits at the receiving end.

Coding maximizing the benefit of transmission over noisy wireless channels by introducing redundancies in the bits transmitted, so that the receiver can still recover a reasonably distorted packet. To be able to recover more

Figure 9: Illustration of amplitude, frequency, and phase modulations (bit sequence: 0110).

errors, more overhead bits have to be sent. Coding efficiency refers to the ratio between data and total bits in the stream. For example, a coding efficiency of 1/2 means that for every bit in the data stream, two bits have to be sent. One important issue in coding schemes is the computational complexity in implementing the code. This is especially important for portable wireless devices, which try to use their energy efficiently.

Antennas

An antenna is a device responsible for emitting or collecting electromagnetic waves for the purposes of transmission and reception. In other words, it is the interface between the transmitter or receiver and the air. In a nutshell, an antenna takes electrical signals from the transmitter and converts them into radio (i.e., electromagnetic) signals sent on the air, and captures radio signals from the air and converts them into electrical signals at the receiver. Antennas are characterized by many parameters including directivity or gain, polarity, and efficiency, among others (www.gigaant.com, 2004).

Before explaining directivity, let's define isotropic antennas. An isotropic antenna is an ideal antenna that radiates the same power in all directions. In other words, if we create a sphere around it and measure the power intensity at any point on the surface, we get the same value. Realistic antennas radiate more in some directions than others. Gain is amount of power "gained" in one direction at the expense of other directions.

Electromagnetic waves consist of coupled electric and magnetic fields. Polarization refers to the position and direction of the electric field with reference to the Earth's surface. An antenna can be horizontally or vertically polarized. The transmitting and receiving antennas have to have the same polarization; otherwise, a great amount of loss will occur. Efficiency of an antenna is defined as the ratio between the radiated power and the input power. An isotropic antenna has a gain of 1.

There are omnidirectional antennas (which provide a 360-degree radiation pattern), directional antennas (which focus radiation in one direction to provide greater coverage distance), and diversity antennas (which actually use more than one antenna for signal reception and transmit through the antenna with the best received signal).

Wireless Problems

Unlike wired transmissions, the wireless channel is impaired, which, along with the scarce spectral bandwidth, makes achieving medium wired quality extremely difficult. In this subsection, we briefly touch on the problems faced in wireless communications.

Path Loss. As a signal propagates from the transmitter to the receiver, it attenuates (i.e., losses its energy) with distance. Thus, the longer the distance, the weaker the signal received. The free space model refers to the signal strength when the path between the transmitter and the receiver is clear of obstacles and resembles a line of sight. In the free space model, the signal attenuates with the square of the distance (i.e., d^2 where d is the distance) (Nicolitidis, Obaidat, Papadimitriou, & Pomportsis, 2003). Realistic modeling of path loss, however, depends

Figure 10: Illustration of a multipath propagation (numbers on the rays refer to the path number).

on many other factors including the reflecting objects and big obstructions in the path between the transmitter and the receiver. Depending on the model at hand, the signal strength decreases with distance and has an exponent ranging from 3 to 6.

Multipath Fading and Shadowing. When a signal is transmitted, multiple versions of the same signal take different paths to the receiver (see Figure 10). The first to arrive at the receiver is the one going through the line of sight (LOS), which is the path that does not have any obstacles between the transmitter and the receiver (Path 2 in Figure 10). Others, delayed versions, follow other paths resulting from obstacles in the path. These delayed copies, when arriving at the receiver, either add constructively or destructively. Notice that the obstacles in the path are not fixed in either number or in position. Mobility of the transmitter, receiver, or the objects in between changes the paths between the transmitter and the receiver. Thus, the signal quality varies with time. This phenomenon, where the signal quality depends on the multipath propagation, is referred to as multipath fading. Another type of fading is shadow fading. When the signal encounters a large obstacle in its way, such as a building, it is attenuated severely. The amount of absorption depends on the characteristics and size of the obstacle.

Interference. Interference refers to extraneous, unwanted signals that affect the proper system operation. Not only does interference affect the quality of the signal communicated from the transmitter to the receiver, it can also affect the functionality of the protocol. For example, the existence of another 802.11 network in the vicinity could make sources sense the channel as busy even though it is not.

Because wireless LANs work in the ISM band, which does not require any licensing, they are especially susceptible to interference. Microwave ovens, photocopying machines, medical equipment, Bluetooth-enabled devices (e.g., PDAs or laptops), and wireless phones are examples of possible sources of interferences. Obviously, the existence of another WLAN segment cannot be ruled out, especially as WLANs gain greater acceptance in the marketplace.

Many things can be done to deal with interference: survey the site to understand the geographic area in which the WLAN will work, transmit high power signals, and shut down other devices that can interfere, for example. Wireless LANs go around this problem by using spread spectrum techniques (<http://www.wi-fiplanet.com>; Geier).

Figure 11: Four-channel FHSS system.

Radio Link

The IEEE 802.11 WLANs use either radio or infrared (IR) electromagnetic waves for transmitting data. In this section and the next we discuss both of these interfaces. Radio-based WLANs, which are more common than IR-based WLANs, operate on the ISM band because this band does not require any licensing from the FCC. The standard defines two physical-layer methods, frequency hopping spread spectrum (FHSS) and direct sequence spread spectrum (DSSS). The basic idea of spread spectrum (whether FHSS or DSSS) involves using a very wide bandwidth to communicate the data. By increasing the bandwidth, communication is more resilient to interference and fading because only a small portion of the bandwidth will be affected.

FHSS

In FHSS, the signal is spread by sending one frequency for a short period of time and then switching (hopping) to another frequency in a seemingly random fashion (see Figure 11). The hopping sequence and hopping rate are predefined and known to both the sender and the receiver. Two types of FHSS systems exist with different hopping rates. If multiple bits are transmitted over the same frequency channel, the system is called slow frequency hopping. On the other hand, if the hopping rate is greater than or equal to the bit rate, that is, if one bit or less is transmitted over a channel, the system is called fast frequency hopping. Because WLANs operate on the ISM band, many sources of interference may exist. If a source of interference happens to be in the vicinity of a slow-frequency-hopping transmission and is operating at a frequency that is also used by the slow-frequency-hopping system, it will corrupt all packets sent at that frequency channel. In a fast-frequency-hopping system, on the other hand, very few noise spikes will take place and the receiver will still be able to recover the data. Thus, fast hopping systems have better interference resilience (Bing, 2000).

The time spent in each frequency, known as the dwell time, is limited by the FCC to a maximum of 400 ms. This means it hops at least 2.5 times per second. In addition, the number of frequency channels used in the hopping sequence cannot go below six channels (i.e., 6 MHz) (Roshan & Leary, 2004). The 802.11 standard splits the available bandwidth into 79 channels, each 1 MHz wide.

The 802.11 physical layer supports two data rates: 1 Mbps and 2 Mbps. It consists of two sublayers: the physical-layer convergence protocol (PLCP) and the physical medium dependent (PMD). PLCP is responsible for adding necessary headers for synchronization, timing, and error control. The PMD is responsible for raw transmission of bits over the air; it mainly performs modulation of the data stream.

The PLCP adds a 128-bit header to frames arriving from the MAC layer (called PLCP service data units, PSDU). The header contains the following fields:

- A preamble, which has two subfields (96 bits).
- Synch, an 80-bit sequence of alternating 0s and 1s starting with a 0. It is used at the receiver for time synchronization. In addition, if the receiver is using any antenna-diversity technique, it uses these bits to choose the best antenna. The transmitter and the receiver must be synchronized so that they switch from one frequency to another at the same time.
- SFD (start of frame delimiter), a specific bit string (0000 1100 1011 1101) used at the receiver for frame timing.
- PSDU length word (PLW), a 12-bit field that indicates the size of the MAC frame.
- PLCP signaling field (PSF), a 4-bit field used to specify the data rate at which the frame was transmitted. Data rates range from 1 Mbps to 4.5 Mbps in increments of 0.5 Mbps. Table 1 shows the possible values along with the data rates they indicate (Nicopolitidis, Obaidat, Papadimitriou, & Pomportsis, 2003).
- HEC (header error control), an ITU-T cyclic redundancy check, CRC16, used for error detection.

Table 1 PSF Field Value and Supported Data Rate

Field value	Data rate
000	1 Mbps
001	1.5 Mbps
010	2 Mbps
011	2.5 Mbps
100	3 Mbps
101	3.5 Mbps
110	4 Mbps
111	4.5 Mbps

Figure 12: FHSS transmitter.

After receiving a bit stream from the PLCP sublayer, the PMD modulates it using Gaussian frequency shift keying (GFSK). Depending on the data rate supported (whether 1 Mbps or 2 Mbps), GFSK or 4 GFSK is used. 4GFSK translates every two bits into one signal element, which allows for doubling the rate. Frequency shift keying schemes, in general, convey the information by changing the frequency of the signal. Thus, the amplitude of the signal does not carry any information. This gives the flexibility of changing the transmission power as needed. In addition, the design of the transmitter and the receiver is simple. An important drawback of FSK-based schemes is that they are not spectrally efficient. That is, the amount of information conveyed per signal element is small when compared with other modulation schemes.

Figure 12 shows a block diagram of a FHSS transmitter. The input bits are fed into a GFSK modulator, which produces an analog signal from the data. A spreader that takes a pseudorandom number as an index for table lookup uses the table entry's frequency as the carrier frequency to be modulated by the output of the GFSK modulator. The resultant signal is the one transmitted in the air. The opposite process takes place at the receiving end to demodulate the received signal (Roshan & Leary, 2004).

DSSS

The main idea of DSSS is to spread the signal energy over a large bandwidth. To other unintended receivers, the signal can be treated as noise that can be easily rejected. As a result, the same frequency band can be used by multiple DSSS signals, which better uses the bandwidth and minimizes interference effects.

To achieve this spreading, DSSS systems map every bit in the data stream to an m -bit pattern called the pseudonoise code or chipping code. The number of bits in the code determines the spreading factor. The higher the spreading factor is, the more resilient the signal is to interference. However, this would be at the expense of bandwidth, which increases dramatically. The FCC specifies a minimum spreading factor of 10. That is, a maximum data rate of 10% of the available channel bandwidth can be provided. IEEE 802.11 uses an 11-chip spreading factor. That is, every bit in the data stream is replaced by 11 bits (chip sequence) to be transmitted via the channel. Even though this may seem very expensive, the fact that it minimizes interference effects results in enhancing channel quality, which translates into fewer corrupted packets, a better overall throughput performance, and a decrease in transmission delay because the need for retransmissions is reduced.

The receiver of a DSSS signal has to know the chipping-code mappings and has to be synchronized to the correct phase of the code. That is why every packet is prefixed with a preamble for synchronization purposes.

An important difference between code division multiple access (CDMA) systems and the DSSS system used by the 802.11 is that CDMA is based on code multiplexing. That is, multiple transmissions can take place at the same time as long as different communication pairs are tuned to different codes. This requires the availability of a code pool to choose from, the logic to choose a code, and complex receivers synchronized for a specific code. In contrast, DSSS wireless LANs use the one code, which allows for broadcast communication (Bing, 2000).

The 802.11 DSSS physical supports two rates: 1 Mbps and 2 Mbps. A subsequent standard, the 802.11b, supports data rates of 5.5 Mbps and 11 Mbps. Similar to the FHSS physical layer, the DSSS physical layer also consists of two sublayers: the PLCP and the PMD. The PLCP of DSSS is very similar to that of FHSS and serves the same purpose. The PMD modulates the data stream for transmission via the channel. The channel bandwidth supported by the 802.11 standard is 11 MHz, and given that the spreading factor is 11, the data rate that can be supported is 1 Mbps or 2 Mbps. The rate depends on the modulation scheme used. The DSSS physical layer uses differential binary phase shift keying (DBPSK), where every symbol carries one bit, which allows for a data rate of 1 Mbps. To support the 2 Mbps rate, differential quadrature phase shift keying (DQPSK) is used, where every symbol carries two bits from the data stream. Thus, in both cases, 1 mega symbols are being communicated. The difference is the number of bits to which a symbol is mapped.

Infrared (IR)

So far, we have discussed the radio-based flavor of wireless LANs. Unlike radio-based WLANs, infrared is not regulated; hence, plenty of bandwidth is available. In addition, it does not suffer from electromagnetic interference, which is a limiting factor for radio-based WLANs. However, IR-based WLANs have their own sources of interference (e.g., sunlight, fluorescent light), which can substantially degrade the network performance. Like visible light, infrared does not penetrate opaque objects (e.g., walls), which entails the need for an access point in every room. Even though this may seem a disadvantage, especially because in radio LANs and AP can provide large coverage, this has great advantages. First, it promises secure communication because eavesdropping or any security attack for that matter (e.g., denial of service) is very difficult from outside. Furthermore, it provides interference immunity by allowing each room to have a separate deployment, and thus large IR LANs can be built (Stallings, 2002).

IR wireless LANs are simpler to implement and hence are less expensive. This is attributed to their use of intensity modulation for data transmission, which only involves detecting the signal's amplitude, unlike radio systems in which the frequency and/or the phase need to be detected.

One main issue with IR LANs is the absence of products in conformance with the standard. This makes deploying

IR LANs limited to small-scale usage under one management domain. Two main flavors exist of IR LANs: directed and omnidirectional. A directed IR LAN is used to create point-to-point connections. The transmitter and the receiver must have a line of sight between them. Depending on the transmission power used, directed transmissions produce high performance in terms of transmission distance, bandwidth, and throughput achieved. Data rates ranging from 1 to 155 Mbps over a distance of 1–5 km can be provided (Bing, 2000).

Directed IR can be used in a campus-sized network where different segments need to be connected to each other. To do that, directed links across buildings are created to connect bridges or routers. Indoors, directed IR can also be used to connect different segments in any suitable arrangement (e.g., to connect Ethernet or token ring segments; Stallings, 2002).

Omnidirectional IR can be used in scenarios similar to radio LANs. A ceiling-mounted transceiver broadcasts to all nodes within line of sight (e.g., in a room). They can be used only in an indoor environment because they rely on reflections off objects (walls, ceilings, desks, etc.) to propagate in all directions. Even though these reflected copies allow for freedom of alignment for the transmitter and receiver, a substantial amount of the energy is lost, which limits the data rate and range of communication. Indoor omnidirectional IR LANs operate at a rate limited to 4 Mbps within a range of 10 to 20 m (Bing, 2000).

Physical-Layer Standards

New standards have been approved that achieve higher data rates. In this section, we briefly discuss the main differences among the 802.11 standards a, b, and g and how these higher rates are achieved.

IEEE 802.11b

802.11b defines the high rate DSSS (HR-DSSS) that allows data rates as high as 5.5 Mbps and 11 Mbps. The PLCP of the HR-DSSS defines two types of frames: long and short. The long-frame format is basically the same as in the case of DSSS. Few fields have been added, mainly to define the data rate communicated (whether 5.5 or 11 Mbps) and the modulation scheme used. The preamble and header are always communicated at a rate of 1 Mbps to ensure backward compatibility with DSSS. The short frame has the same format as the long one, with the exception that the number of bits used for a field is less, to minimize overhead. For example, as opposed to 128 bits for synchronization in the long frame, only 56 are used in the short one. The other difference is that the short frame's preamble and header are communicated at a rate of 2 Mbps (as opposed to 1 Mbps in the case of the long frame). Like before, the PMD basically is responsible for modulating the bit stream that it receives from the PLCP (Roshan & Leary, 2004).

Two modulation schemes are used: complimentary code keying (CCK) and packet binary convolutional coding (PBCC). Higher data rates are achieved in this way: like before, an 11-MHz bandwidth is used. However, the spreading code is 8 chips long rather than 11 chips, as in

the 1-Mbps and 2-Mbps cases. In addition, the number of bits coded in an 8-chip code is different. Using the CCK modulation, every 4 bits from the data stream are encoded in an 8-chip code, thus allowing for a data rate equal to

$$11 \times 10^6 \times \frac{4 \text{ bits}}{8 \text{ chips}} = 5.5 \text{ Mbps.}$$

Similarly, the PBCC modulation scheme codes 8 bits in an 8-chip code, allowing for a data rate of 11 Mbps.

IEEE 802.11a

Unlike the 802.11b, which works in the 2.4-GHz ISM band, the 802.11a works in the unlicensed national information infrastructure (UNII) 5-GHz band. It supports data rates up to 24 Mbps and optionally up to 54 Mbps. In 802.11a, 300 MHz is used, which is divided into three 100-MHz bands, each with different maximum power output. The three bands used are 5.15–5.25 GHz, 5.25–5.35 GHz, and 5.725–5.825 GHz. Devices operating at these bands produce a power equal to 50 mW, 250mW, and 1W, respectively. The high power output allowed in the high band makes it more suitable for building-to-building devices (e.g., bridges connecting two LAN segments). The other two bands are suitable for indoor environments. Data is modulated using the orthogonal frequency division multiplexing (OFDM) scheme. The basic idea of OFDM is to minimize the inter-symbol interference (ISI) problem. ISI results when a symbol takes longer to reach the receiver. This delay, called delay spread, results from the multipath propagation discussed earlier. As a result of this delay, a symbol may arrive at the same time as another subsequent symbol. This can be dealt with by decreasing the number of symbols per second and thus ensuring that a symbol has an ample amount of time to reach before a subsequent symbol is sent. Obviously, this decreases the data rate achieved. Hence, what OFDM does is to break the channel bandwidth into subchannels. Each subchannel has a low symbol rate and thus low ISI. The subchannels are chosen to be orthogonal and thus low cochannel interference occurs. Hence, a receiver tuned at a given frequency sees all other signals as zero. Table 2 shows the data rates supported by the 802.11a standard along with the modulation scheme used.

IEEE 802.11g

The 802.11g standard is very recent. It was approved in 2003 and supports data rates up to 54 Mbps. Unlike

Table 2 Supported Data Rates and Modulation Schemes

Data rate (Mbps)	Modulation scheme
6	BPSK
9	BPSK
12	QPSK
18	QPSK
24	16-QAM
36	16-QAM
48	64-QAM
54	64-QAM

Figure 13: HIPERLAN/1 reference model.

802.11a, 802.11g operates in the ISM 2.4-GHz band and has backward compatibility with 802.11b. If all the devices in the network use 802.11g, the high data rates of 802.11g can be used. However, if any of the devices in the network uses 802.11b, all other devices have to switch to the low data rates supported by the 802.11b. The mandatory data rates are 6, 12, and 24 Mbps. The rest are optional. To ensure backward compatibility, the packet header and preamble are sent using CCK modulation, which is also used by the 802.11b, and the payload is sent using OFDM.

HIPERLANs

HIPERLAN Type 1

The high-performance radio LAN (HIPERLAN) Type 1 is the European counterpart of IEEE 802.11. It was developed by the European Telecommunications Standards Institute (ETSI). The protocol provides data rates of up to 23.5 Mbps and supports low mobility conditions (1.4 m/s). Similar to its counterpart, its reference model, shown in Figure 13, covers both the physical (PHY) and the MAC layers. The physical layer is responsible for transmission and reception of raw data via the wireless channel. The channel access control (CAC) sublayer determines how nodes will access the channel and which nodes have the right to access by allowing access priority to be specified. The MAC defines the different protocols responsible for power conservation, multihop forwarding, security, and data transfer to upper layers (BRAN, 1998; Jain, 2004; Papadimitriou, Lagkas, Obaidat, & S. Pomportsis, 2003).

Unlike 802.11, HIPERLAN/1 has a single physical layer that is not based on spread spectrum techniques. It uses a narrowband modulation in the 5.15–5.30-GHz range. It is important to notice that HIPERLAN does not provide an IR physical interface. Two data rates are supported: a lower rate, 1.47 Mbps, which uses FSK modulation, and a high rate, 23.5 Mbps, which employs GMSK as a modulation scheme. Thus, every packet contains a low-rate header (sent at 1.47 Mbps) followed by a high-rate header

and payload (sent at 23.5 Mbps); see Figure 14. By merely looking at the low-rate header, a node can decide whether it needs to listen to the rest of the packet. This way, if a packet is not meant for a node, it can save power by turning off its error correction, equalization, and other functionalities. The next paragraph contains more information about Figure 14 (Bing, 2000).

As the rate of data transmitted via a wireless channel increases, the effect of ISI increases. This is because symbol duration becomes smaller, and hence the delay spread effect becomes higher. To go around this problem, decision feedback equalization is employed. An equalizer eliminates the effect of ISI without enhancing the noise. Equalization involves a training sequence, which is known to the receiver to be transmitted by the sender. Upon receiving this sequence, the receiver compares it with the known sequence and adjusts its filter coefficients. At this moment, the receiver is ready to receive user data. Periodically, the receiver will need retraining to ensure effective ISI cancellation. The HIPERLAN standard does not specify what equalization technique to be used and leaves it to protocol implementers. GMSK has excellent power efficiency and spectral efficiency. It is a constant envelope scheme, which means the amplitude of the signal is constant. Hence, highly efficient power amplifiers can be used (no information loss will occur from nonlinear amplification because the signal amplitude is not carrying any information; Rappaport, 1996). In addition, forward error control (FEC) is used to increase the throughput by minimizing the need for retransmissions of bad packets. BCH is used where every 26 bits are coded into 31 bits (Nicopolitidis, Obaidat, Papadimitriou, & Pomportsis, 2003).

The MAC protocol of HIPERLAN/1 supports both asynchronous (data) as well as isochronous (audio and video) applications. The protocol does not reserve bandwidth for different users or application classes. However, it provides some kind of quality of service (QoS) by means of the supported priority scheduling scheme, which favors higher priority packets and takes into account their lifetime. HIPERLAN/1 MAC protocol is distributed, allowing for both infrastructure as well as ad hoc, multihop topologies. A node that senses the channel idle for 1700-bit times (in the high data rate) can transmit its packet with no overhead. However, the chances of the channel being idle for 1700-bit times are extremely low even for moderate load conditions. Thus, another mechanism can also grant channel access, which involves the use of the elimination yield—nonpreemptive multiple access (EY-NPMA). A station that senses a busy channel waits until the channel becomes idle, waits for 256-bit times (called the synchronization slot), and then runs EY-NPMA. In the

Figure 14: HIPERLAN/1 packet format. Source: Bing, 2000.

EY-NPMA scheme, channel access involves going through three phases, each of which can be thought of as a screening phase. In every phase, some nodes will drop from the competition, and the rest will move on to contend in the next phase. The third phase, however, does not guarantee a single winner, and thus collisions, even though unlikely, are still possible.

1. The prioritization phase consists of five slots, which allows for five priority levels. A station with priority r transmits a burst in slot $r + 1$, indicating a busy channel if and only if it does not sense a higher priority burst. The higher the node's priority, the faster it can get hold of the channel. At the end of this phase, one or more nodes (all with the same priority) will move on to the next phase. All others will have to wait until the next synchronization slot.
2. The elimination phase is 13 slots long. In this phase, stations that survived the previous phase transmit a burst for a number of slots geometrically distributed with a parameter $P = 0.5$. Thus, the burst length is one slot with probability $1/2$, two slots with probability 0.25 , and so on. Each station, at the end of its burst, senses the channel to see if a longer burst has been transmitted by others. If yes, the station quits contending for the channel. If not, however, it goes to the next phase. Obviously, the chances of more than one winner in this phase increases with the increase in the number of nodes that made it from the previous phase.
3. The yield phase: 15-slots long, all stations that made it to this phase back off for s slots, where s is also geometrically distributed with a parameter $P = 0.1$. A station sensing an idle channel at the end of its back-off interval can transmit its packet.

An overview of the EY-NPMA protocol is shown in Figure 15.

As we mentioned earlier, HIPERLAN/1 supports ad hoc topologies. This is achieved using a process called interforwarding. In simple terms, nodes can communicate with nodes out of their reach by transmitting to their neighbors, who forward the packet to their neighbors, and so on until it reaches its destination. For this to work properly, nonforwarding nodes need to know their direct neighbors,

and forwarding nodes need to know routing information, that is, the next hop to get to a particular destination and the path length. The forwarding function is optional; a node may choose not to forward traffic. A node can forward packets in two modes: point to point and broadcast. In broadcast mode, the forwarding node, called a multipoint relay, forwards the packet to all neighbors. Non-multipoint relays do not forward packets. The set of multipoint relays is chosen as the minimum set that covers all nodes within two hops from the node, thus minimizing the number of forwarding nodes.

Similar to other ad hoc networks, the multihop mode of HIPERLAN suffers from many problems. The dynamic nature of the network where nodes come and go makes maintaining correct information about the topology very difficult. In addition, the overhead involved in maintaining this information is very costly, especially in terms of energy, because mobile nodes are battery operated. Another problem that is aggravated in multihop networks is the wireless channel conditions. Dual Doppler effect (because both sender and receiver are both mobile), interference caused by parallel transmissions, and fading all make the chances of a packet reaching its destination successfully very small.

HIPERLAN Type 2

Upon completion of the HIPERLAN/1 standard, the ETSI decided to merge WLANs and wireless local loops, the communication between the end user and the service provider, into one protocol that is called broadband radio access networks (BRAN). The BRAN project standardizes wireless ATM protocols. This includes HIPERLAN Types 2, 3, and 4.

HIPERLAN/2 is very different from HIPERLAN/1 and has many salient advantages including these (Johnsson, 1999; Nicopolitidis, Obaidat, Papadimitriou, & Pomportsis, 2003):

- High data rates: HIPERLAN/2 supports data rates up to 54 Mbps.
- Connection-oriented: Communication between stations and the AP is connection oriented. A connection is established prior to any data transmission.

Figure 15: EY-NPMA protocol.

Figure 16: Format of the MAC frame in HIPERLAN/2.

- QoS support: HIPERLAN/2 provides QoS support because it is connection oriented and provides high data rates.
- Automatic frequency allocation: Unlike cellular networks where static radio-frequency planning is performed, the AP in HIPERLAN/2 performs dynamic frequency channel selection that is not in use by other APs, and that minimizes cochannel interference.
- Power saving: A mobile station can communicate to the AP its desire to schedule sleep periods to minimize power consumption. At the end of every sleep period, the station wakes up to see if the AP has sent any wake-up indication. If not, the station can go back to sleep for another period.

The physical layer of HIPERLAN/2 is very similar to that of 802.11a. They both operate in the 5-GHz band and use OFDM. In addition, they both offer data rates as high as 54 Mbps. To a great extent, the same modulation and coding schemes are used. However, synchronization and training sequences used are different.

Differences between the two protocols appear in the MAC layer. 802.11 is based on the CSMA/CA protocol. One problem is CSMA/CA that is probabilistic. A station does not have any guarantee that within a given time period it will be granted the channel to transmit. These delays would render supporting any real-time application very difficult even under moderate load conditions. HIPERLAN/2 is based on dynamic time division multiple access (TDMA) with time division duplexing (TDD). In a TDMA scheme, stations are dynamically assigned time slots according to their needs. Time slots are dynamically allocated depending on transmission needs. TDD means that part of the frame is used for the uplink (communication between the stations and the AP) and part for the downlink (from the AP to the stations). Once assigned a time slot, a station can transmit at regular basis during its slot. The AP notifies the stations when it is their time to transmit (Doufexi, Armour, Karlsson, Nix, & Bull, 2002; Papadimitriou, Lagkas, & Pomportsis, 2003).

A MAC frame has a duration of 2 ms and consists of different channels as shown in Figure 16. The broadcast channel (BCH) is a downlink channel through which the AP sends control information to all nodes in the network. This includes transmission power level, wake-up indicator, and identifier of the AP and the network, among other things. The frame control channel (FCH) is also a downlink channel that is used to announce how the rest of the current MAC frame has been allocated, that is, how much is allotted for the uplink, for the downlink, and for contention. The access feedback channel (ACH), also a downlink channel, conveys information regarding previous random access attempts that took place in the RCH. The downlink and uplink phases consist of a number of

packets to be communicated from and to the AP, respectively. The number of slots and how much per station is based on the AP announcements during the FCH channel. The random access channel (RCH) is an uplink channel used to compete for slots in subsequent MAC frames. Results of contention are reported back to stations in subsequent frames' ACH channel (Johnsson, 1999).

WLAN SECURITY

Wireless networks are more vulnerable to security threats than wired networks. This is because of the broadcast nature of the wireless channel. Any node within the transmission range of a WLAN can access it. Thus, enforcing security measures is of high importance in a WLAN. Two mechanisms are usually used to minimize security threats: authentication and encryption. Authentication ensures that only authorized nodes can access the network and encryption ensures that confidentiality is maintained.

Encryption in 802.11

Encryption is the process of transforming human-readable data (called plain text) into an unreadable form (called cipher text). Encryption and decryption typically involve the use of a common secret between the sender and the receiver (called the encryption key). Figure 17 illustrates the idea of encryption. Two types of encryption exist: block cipher and stream cipher. They both involve generating a key (called a stream key) from a basic secret key. In block cipher, the plain text is divided into blocks, and each block is encrypted using a fixed-size stream key. In a stream cipher, on the other hand, the data stream is processed continuously (e.g., taking one byte at a time). In addition, the stream key size is not fixed. Block ciphers provide a higher level of security than stream ciphers. This, however, comes at the cost of being more computationally demanding.

The 802.11 standard uses the wired-equivalent privacy (WEP) protocol, which is based on the RC4 encryption algorithm. RC4 is a stream cipher that uses symmetric keys. That is, if the sender uses a key K_1 to encrypt the

Figure 17: Block diagram of the encryption process.

data, the receiver uses the same key (i.e., K_1) to decrypt it. Symmetric key encryption is simple and requires a very trivial amount of computation. As we can see, the protocol tries to minimize the computation penalty introduced by encryption by using a stream, symmetric algorithm. The protocol does not provide any key distribution mechanism and thus assumes the keys to be manually configured in the client stations and the access point. Two key lengths are supported: 40 and 104 bits. The longer the key, the more difficult it is for an attacker to do a brute force attack in which all possible keys are tried.

If every time an encryption algorithm is that fed plain text P generates the same cipher text C , the algorithm is described as electronic code book (ECD). An attacker can do cryptanalysis to find patterns in the cipher text that can help him break the encryption. To provide more security, WEP goes around this problem by using a concept called initialization vectors (IVs). The goal is to change the encryption algorithm's output even if fed the same plain text. Thus, the encryption of a string P would result in a cipher text C_1 , and if the algorithm is run again, using the same string P , it would produce a cipher text C_2 , and so on.

An IV is nothing but a number to be added to the key that results in a new key. To ensure high randomness in the cipher text, it is good to change the IV for every frame sent. For the receiver to be able to decrypt the message, it needs access to the IV value used at the sender, and that is why every frame sent carries with it the IV used. The encryption process involves the following steps (Roshan & Leary, 2004):

1. For every arriving frame, generate a 24-bit IV and append it to the secret key K_1 , resulting in a stream key K_2 .
2. Calculate the integrity check value (ICV) of the arriving frame. The ICV is a CRC-32 that is used to ensure that the frame has not been tampered with and has not been corrupted in transmission.
3. Encrypt both the frame payload and the ICV using K_2 .
4. Create a frame that contains the encrypted payload, the encrypted ICV, and the IV used for the encryption.

The opposite process takes place at the receiving end. Receiver extracts the IV value, constructs the stream key, uses it to decrypt the payload and the ICV, and finally compares the decrypted ICV with an ICV it calculates for the arriving payload. If both match, the frame is good.

Authentication in 802.11

802.11 supports two authentication mechanisms: open system authentication and shared key authentication. Open system authentication is a two-way authentication that is used when a high security level is not required. A station requesting authentication sends a request to the access point. The access point responds back with a frame indicating either approval or disapproval. The shared key algorithm is based on WEP and requires both the station and the access point to have a shared key. A four-way authentication process takes place, which can be described as follows:

1. Client sends authentication request to the AP.
2. AP sends back a challenge.
3. Client sends back the challenge encrypted.
4. The AP decrypts what is received and compares it with the challenge. A match results in successful authentication.

Another authentication method that is not part of the 802.11 standard, yet implemented by many vendors, is the MAC address authentication. Here the client's MAC address is compared against a list of MAC address considered to be authorized to access the network. This is vulnerable to device theft. Thus, it is better to be used in combination with the other two approaches to allow for more security. The MAC address list is stored in a separate server called the RADIUS server. During the authentication process, the AP communicates with the RADIUS server to see if the latter has the MAC address in question.

Vulnerabilities

It is well known that the 802.11 security mechanisms are vulnerable to all sorts of attacks. As an example, consider the shared key authentication process. The AP sends the challenge in clear text format, which makes the authentication procedure exposed to clear text attacks. An eavesdropper can get the challenge and the response, and, from these two, extract the stream key. This is easy because the encryption is a simple XOR operation between the plain text and the stream key. XORing the cipher text and the clear text gives the stream key. Using the stream key, the hacker can now be authenticated easily because he can encrypt any challenge the AP sends. Listening to the channel and obtaining all the information sent back and forth is very simple. All a hacker needs is a sniffing software tool, which can log all the communications taking place on the channel.

An easier way to get the key is to make an educated guess. Remember that the keys have to be manually set up. In many cases, users do not change the key as it comes from the manufacturer, which makes guessing a matter of knowing the default key/keys that come from different vendors.

The IV length (24 bits) is another security threat. Given a highly loaded network or a patient hacker, the AP will exhaust all IVs and start reusing them. The hacker can thus collect enough frames with the same IV, and can extract the common parts between them. This would therefore expose the secret key and expose the whole wireless LAN.

Yet another vulnerability is the lack of AP authentication, that is, having the AP authenticating itself to the station. A hacker passively listening on the channel for an ample amount of time can collect useful information that enables him to set up an AP. Nodes closer to this (rogue) AP will connect to it. This way, the attacker will collect valid users' information and use it in accessing the network. This would not have been possible if the AP needed to authenticate itself to the stations (<http://www.wi-fiplanet.com/>, Geier). Many other vulnerabilities have been pointed out by the research community and this reference contains a good list of such sources.

QoS SUPPORT: IEEE 802.11E

As users are getting used to wireless LANs, their expectations are becoming higher. Users want WLANs to provide the same functionality as that of a wired counterpart. In addition, the new applications of WLANs, including home-office networking and wireless local loop, that require delay- and loss-sensitive multimedia communication makes QoS support an inevitable extension. Corporate wireless networks are expected to provide voice over IP (VoIP) services that can reduce or even replace the need to use cell phones in the work environment. Home networks, where a wireless network can eliminate all the wires and connect different devices together, are another foreseeable use. Service providers would appreciate a wireless local loop to provide their services. This would provide be cost-effective and give them a competitive edge.

Challenges in Providing QoS Support over Wireless

The wireless channel is highly dynamic. The signal strength and quality are affected by fading, self-interference, and cochannel interference and noise, among others. In addition, nodes move in random patterns and change their access point as they move around. At the same time, energy consumption has to be minimized because the devices (laptops, PDAs, etc.) are battery operated. All these and other issues make supporting QoS over wireless a very challenging task.

As we have seen, the hidden terminal problem imposes difficulties in sensing channels and thus is a limiting factor of the performance of the MAC protocol used. The DCF of 802.11 uses a CSMA-based protocol, which involves back-off periods of random length. Therefore, by definition the DCF is not suitable for QoS support. The PCF, even though was proposed to address delay-sensitive applications, was found to provide poor performance for even a small number of voice communications. This is readily apparent because an increase in the number of PCF nodes results in an increase in the polling list. Hence, nodes wait for longer periods to get their chance to transmit. Another problem with PCF is its lack of different priority levels. One last thing: PCF works only in the infrastructure mode and not the ad hoc mode. Because of these reasons, 802.11e is being developed.

QoS Mechanisms

Before discussing IEEE 802.11e, it is important to note that it is still a draft and has not yet reached the standardization level. The 802.11e draft provides QoS support using two coordination functions: the hybrid coordination function (HCF) with contention avoidance and the HCF with polled access operation. The first is more commonly referred to as the enhanced DCF (EDCF).

Enhanced DCF (EDCF)

802.11e (i.e., both EDCF and HCF) supports four traffic classes known as access categories (AC) in the 802.11e terminology. Table 3 shows the different ACs and what applications they address. The protocol assumes the existence

Table 3 ACs and Applications Addressed

AC	Applications targeted
0	Low priority/best-effort traffic
1	Video probe
2	High-rate real-time (e.g., video)
3	Low-rate real-time (e.g., voice)

of a mechanism to classify the traffic. In other words, the protocol works with packets already marked with one of the four ACs.

To put it in a nutshell, the protocol supports the different priorities mainly by changing two parameters: the interframe spacing and the limits of the contention window. Traditional DCF supports priority to gain the channel by introducing different IFSSs for ACKs, PCF, and DCF. Similarly, EDCF uses different IFSSs for different ACs (called arbitration IFSSs, AIFSSs). Thus, higher priority packets can acquire the channel before others. In addition, the size of the contention window is smaller for higher priority packets. The smaller the contention window size, the faster a node can gain the channel. The smaller the CW_{min} is, the smaller the back-off time. Furthermore, the faster a station reaches the CW_{max} , the faster it increments its retry counter, which results in faster channel gain.

In traditional DCF, a station has to contend for the channel for every packet it needs to transmit. EDCF, in contrast, allows transmission of more than one packet. The transmit opportunity (TXOP) is a parameter that defines the duration of time a station can seize the channel once it has gained access.

If you have ever been trying to make a phone call and heard the "all circuits are busy" message, then you are familiar with admission control. Given the limited amount of resources available, a network can support a defined volume of traffic for every AC. If the input traffic of a particular AC exceeds its defined limit, all sources belonging to that AC will suffer. To prevent such behavior, admission control is applied. The goal of admission control is to deny access to any source attempting to use the channel once the predefined limit has been reached. The distributed admission control (DAC) scheme of the EDCF monitors channel utilization and announces that information to all stations in its beacon message. When the available resources approach 0, sources stop initiating new stream sessions.

HCF with Polled Access Operation

The HCF operation is very similar to the PCF function. It relies on polling to meet different nodes' requirements. A logical entity called the hybrid coordinator (HC) that runs in the AP is responsible for scheduling and other processing related to the polling operation. Unlike the EDCF where the TXOP is predefined, the HCF provides a mechanism for stations to request a TXOP with specific characteristics. The HCF can operate in one of two modes: contention-free HCF and coexistence with the EDCF.

In the contention-free HCF, the AP polls the stations. In its poll message, the AP specifies the TXOP. A station that

has some traffic to send replies back to the poll within an SIFS period. If the station does not have traffic or if the length of the TXOP is not enough, it replies with a null frame.

The HCF function can operate with both the EDCF and the DCF at the same time. To poll the stations, the AP waits a PIFS time, which is shorter than what a DCF or EDCF station would need to wait. Thus, the AP can gain the channel. Similarly, a polled station has to wait only an SIFS time to respond to a poll. Therefore, the HCF function can work smoothly during the contention period of EDCF or DCF.

The EDCF, even though it has the logic to indicate whether new traffic should be initiated, does not enforce any type of behavior on the nodes. The AP simply announces the available capacity. Whether to honor this information is totally up to the stations. HCF, on the other hand, has a strict admission-control mechanism. A station willing to initiate a stream has to consult with the AP, which determines whether the stream can be supported without affecting other streams. Stations communicate to the AP the QoS parameters they desire using the transmission specification (TSPEC). In the TSPEC, a station specifies the priority, data rate, delay, and frame size, among other parameters. The AP checks these requirements against the current network conditions and decides accordingly whether to honor the request, reject it, or provide the station with TSPEC that it can afford to support (i.e., renegotiate the requirements). The station may accept the offer or turn it back. A station is removed from the pollable list either when it explicitly deletes the TSPEC or when the TSPEC timer expires. The timer expires when the station sends a null-frame for a number of poll requests within a time interval defined by the TSPEC timer.

ADVANCED TOPICS

Bluetooth

Bluetooth is a low-power (1-mW), short-range (within 10 m) technology. It was initially proposed by Ericsson as a way for users to use their laptops for making phone calls via cell phones. Since then, the technology was adopted by many companies and for different applications, mainly for cable replacement and ad hoc networking (intercommunication among Bluetooth-enabled devices). Similar to WLANs, it works in the ISM band, and that is the reason why it uses high-rate frequency-hopping scheme.

A Bluetooth network is organized in piconets and scatternets. A piconet is a small network consisting of a master node and between one and seven slaves. The master node is responsible for choosing the communication channel, including frequencies and the hopping sequence used. Nodes in a piconet communicate through the master node and not directly. A node may belong to one or more piconets. This overlapping creates what is called a scatternet. This allows for multihop communication where overlapping nodes serve as forwarders from one piconet to another.

The protocol consists of the following five layers, which are responsible for link establishment and maintenance, security and error control, service discovery, and com-

munication with higher layer protocols (Stallings, 2002; Nicopolitidis, Obaidat, Papadimitriou, & Pomportsis, 2003):

1. Radio layer: This layer deals with the specifications of the air interface. Frequency bandwidth, modulation, transmission power, and channel access are specified. The standard specifies the use of GFSK for modulation. It also specifies the use of FHSS operating in a 78-MHz bandwidth with each channel occupying 1 MHz. The hopping rate is equal to 1600 hops/sec and a maximum data rate of 1 Mbps.
2. Baseband layer: It specifies how FHSS with TDD/TDMA is to be used for communication between nodes in a piconet. To prevent interference, nodes in different piconets use code division multiple access (CDMA). That is, different piconets use different hopping sequences. Two types of communication can be used. The synchronous connection oriented (SCO) method is used for communication between a slave and a master and involves the allocation of fixed bandwidth. The other, asynchronous connectionless (ACL) method, is a point-to-multipoint communication between the master and all the slaves in a piconet.
3. Link manager protocol (LMP): As its name implies, this protocol specifies link setup and management between two Bluetooth devices, including issues of clock synchronization, authentication and key distribution for security purposes, the protocol version used, and the nodes' mode (master, slave), and so forth.
4. Logical link control and adaptation protocol (L2CAP): This protocol defines connectionless as well as connection-oriented services. It also allows for QoS support by letting a transmitter and a receiver negotiate QoS flow parameters such as delay and delay variation.
5. Service discovery protocol (SDP): It specifies how Bluetooth devices search for other Bluetooth devices and establish communication with them.

One domain where Bluetooth is envisaged to serve greatly is in home networking. Connectivity among different devices at home that provides both coordination and freedom from cables will be user-friendly technology.

Voice over 802.11

Even though wireless LANs were initially thought of as wireless versions of wired LANs, which implied they are solely for data communications, the fact that they are wireless introduces higher expectations. Voice over WLANs is one such example. A common network for both voice and data has a lower cost than operating two separate networks.

As we have seen, 802.11 DCF is the fundamental access method of the 802.11 and is used for data communications. It uses CSMA/CA for channel access with a back-off algorithm to reduce the possibility of collisions. Even though DCF was meant for data communications, studies have shown that it can be used for voice. However, the performance is relatively low (Prasad, 1999). Because it is a random assignment scheme, DCF provides unbounded

delays under high loads. Randomness means that the network cannot provide deterministic guarantees regarding delay. It is important to mention that delay and delay variation (jitter) are the key impairments for voice communications (Obaidat & Obeidat, 2002; McDysan & Spohn, 1999).

The inability of CSMA protocols to support real-time traffic has been studied in the context of voice and data integration via Ethernet. It has been shown that Ethernet can provide good performance at low loads. Moreover, it is argued that the need for priority in WLANs is more pressing than in Ethernet for the following reasons:

1. WLANs provide lower rates than Ethernet, which result in high queuing and transmission delays.
2. CSMA/CA has throughput/delay characteristics that are worse than those of CSMA/CD.

It has been also shown that CSMA/CA “is not robust with respect to the network topology and the choice of routing protocol.” This is with respect to non-real-time traffic, which means that the protocol performs worse with real-time traffic.

The PCF is used for real-time traffic that has delay bounds. However, it can operate only under the centralized scheme where there is a base station. This is because PCF uses polling to grant stations channel access. Many researches addressed the performance of voice and data over the PCF function of the IEEE 802.11. The performance of voice and data over the PCF function was studied with the assumption that voice communication takes place between stations that are in different BSSs. The conclusion is that the performance of the PCF function is poor and that only a few voice conversations can be supported. No echo cancellation was used; therefore, a small super-frame size of 20 ms, which limits how many conversations can be in the polling list, is considered.

Crow, Widjaja, Kim, & Sakai (1997b) propose the use of echo cancellation for voice communication. However, they use a 420-ms superframe size that consumes most of the delay budget of voice. This implies that if voice has to go through an IEEE 802.11 link, it has to be the only link. In other words, you cannot have the wireless link as the last hop in the path between the source and the destination of the call. The authors suggest that when a voice station does not have any data to transmit or receive, it should be dropped from the polling list immediately. This way, the remaining bandwidth can be used by other stations. Nonetheless, leaving the list every time a station’s silence period starts (i.e., the voice source is in the OFF state) will result in more delay at the beginning of every talk spurt, which will not be acceptable.

The performance of uncompressed voice (64 kbps) and data over IEEE 802.11 has been studied using an analytic approach. The conclusion is that the performance is low and, with the introduction of echo cancellation, more voice conversations can be achieved, but this will affect the bandwidth available to the data stations. A recommendation made to deal with voice traffic is not to drop a voice station from the polling list, even when it is silent. The point is that even though this will limit the

number of voice communications, it controls delays and delay variations that result in a “reasonable” number of voice conversations.

All of the aforementioned studies use the same PCF parameters and trade one thing for another. The key parameters here are the super-frame size and the packet size. However, they all reach the same conclusion: that voice performance via PCF is poor. Choi, Prado, Shankar, and Mangold (2003) compare the performance of DCF and EDCF for voice, video, and data. They show that EDCF provides better performance in terms of frame loss and delay for voice. However, PCF is not considered in the comparison.

GLOSSARY

AC Access categories supported by the IEEE 802.11e standard to provide quality of service.

ACH Access feedback channel is a time channel used in the MAC protocol of the HIPERLAN/2 standard. It is a downlink channel used by the AP to inform the stations of previous random access attempts.

ACK Acknowledgement packet transmitted by the destination node to the source node to acknowledge the successful reception of a data packet.

ACL In a Bluetooth network, the asynchronous connectionless (ACL) is a point-to-multipoint communication between the master and all the slaves in a piconet.

Ad Hoc Network A network topology where there is no central control (base station or access point) and the stations are able to communicate directly.

AP Access point is a station that provides central control in a network cell

ATM Asynchronous transfer mode, a network technology based on transferring data in cells or packets of a fixed size.

Authentication The process of identifying an individual, usually based on a username and password.

Band A contiguous range of frequencies.

BCH Broadcast channel is a downlink channel through which the AP sends control information to all nodes in a HIPERLAN/2 network.

Block Ciphers An encryption type where the plain text is divided into blocks and each block is encrypted using a fixed-size stream key.

Bluetooth A low-power (1-mW), short-range (within 10-m) wireless network technology.

BRAN Broadband radio access networks is an ETSI project that standardizes the wireless ATM protocols, including HIPERLAN Types 2, 3, and 4.

BSA Basic service area is the coverage area of a BSS.

BSS The basic service set resembles the basic building block in the 802.11 architecture. It is analogous to a cell in a cellular network.

Carrier A wave form in a communications channel modulated to carry analog or digital signal information.

CCK Complimentary code keying is a modulation technique used in the IEEE 802.11b standard. Using CCK modulation, every four bits from the data stream are encoded in an eight-chip code, thus allowing for a data rate equal to 5.5 Mbps.

- CDMA** The code division multiple access technique is used to prevent interference among different nodes, which transmit simultaneously at the same frequency band.
- CFP** The contention-free period is a time interval defined by the PCF access mode.
- Chip** A chip sequence is used to replace a data bit in the IEEE 802.11 standard.
- Coding Techniques** Coding techniques maximize the benefit of transmission over noisy wireless channels by introducing redundancies in the bits transmitted so that the receiver can still recover a reasonably distorted packet.
- Collision** The situation that occurs when two or more nodes attempt to send a signal along the same channel at the same time. The result of a collision is generally a garbled message. All computer networks require some sort of mechanism to either prevent collisions altogether or to recover from collisions when they do occur.
- Contention-Based Protocol** A MAC protocol type, usually used in ad-hoc network topology, in which the nodes contend for medium access and there is no central control.
- Contention-Free Protocol** A MAC protocol type, usually used in infrastructure network topology, in which the nodes do not contend for medium access, but there is a central control that decides which node can transmit.
- CSMA/CA** Carrier sense multiple access with collision avoidance is a MAC protocol used by the IEEE 802.11 standard.
- CSMA/CD** Carrier sense multiple access with collision detection is a MAC protocol used by the IEEE 802.3 (Ethernet) networks.
- CTS** A clear-to-send packet is transmitted to the source node by the destination node in a IEEE 802.11 WLAN to show that it ready to receive data.
- CW** The contention window is a time interval that defines the range of the back-off time in a IEEE 802.11 WLAN.
- DBPSK** In a IEEE 802.11 WLAN, the DSSS physical layer uses a differential binary phase shift keying (DBPSK) modulation technique, where every symbol carries one bit, which allows for a data rate of 1 Mbps.
- DCF** The distributed coordination function is a contention-based protocol, which resembles the basic access mode of the 802.11 standard. It is based on the CSMA/CA scheme and assumes an ad hoc network topology.
- DIFS** The distributed coordination function IFS is the time delay used by the DCF frames.
- Directional Antennas** Directional antennas focus their radiation in one direction to provide greater coverage distance.
- Diversity Antennas** Diversity antennas receive on more than one element, and when transmitting, they send through the element with the best received signal.
- DQPSK** In a IEEE 802.11 WLAN, the differential quadrature phase shift keying (DQPSK) modulation technique is used to support a data rate of 2 Mbps, in which every symbol carries two bits from the data stream.
- DSSS** The direct sequence spread spectrum is a physical-layer protocol used by IEEE 802.11. The main idea of DSSS is to spread the signal energy over a large bandwidth so that to other unintended receivers the signal can be treated as noise that can be easily rejected.
- ECD** Electronic code book is any encryption algorithm that generates the same cipher text every time it is fed the same plain text.
- EDCF** The enhanced DCF protocol is used by the IEEE 802.11e standard. It uses traffic categories to support QoS.
- ESS** Multiple BSSs can be connected to each other by connecting their APs to a distribution system, forming what is called an extended service set (ESS).
- ETSI** The European Telecommunications Standards Institute.
- Exposed terminal:** The exposed terminal problem can appear in an ad hoc WLAN topology. Specifically, a node postpones its transmission because it wrongly estimates that its data would collide with another node's.
- EY-NPMA** The elimination yield—nonpreemptive multiple access protocol is a contention-based MAC protocol used by the HIPERLAN/1 standard.
- FCC** The main duty of the Federal Communications Commission is to regulate public airwaves in the United States.
- FCH** The frame control channel is a downlink channel that is used by the AP to announce how the rest of the current MAC frame has been allocated. It is used by the HIPERLAN/2 WLAN standard.
- FEC** Forward error control increases the throughput by minimizing the need for retransmissions of bad packets (used by HIPERLAN).
- FHSS** In frequency hopping spread spectrum (FHSS), the signal is spread by sending at one frequency for a short period of time and then switching (hopping) to another frequency in a seemingly random fashion. It is a physical layer protocol used by the IEEE 802.11 standard.
- GFSK** According to the IEEE 802.11 standard, the PMD sublayer modulates the data using the Gaussian frequency shift keying technique. Depending on the data rate supported (whether 1 Mbps or 2 Mbps), GFSK or 4GFSK is used. 4GFSK translates every two bits into one signal element, which allows the rate to be doubled.
- GMSK** The Gaussian minimum shift keying modulation scheme is used by the HIPERLAN/1 standard.
- HCF** The hybrid coordination function is a QoS supportive protocol used by the IEEE 802.11e standard.
- HEC** The header error control is an ITU-T cyclic redundancy check, CRC16, used for error detection by the IEEE 802.11 standard.
- Hidden Terminal** The hidden terminal problem can appear in an ad hoc WLAN topology using carrier sense. Specifically, a node's transmission collides with another node's because it is not able to detect the transmission of another node.
- HIPERLAN** High performance local area network is a WLAN standard defined by ETSI.

- HR-DSSS** The 802.11b defines the high-rate DSSS (HR-DSSS), which allows data rates as high as 5.5 Mbps and 11 Mbps.
- IBSS** The independent BSS resembles the infrastructureless ad hoc arrangement. In an IBSS, stations communicate in a peer-to-peer fashion where no AP or any other intermediary is needed. At least two stations are needed to form an IBSS.
- IFS** In a IEEE 802.11 WLAN, access priority to the wireless channel is provided through the use of interframe spacing (IFS), which is the duration of time that has to pass before a node can try to access the channel.
- Infrastructure Topology** A network topology where the medium access is controlled centrally (using a base station or access point).
- Interference** Interference refers to the extraneous, unwanted signals that affect the proper system operation. Not only does interference affect the quality of the signal communicated from the transmitter to the receiver, it can also affect the functionality of the protocol.
- IR** Infrared.
- ISI** The intersymbol interference problem results when a symbol takes a long time to reach the receiver. This delay, called delay spread, results from multipath propagation. As a result of this delay, a symbol may arrive at the same time as another subsequent symbol.
- ISM** The industrial, scientific, and medical band is a frequency band that does not require any licensing, so it is used by many wireless applications.
- L2CAP** The logical link control and adaptation protocol (L2CAP) is used by the Bluetooth standard and defines connection-less and connection-oriented services. It also allows for QoS support by letting a transmitter and a receiver negotiate QoS flow parameters such as delay and delay variation, among other things.
- LMP** The link manager protocol specifies link setup and management between two Bluetooth devices, including issues of clock synchronization, authentication, and key distribution for security purposes, the protocol version used, and the nodes' mode (master, slave).
- MAC** Medium access control.
- Modulation Techniques** Techniques used to modulate the data stream into a form suitable for physical transmission.
- Multipath Fading and Shadowing** When a signal is transmitted, multiple versions of the same signal take different paths to arrive at the receiver. The first to arrive at the receiver is the one going through the line of sight (LOS), which is the path that does not have any obstacles between the transmitter and the receiver. Other, delayed versions, follow other paths resulting from impinges on obstacles in the path. These delayed copies, when they arrive at the receiver, either add constructively or destructively. This phenomenon, where the signal quality depends on the multipath propagation, is referred to as multipath fading.
- NAV** In an IEEE 802.11 network, every node maintains what is called a network allocation vector (NAV). Nodes adjust the values of their vectors as they overhear packet transmissions. A node attempts to check the channel status (whether idle or not) only when the duration in the NAV elapses.
- OFDM** According to the IEEE 802.11a standard, the data is modulated using the orthogonal frequency division multiplexing (OFDM) scheme. OFDM breaks the channel bandwidth into subchannels. Each subchannel has a low symbol rate and thus low ISI. The subchannels are chosen to be orthogonal and thus low cochannel interference occurs.
- Omnidirectional Antennas** Omnidirectional antennas provide a 360-degree radiation pattern.
- Path Loss** As a signal propagates from the transmitter to the receiver, it attenuates (i.e., losses its energy) with distance. This phenomenon is called path loss. It depends on many other factors including the reflecting objects and big obstructions in the path between the transmitter and the receiver.
- PBCC** The packet binary convolutional coding is a modulation technique used in the IEEE 802.11b standard. Using the PBCC modulation, every eight bits from the data stream are encoded in an eight-chip code, thus allowing for a data rate equal to 11 Mbps.
- PCF** The point coordination function provides a contention-free protocol that can be used for connection-oriented real-time traffic such as voice in an IEEE 802.11 network. This is done by polling the stations one at a time. This polling is done by the AP.
- PIFS** In a IEEE 802.11 network, PCF interframe space (PIFS) is the short time interval that the AP has to wait to gain access to the channel before any other node.
- PLCP** The physical layer convergence protocol is a 802.11 sublayer protocol responsible for adding necessary headers for the purposes of synchronization, timing, and error control.
- PLW** A PSDU length word (PLW) is a 12-bit field that indicates the size of the MAC frame used by the physical layer of the IEEE 802.11 standard.
- PMD** The physical medium dependent sublayer is responsible for raw transmission of bits over the air; mainly performs modulation of the data stream. It is defined by the IEEE 802.11 standard.
- PSF** The PLCP signaling field (PSF) is a four-bit field used to specify the data rate at which the frame was transmitted. Data rates range from 1 Mbps to 4.5 Mbps in increments of 0.5 Mbps. It is defined by the IEEE 802.11 standard.
- QoS** Quality of service.
- RC4** A stream cipher encryption algorithm that uses symmetric keys.
- RCH** The random access channel is an uplink channel used by the nodes to compete for slots in subsequent MAC frames. It is used by the HIPERLAN/2 MAC protocol.
- RTS** In an IEEE 802.11 WLAN, a request-to-send (RTS) control packet is initially transmitted by the source node to the destination node to get permission to transmit data.
- SCO** In a Bluetooth network, the synchronous connection oriented (SCO) method is a communication between a slave and a master and involves the allocation of fixed bandwidth.
- SDP** The service discovery protocol specifies how Bluetooth devices search for other Bluetooth devices and establish communication with them.

SIFS According to the IEEE 802.11 MAC protocol, the short IFS (SIFS) is the shortest amount of time and hence the highest priority followed by the PIFS and the DIFS.

Stream Ciphers In a stream-cipher encryption algorithm, the data stream is processed continuously (e.g., taking one byte at a time).

TDD The main idea of a time-division duplexing (TDD) protocol is that part of the frame is used for the uplink and part for the downlink.

TDMA In a time-division multiple access scheme, stations are dynamically assigned time slots according to their needs. Time slots are dynamically allocated depending on transmission needs.

TSPEC In an IEEE 802.11e network, stations communicate to the AP the QoS parameters they desire using the transmission specification (TSPEC). In the TSPEC, a station specifies the priority, data rate, delay, and frame size, among other things.

UNII The unlicensed national information infrastructure (UNII) band is a 5-GHz frequency band used by IEEE 802.11a and the HIPERLAN networks.

WEP The 802.11 standard uses the wired-equivalent privacy (WEP) protocol, which is based on the RC4 encryption algorithm. A better and more secure protocol called wi-fi protected access (WPA) has been released recently.

WLAN Wireless local area network.

INTRODUCTION

Recent technological breakthroughs in ultrahigh integration and low-power electronics have enabled the development of miniaturized battery-operated sensor nodes (sensors, for short) that integrate sensing, signal processing, and wireless communications capabilities (Akyildiz, Su, Sankarasubramaniam, & Cayirci, 2002; Estrin, Govindan, Heidemann, & Kumar, 1999; Pottie & Kaiser, 2000; Sohrabi et al., 2000; Min et al., 2001; Rabaey et al., 2000; National Research Council 2001). Together with innovative and focused network design techniques that will make possible massive deployment and sustained low-power operation, the small size and cost of individual sensors are key enabling factors for a large number of applications. Aggregating sensors into sophisticated computation and communication structures (the wireless sensor networks) will have a significant impact on the way people interact with their environment. Indeed, a large number of networked sensors will enable collecting, sharing, and processing enormous amounts of spatial and temporally dense data over, possibly, large geographical regions.

An example application of WSNs would be to enable the elderly and the disabled to live more independent lives. Sensors record and store a variety of information about individuals and their activities. Such information can be shared with other people or with a “smart” environment to offer needed services. Clearly, one of the issues involved here is *privacy*—the information is of sensitive nature and must be protected. At the same time, quick access to it may be necessary in the event of an emergency medical situation. Another example is effective monitoring and management of public infrastructure systems in a metropolitan area using an integrated information grid. The grid includes, among other components, WSNs that will capture, transport, and store a variety of information

to be used to discover patterns in infrastructure state information, which can be presented to decision makers. Again, integrity and privacy of such information as well as timely access to it could be critical, especially in emergency situations.

The range of applications for WSNs continues to expand with continued research and development. In addition to these applications, many other applications, such as battlefield command and control, hazardous material detection, and emergency response, will use WSNs as mission-critical components. Consequently, this requires WSNs to provide timely, high-quality information with commensurate security protection in the face of adverse deployment conditions. This is complicated, however, by a number of limiting factors including the following:

- (1) Characteristics of sensors: small size; modest computing, communication, and energy capabilities; and anonymity of sensors resulting from lack of fabrication-time identifiers.
- (2) Features of current sensor and WSN technology: lack of security features at the physical level, structural weakness of WSNs, protocol-specific virtual infrastructures, and sporadic connectivity.
- (3) WSN deployment: massive and dense deployment covering large geographical areas, unattended operation in hostile environments, and multihop ad hoc communications.

Another complicating factor is the WSN operation, which requires the collaboration of dynamic groups of sensors to accomplish their mission. Moreover, the staggering amounts of data that can be collected by WSNs further exacerbate the security problem. These factors greatly increase the number of possible points of failure

and make sensors and WSNs increasingly vulnerable to a multitude of security threats including physical tampering, spoofing, denial of service, and impersonation, among many others. If an adversary can thwart the work of the network by altering the information produced, stopping production, or pilfering information, then the perceived usefulness of WSNs would be drastically curtailed.

A recent report by the National Research Council (2001) on embedded networks (including WSNs) states that “defining and then protecting system boundaries where physical boundaries are likely to be nonexistent and where nodes can automatically move in and out of the system will be a serious challenge. Further, managing the scale and complexity of EmNets, while at the same time handling the security challenges of mobile code and the vulnerability to denial-of-service attacks, will require significant attention from the research community.” It follows that security is a fundamental issue that must be resolved for the potential of WSNs to be fully exploited.

The main goal of this chapter is to survey recent results in the area of WSN security and countermeasures. Further, to mitigate security threats, especially in massive deployment of networked sensors, a security solution is presented that provides managed network mission and tasks, communication anonymity and confidentiality, continuity of (secure) operation, and protection against physical tampering, impersonation, and denial of service. In general, salient characteristics of WSN security solutions include the following:

- lightweight, with minimal communication, storage, and computation overhead;
- scalable to massive deployment;
- minimal management at both sensor and network levels;
- high resiliency to dynamic configuration of the network and the task workgroups;
- dynamic adaptation to deployment context (e.g., hostile versus friendly environments);
- graceful degradation when the network becomes sparse over time; and
- high resiliency to node capture.

The remainder of this chapter is organized as follows: the second section provides a model for WSNs, the third section discusses security issues in WSNs; the fourth section presents countermeasures and reports on contemporary WSN security research. The fifth section describes a fresh approach to securing WSNs. The sixth section presents a proposal to securing sensors and WSNs based on the new approach. Finally, the seventh section concludes the chapter and outlines directions for future research.

WIRELESS SENSOR NETWORKS

Securing WSNs presents formidable scientific and engineering challenges to sensor and WSN researchers and designers. Numerous factors are at play. The capabilities and constraints of sensor hardware influence the type of security mechanisms that can be hosted on a sensor node

platform. Also, the constraints on WSN communications and deployment greatly affect the selection of security mechanisms. In light of these constraints, it is necessary to describe the basic components of WSNs and to discuss security goals, threats models and attacks, and security countermeasures. After describing the components of sensors and WSNs in this section, the next sections discuss the main design issues, security issues, and related work. Our analyses reveal that although previous security solutions for WSNs are appropriate for networks of limited size, they are not applicable to large-scale WSNs.

From a purely architectural perspective, a WSN is a collection of individual sensors connected and dynamically configured in ad hoc wireless network topologies to provide support for detection and monitoring applications.

The Sensor Node

A sensor is an electronic device that is capable of detecting environmental conditions such as temperature, sound, or the presence of certain objects. Sensors are generally equipped with data processing and communication capabilities. The sensing circuitry measures parameters from the environment surrounding the sensor and transforms them into electric signals. Processing such signals reveals some properties about objects located and/or events happening in the vicinity of the sensor. The sensor sends such sensed data, usually via radio transmitter, to a command center either directly or through a data collection station (a base station or sink). The base station can perform fusion of the data to filter out erroneous data and anomalies and to draw conclusions from the data over a period of time. For example, in a reconnaissance-oriented WSN, sensor data indicates detection of a target and fusion of multiple sensor reports can be used for tracking and identifying the detected target.

A block diagram design of a typical sensor is depicted in Figure 1. The functionality of the sensing circuitry depends on the sensor capabilities. In general, the sensing circuitry generates analog signals whose properties reflect the surrounding environments. These signals are sampled using an A/D converter and stored in the on-board memory as a sequence of digital values. The sensed data can be further processed using a data processor (microprocessor

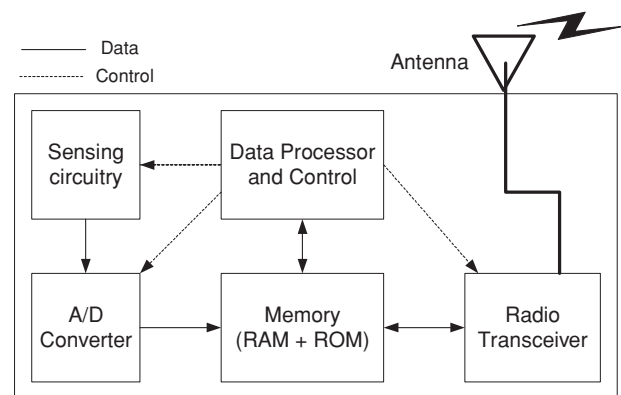

Figure 1: Block diagram of a typical sensor.

or DSP) prior to sending them over to the base station using the radio transceiver. The capabilities of the data processor are subject to a trade-off. A powerful DSP can be advantageous because it will allow the sensor to transmit only important findings rather than excessive raw readings. Reducing the sensor's traffic generation rate can save the energy consumed by the radio transmitter and can decrease radio signal interference and collisions among the deployed sensors. On the other hand, sophisticated data processing can consume significant energy and can be a cost and a design burden by increasing the complexity of the sensor design. In terms of WSNs, however, it may be better to have sensors where there is more processing at the processor rather than transmit all the values. This is because the energy expended in the execution of 800–1000 instructions is approximately equivalent to the energy expended in one transmission. In all cases, the sensor has to include some control logic to coordinate the interactions among the different functional blocks. Such control functions are also performed by the data processor.

Wireless sensors are not all created equal—they may have varied roles and capabilities depending on their intended application. Some sensors may be part of a mobile robot where commands can be given regarding location and mobility as well as regarding power supplied by a power generator. Others might be nanotechnology-based with no fabrication-time identifiers and nonrenewable power sources. Some may be incorporated into swarm devices that have considerable processing power. The vast majority of sensors, however, are small in size, with limited capabilities and low cost. The small form factor prohibits the use of long-lasting batteries and constrains sensors to low-power processors and small radios with limited bandwidth and transmission ranges. Likewise, deployment in massive numbers, combined with remote operations, preclude recharging or replacing batteries. Thus, sensors have to operate with the initial power budget: once the batteries are depleted, the sensor expires.

Recently, a number of advanced sensor devices have started to emerge. Most notable among these sensors is the MICA Mote developed by the University of California at Berkeley (Horton et al., 2002; Warneke, Last, Leibowitz, & Pister, 2001). A typical Mote node has 128 KB of flash memory, 4 KB of RAM, a low-power Atmel ATmega 128 processor (8-bit, 4 MHz), and runs with 2 AA batteries. Figure 2 hints at the size of one of the available configurations of Mote nodes. Motes are managed by the TinyOS operating system, also developed at the University of California Berkeley. The TinyOS has a very small footprint and support self-configuration and power-down modes. A single-chip implementation of a Mote node is expected to be commercialized soon and to bring the cost of Motes to a very low level when mass produced.

Network Components

Typically, wireless sensors can be deployed either by strategically placing them at specific locations or by air-dropping them in a remote area. Oftentimes, these sensors are deployed in a hostile environment where human oversight is very difficult, if not impossible. Such deployment

Figure 2: A picture of a Mote node, courtesy Univ. of California Berkley.

of sensors implies that the nodes are expected to perform sensing and communication with no continual maintenance or battery replenishment. Hence, they are built to be as self-sufficient as possible. Other forms of WSNs exist, for example, a WSN established among mobile robots. However, a detailed discussion of such networks is beyond the scope of this chapter.

Wireless communications may use protocols to implement multidrop topologies by emulating wired connections with radio frequency (RF) links using standards such as IEEE 802.11 to bring Ethernet connectivity to wireless networks. Alternatively, they may use lightweight communications protocols, such as the one described by Wadaa, Olariu, Wilson, Eltoweissy, and Jones (2005). Figure 3 illustrates the basic elements of a typical WSN, including sensors producing sensor information distributed in sensor patch(es), a sink or base station or gateway, and a route for sensor information. From a conceptual perspective, the sensors can be distributed in a patch (or field) to carry out some monitoring or detection function. As they detect an event or phenomenon, the relevant information is transmitted from sensor to sensor to local sink nodes (aggregation sensor nodes) to base station and on to user or command center and the outside world.

Because sensors are battery operated and their batteries typically cannot be recharged, keeping the sensor active all the time will limit the duration that the battery can last. Therefore, optimal organization and management of the WSN is very crucial to perform the desired function with an acceptable level of quality and to maintain sufficient sensor energy to last for the duration of the required mission. Mission-oriented organization of a WSN enables the appropriate selection of only a subset of the sensors to be turned on and thus avoids wasting the energy of sensors that do not have to be involved. Examples of energy-conscious network management techniques include multihop routing, data aggregation, and clever medium access control (Akyildiz, Su, Sankarabramaniam, & Cayirci, 2002; Shah & Rabaey, 2002; Akkaya & Younis, 2005; Chandrakasan & Balakrishnan, 2000; Intanagonwiwat, Govindan, & Estrin, 2000; Younis, Youssef, & Arisha, 2003; Woo & Culler, 2001; Shih et al., 2001; Singh & Raghavendra, 1998; Jolly & Younis, 2005).

SECURITY ISSUES IN SENSORS AND WIRELESS SENSOR NETWORKS

The main goal of this section is to discuss security goals, challenges to securing WSN, a classification of possible attackers, and a taxonomy of possible forms of attack and countermeasures.

Security Goals

Security goals for WSN are determined by the nature of the WSN applications. A general set of goals that may be representative of the requirements of a broad spectrum of WSN applications include confidentiality, authenticity, integrity, and availability. Related goals include authorized access, adaptive multilevel security, and interoperability.

- *Confidentiality* requires that the sender of data should be able to determine the set of receivers that have a right to read the data content. In WSN communications, because of changes in network membership, two types of confidentiality exist: backward (before joining) and forward (after departure) confidentiality.
- *Authenticity* means that the communicating partners should be able to unambiguously identify each other.
- *Integrity* of data means that data content remains unchanged inside the sensor and during transmission.
- *Availability* ensures that eligible participants with appropriate privileges will receive services as authorized. In WSNs, it is important to ensure the availability and continuity of secure services given an environment characterized by intermittent connectivity and autonomous sensor behavior.

In addition to the security goals mentioned, there are also extra requirements in terms of location confidentiality, cooperation fairness, and the absence of traffic diversion, according to Buchegger & Le Boudec (2002). Furthermore, for routing protocols to achieve availability and security, (Lundbey, 2000) addresses additional security objectives, such as certainty of discovery, isolation, lightweight computations, location privacy, self-stabilization, and byzantine robustness.

- *Cooperation and fairness*: There is a trade-off between cooperation and resource consumption. Nodes have to economize on their resources. Simultaneously, if the nodes do not forward messages, others might not forward either, thereby denying service.
- *Confidentiality of location*: In some situations, for example, in a military application, routing information can be equally or even more vital than the message content itself (Buchegger & Le Boudec, 2002). According to (Lundbey, 2000), the location of nodes should not be available to a malicious user.
- *No traffic diversion*: Routers (routing nodes) should be advertised and operated based on the selected routing protocol and should honestly reflect the knowledge of the network topology. By diverting the network traffic, nodes can work against that requirement.
- *Certainty of discovery*: This requires that if a route between two nodes exists, the route should be identified and correct.
- *Isolation*: Routing protocols should identify and can isolate misbehaving nodes. As an alternative, the routing protocol should be resistant to malicious nodes.
- *Lightweight computations*: Lengthy and demanding computations should be avoided if possible. Otherwise, the computations should have an effect on as few nodes as possible. The preferable case is that only the peer nodes should be required to be involved in the computations.
- *Self-stabilization*: If an attacker injects forged information into the routing path, the routing protocol should be able to recover in a limited amount of time.
- *Byzantine robustness*: This property is even more stringent than the self-stabilization property in that the routing protocol should be able to recover from attack as well as function properly during an attack.

Challenges for Securing WSNs

Whereas contemporary security mechanisms have tackled many identified attacks in general wire-based and wireless networks, numerous constraints and attributes make developing security solutions for sensors and WSNs

both unconventional and challenging. For example, sensors are typically at the low end of computational and storage capabilities and do not have the capacity for performing hefty cryptographic transformations. In addition, the limited energy supply and available bandwidth, the deployment of large number of sensors, and the high error rate do not favor elaborate security protocols with frequent message exchange. Other factors that affect the security approach include the following:

- (1) unattended operation, weak tamper protection, and hostile environment, which increase the likelihood of compromising stored security material;
- (2) intermittent and ad hoc connectivity, which may result in failure to maintain synchronized security material that could isolate a sensor(s) from communicating with the rest of the network;
- (3) limited preconfiguration resulting from the ad hoc nature, which limits the amount and type of security-enabling material necessary to deploy a secure WSN; and
- (4) possibility of untrustworthiness of data paths resulting from unknown nodes in multihop communications.

An example of a major challenge to most contemporary security solutions for WSNs, especially those espousing flat structures (Perrig et al., 2002; Du, Deng, Han, & Varshney, 2003, is the (implicit) assumption of synchronized time. Assume that each packet is 240 bits long with transmission rate of 10 kbps; the required accuracy is 0.048 sec. This accuracy of the time synchronization is not really a problem; such granularity is easily achievable with most time synchronization protocols. The real problem is the feasibility of implementing contemporary energy-consuming time synchronization protocols in large-scale WSNs. Some approaches have suggested using broadcast communications to transfer time synchronization information in a more efficient manner. To secure the time synchronization information, however, the broadcast information must be authenticated. But the purpose of the time synchronization mechanism was to implement a broadcast authentication! In conclusion, we argue that most contemporary solutions are more suited for smaller-scale WSNs.

Classification of Attackers

Attackers may mount software as well as physical attacks on WSNs. Attackers may physically tamper with sensor nodes, damaging part of the network. For example, the WSN introduced by Buczak & Jamalabad (1998) is subject to enemy attacks that could destroy a subset of nodes. On the other hand, referring to software attackers, Karlof and Wagner have classified security attackers, based on their capabilities, into *mote-class* attackers and *laptop-class* attackers. The mote-class attacker may have access only to a few nodes with the same level of capabilities of the deployed sensors, whereas the laptop-class attacker may have access to more powerful devices. In the latter case, malicious nodes have significant advantages over legitimate sensors through greater battery power, a more

capable CPU, a high-power RF transmitter, or a highly sensitive antenna. A laptop-class attacker may jam or eavesdrop on an entire network and can launch a more damaging coordinated attack. Another distinction can be made between outsider attacks, such as the ones discussed so far, and insider attacks. In the latter case, an authorized participant in the WSN acts abnormally. Insider attacks can be conducted either through compromised sensors that are injected with the malicious code or by stealing secret material and then using laptop-class devices to clone native sensors' behavior to mount attacks.

Attacks on WSNs

In this chapter, attacks are classified according to their violation of the main security goals of confidentiality, integrity, authenticity, and availability.

Confidentiality attacks attempt to expose the data being stored or sent. Four types of attacks appear to be commonplace: traffic analysis, eavesdropping, man in the middle, and tampering. *Traffic analysis* allows an attacker to determine that there is activity on the network, the location of base stations, and the type of protocol being used in the transmission. *Eavesdropping* can be passive or active. An attacker who passively monitors traffic can read the data transmitted in the stream and also can gather information indirectly by examining the source of a packet, its destination, size, number, and time of transmission. Active eavesdropping extends the passive method to inject the attackers' packets into the data stream. The goal is to help the attacker decipher the data payload of the stream. Address spoofing is a typical example of active eavesdropping. A *man-in-the-middle* attack establishes a rogue intermediary that, for example, pretends to be a base station, and acts as a proxy to the actual network (impersonation). *Tampering* involves an attacker compromising data content stored in sensors' memory, usually by node capturing. The potential for tamper attacks is significant in a WSN with unattended deployment.

Attacks against integrity and authenticity generally require successful system intrusion and the use of one or more of the confidentiality-type attacks. Three primary classes of integrity and authenticity attacks can be identified: session hijacking, replay, and man in the middle. The objective in session hijacking is to break into an authenticated and authorized session that is underway and take it away from the owner. One of the attacker advantages here is that, if successful, the victim might not even realize that they are under attack. If the attacker can gain access to the session, the attacker can use it for any previously authorized purposes. The session can also (if unchecked by the host) be extended for long periods and be used multiple times. An identifying characteristic of the replay attack is that, for example, while a hijack attack will occur in real-time, replay attacks occur only after the fact. The object is to gain access by convincing the host that a valid client wants to associate. Information that has been previously gained through any means can be used for this purpose. Usually, the session that is the source of any information used in the replay is not altered or interfered with in any way, which can make detecting this kind of attack very difficult.

Availability or denial of service (DoS) attacks (Chan, Perrig, & Song, 2003; Wood & Stankovic, 2002) can be grouped into three categories, namely disabling service (e.g., sinkhole, HELLO flood [Karlof & Wagner, 2005]), exhaustion (e.g., inducing false positives), and service degradation (e.g., selective forwarding attack).

Karlof and Wagner (2005) describe some of the major network layer attacks on routing protocols used in WSNs. These attacks are described below:

- *Spoofed, altered, or replayed routing information*—these are grouped together because they achieve a similar goal for the attacker.
- *Selective forwarding*—the attacker inserts a compromised node in the data flow and may refuse to forward some but not all of the packets.
- *Sinkhole attacks*—the attacker tries to lure nearly all the traffic from a particular area through a compromised node, creating a metaphorical sinkhole with the adversary at the center.
- *Sybil attacks*—the attacker uses a single node that presents multiple identities to other nodes in the network (Douceur, 2002).
- *Wormholes*—the attacker, possibly more than one, creates a tunnel that appears to transfer data faster than routes in the original network. The attacker can then direct traffic to the tunnel or wormhole using selective forwarding (Hu, Perrig, & Johnson, 2002).
- *HELLO flood attacks*—the attacker broadcasts routing or other information with large enough transmission power in an attempt to convince every node in the network that the adversary is its neighbor.
- *Acknowledgement spoofing*—the attacker spoofs link layer acknowledgments for “overheard” packets addressed to neighboring nodes, thus convincing the sender that a weak link is strong or that a dead or disabled node is alive.

In addition to these general attacks, attackers can also exploit vulnerabilities within specific routing protocols. For more details on attacks on specific routing protocols, please refer to Karlof and Wagner (2005).

Attack Countermeasures

As stated in Karlof and Wagner (2005), the majority of outsider attacks against sensor network routing protocols can be prevented by simple link layer encryption and authentication using a globally shared key. The Sybil attack can be prevented with this countermeasure because strong authentication techniques will not allow nodes to accept multiple identities from the same node. The majority of selective forwarding and sinkhole attacks can be avoided because the adversary is prevented from joining the topology. Link layer acknowledgments can also be authenticated.

Major classes of attacks not countered by link layer encryption and authentication mechanisms are wormhole attacks and HELLO flood attacks (Karlof and Wagner 2005). Although an adversary is prevented from joining the network, nothing prevents him or her from using a

wormhole to tunnel packets sent by legitimate nodes in one part of the network to legitimate nodes in another part to convince them they are neighbors or by amplifying an overheard broadcast packet with sufficient power to be received by every node in the network.

Link layer security mechanisms using a globally shared key are completely ineffective in the presence of insider attacks or compromised nodes (Karlof and Wagner 2005). Insiders can attack the network by spoofing or injecting bogus routing information, creating sinkholes, selectively forwarding packets, using the Sybil attack, and broadcasting HELLO floods. More sophisticated defense mechanisms are needed to provide reasonable protection against wormholes and insider attacks. The rest of this subsection concentrates on insider attacks. *The Sybil attack*: An insider cannot be prevented from participating in the network, but she should only be able to do so using the identities of the nodes she has compromised. Using a globally shared key allows an insider to masquerade as *any* (possibly even nonexistent) node. Identities must be verified. In the traditional setting, this might be done using public key cryptography, but generating and verifying digital signatures is beyond the capabilities of sensor nodes. One solution is to have every node share a unique symmetric key with a trusted base station. Two nodes can then use a Needham–Schroeder–like protocol to verify each other’s identity and establish a shared key. A pair of neighboring nodes can use the resulting key to implement an authenticated, encrypted link between them. To prevent an insider from wandering around a stationary network and establishing shared keys with every node in the network, the base station can reasonably limit the number of neighbors a node is allowed to have and send an error message when a node exceeds it. Thus, when a node is compromised, it is restricted to (meaningfully) communicating only with its verified neighbors. This is not to say that nodes are forbidden from sending messages to base stations or aggregation points multiple hops away, but they are restricted from using any node except their verified neighbors to do so. In addition, an adversary can still use a wormhole to create an artificial link between two nodes to convince them they are neighbors, but the adversary will not be able to eavesdrop on or modify any future communications between them (Douceur, 2002).

HELLO flood attacks: The simplest defense against HELLO flood attacks is to verify the bidirectionality of a link before taking meaningful action based on a message received via that link. However, this countermeasure is less effective when an adversary has a highly sensitive receiver as well as a powerful transmitter. Such an adversary can effectively create a wormhole to every node within range of its transmitter/receiver. Because the links between these nodes and the adversary are bidirectional, this approach will unlikely be able to locally detect or prevent a HELLO flood. One possible solution to this problem is for every node to authenticate each of its neighbors with an identity verification protocol using a trusted base station. If the protocol sends messages in both directions via the link between the nodes, HELLO floods are prevented when the adversary only has a powerful transmitter because the protocol verifies the bidirectionality of the link. Although this does not prevent a compromised node with

a sensitive receiver and a powerful transmitter from authenticating itself to a large number of nodes in the network, an observant base station may be able to detect a HELLO flood is imminent. Because such an adversary is required to authenticate itself to every victim before it can mount an attack, an adversary claiming to be a neighbor of an unusually large number of the nodes will raise an alarm.

Wormhole and sinkhole attacks: Wormhole and sinkhole attacks are very difficult to defend against, especially when the two are used in combination. Wormholes are hard to detect because they use a private, out-of-band channel invisible to the underlying sensor network. Sinkholes are difficult to defend against in protocols that use advertised information such as remaining energy or an estimate of end-to-end reliability to construct a routing topology because this information is hard to verify. Routes that minimize the hop-count to a base station are easier to verify, however hop-count can be completely misrepresented through a wormhole. When routes are established simply based on the reception of a packet, sinkholes are easy to create because there is no information for a defender to verify. A technique for detecting wormhole attacks is presented in Hu, Perrig, and Johnson (2002), but it requires extremely tight time synchronization and is thus infeasible for most sensor networks. Because it is extremely difficult to fit existing protocols with defenses against these attacks, the best solution is to carefully design routing protocols in which wormholes and sinkholes are meaningless (Karlof & Wagner, 2005). For example, one class of protocols resistant to these attacks is geographic routing protocols. Protocols that construct a topology initiated by a base station are most susceptible to wormhole and sinkhole attacks. Geographic protocols construct a topology on demand using only localized interactions and information and without initiation from the base station. Because traffic is naturally routed toward the physical location of a base station, it is difficult to attract it elsewhere to create a sinkhole. A wormhole is most effective when used to create sinkholes or artificial links that attract traffic. Artificial links are easily detected in geographic routing protocols because the “neighboring” nodes will notice the distance between them is well beyond normal radio range (Karlof & Wagner, 2005).

Selective forwarding: Even in protocols completely resistant to sinkholes, wormholes, and the Sybil attack, a compromised node has a significant probability of including itself in a data flow to launch a selective forwarding attack if it is strategically located near the source or a base station. Multipath routing can be used to counter these types of selective forwarding attacks. Messages routed via n paths whose nodes are completely disjointed are completely protected against selective forwarding attacks involving at most $n - 1$ compromised nodes and still offer some probabilistic protection when n or more nodes are compromised. However, completely disjointed paths may be difficult to create. Braided paths (Ganesan, Govindan, Shenker, & Estrin, 2001) may have nodes in common, but have no links in common (i.e., no two consecutive nodes in common). The use of multiple braided paths may provide probabilistic protection against selective forwarding and use only localized information. Allowing nodes to

dynamically choose a packet’s next hop probabilistically from a set of possible candidates can further reduce the chances of an adversary gaining complete control of a data flow.

Authenticated broadcast and flooding: Because base stations are trustworthy, adversaries must not be able to spoof broadcast or flooded messages from any base station. This requires some level of asymmetry: because every node in the network can potentially be compromised, no node should be able to spoof messages from a base station, yet every node should be able to verify them. Authenticated broadcast is also useful for localized node interactions. Many protocols require nodes to broadcast HELLO messages to their neighbors. These messages should be authenticated and impossible to spoof. Proposals for authenticated broadcast intended for use in a more conventional setting either use digital signatures and/or have packet overhead that will exceed the length of typical sensor network packet. μ TESLA is a protocol for efficient, authenticated broadcast and flooding that uses only symmetric key cryptography and requires minimal packet overhead (Perrig et al., 2002). μ TESLA achieves the asymmetry necessary for authenticated broadcast and flooding by using delayed key disclosure and one-way key chains constructed with a publicly computable, cryptographically secure hash function. Replay is prevented because messages authenticated with previously disclosed keys are ignored.

Prevention of denial-of-service attacks: Layered network architecture can improve robustness by circumscribing layer interactions and interfaces. A clean division of layers may be sacrificed for performance in sensor networks, however, reducing robustness. Each layer is vulnerable to different DoS attacks and has different options available for its defense. Some attacks crosscut multiple layers or exploit interactions between them. Wood and Stankovic, (2002) list the layers of a typical sensor network and describe each layer’s vulnerabilities and defenses.

Resilience to physical node capture: One of the most challenging issues facing sensor networks is resiliency against node capture attacks. In traditional computing, physical security is often taken for granted: attackers can be denied physical access to our computers. Sensor networks disrupt that paradigm. In most applications, sensor nodes are likely to be placed in locations accessible to an attacker. This raises the possibility that an attacker could capture sensor nodes, extract cryptographic secrets, modify their programming, or replace them with malicious nodes under the attacker’s control. Tamper-resistant packaging might be one defense, but this is expensive. Also, current tamper-resistance technology does not provide a very high level of security. Therefore, algorithmic solutions to the problem of node capture are preferable.

WIRELESS SENSOR NETWORK SECURITY RESEARCH

Although the problem of securing ad hoc networks has received a great deal of well-deserved attention in the literature (Chan, Perrig, & Song, 2003; Marti et al., 2000; Canetti & Pinkas, 1998; Wong, Gouda, & Lam, 1998;

Chang et al., 1999; Moharum, Mukkamala, & Eltoweissy, 2004). WSN are sufficiently different in their characteristics that security solutions designed specifically for ad hoc networks do not apply to them. In general, wireless sensor networks need to work unattended. In addition, the level of security in a WSN versus scalability and the efficiency with respect to energy, computation, and memory constitute the main design trade-offs. Recently, researchers focusing on WSN security have proposed a number of solutions (Perrig et al., 2002; Du, Deng, Han, & Varshney, 2003; Chang et al., 1999; Wang, Velayutham, & Guan, 2003; Kong et al., 2001; Zhu, Setia, & Jajodia, 2003; Wadaa, Olariu, Wilson, & Eltoweissy, 2004). These solutions address security goals to varying degrees. Although some solutions implement security at the link layer (e.g., SPINS; Chan, Perrig, & Song, 2003), most solutions use cryptographic key agreement/management schemes at higher layers (e.g., LEAP). Contemporary solutions overwhelmingly either assume or provide probabilistic tamper proofing. All key-based schemes, at least those known to us (except our own) assume nodes with unique identifiers and therefore do not address the case of anonymous nodes. Also, these solutions, in general, do not address “freshness” of keying material to support secure dynamic reconfiguration of the WSN and do not provide adaptive security at different levels of granularity.

Link Level Security Solutions

The pursuit of link layer mechanisms for tackling security concerns has been the choice for some research efforts. For example, enhancements were proposed to the IEEE 802.11 link layer protocols to ensure authenticated access and to detect denial of service attacks (Kyasanur & Vaidya, 2002). Although traffic authentication is applied per packet in Binkley and Trost (2001) to filter out bogus traffic, a per-session approach is proposed in Wang, Velayutham, and Guan (2003) to minimize overhead. In addition, using encryption keys to maintain data confidentiality and integrity at the link layer has been proposed in Perrig, et al. (2002) and http://www.bluetooth.com/upload/24Security_Chapter.PDF. We propose an approach that relies on frequency hopping and the sensor’s genetic material to provide a simple and comprehensive solution to ensure authentication, confidentiality, and integrity. In addition, our approach is lightweight in terms of energy consumption. Cryptographic and encoded schemes extend the effective number of bits per packet transmitted, leading to increased energy consumption. In contrast, our approach can be very energy efficient because of the frequency hopping that limits traffic collision and the avoidance of the incorporation of data keys.

Cryptographic Key-Based Solutions

Solutions to securing sensors and WSNs mostly use cryptographic techniques (Perrig et al., 2002; Zhu, Setia, & Jajodia, 2003; Jolly, Kuşçu, & Kokate, 2002; http://www.bluetooth.com/upload/24Security_Chapter.PDF; Eschenauer & Gligor, 2002). Key agreement to bootstrap trust between communicating nodes is at the heart of these solutions (for a comprehensive survey, refer to

(Kongial, 2000). There are three general types of key agreement schemes: predistribution, trusted server-based, and self-enforcing schemes. Predistribution keying protocols attempt to defray the high sensor transmission costs through a more intensive initial preconfiguration (Perrig et al., 2002; Du, Deng, Han, & Varshney, 2003). Some preconfiguration is always necessary but can reduce flexibility and impact security. Other techniques require less initial configuration. Trusted server-based keying protocols employ a centralized key distribution point to establish and maintain keys for a WSN. The central point can be a single centralized entity or distributed among trusted sensors (e.g., cluster or region heads; http://www.bluetooth.com/upload/24Security_Chapter.PDF). Energy consumption for centralized key distribution is typically localized with the center performing most of the work; however, the use of asymmetric cryptographic schemes can possibly lessen this cost by distributing the computational energy away from the center. Self-enforcing keying schemes, in general, depend on asymmetric cryptography, for example, public key certificates to distribute the establishment of keys throughout the group, sometime in a pair-wise fashion.

Carman, Kruus, and Matt (2000) studied energy consumption of a wide array of protocols for key agreement supporting confidentiality and authentication services in WSNs. Both symmetric key and asymmetric key protocols were included. The study concluded that although symmetric key-based protocols consume less energy, some of these protocols are not sufficiently flexible for use in dynamically reconfigurable networks, because they cannot efficiently handle unanticipated additions of sensors to the network. Public key-based establishment protocols offer more flexibility and scalability. The public key algorithms used in these protocols consume a great deal of computational and communications energy, however.

In the remainder of this section, some of the major research efforts in WSN security are discussed. The focus is primarily on broadcast authentication and key management.

Broadcast Authentication

Communications energy consumption has a great effect on the battery life of the sensor nodes. Communications energy can be conserved significantly by using broadcast transmissions in tasks such as distribution of initial keying material or transmission of sensor-reading data. These tasks could also be done using unicast transmissions but that would incur greater energy consumption.

In many cases, the broadcasted messages need to be *authenticated*. Authenticating a message means that the sender corroborates the origin and the content of the information using cryptographic tools. Note that message authentication implicitly provides data integrity (for if a message is modified, then the source has changed).

In the past few years, several broadcast authentication schemes for WSNs have been proposed (e.g., Perrig et al., 2002; Liu & Ning, 2003). Most schemes are variations of the μ TESLA protocol (Perrig et al., 2002), which is designed to provide authenticated streaming broadcast for severely resource-constrained environments. In μ TESLA,

time is divided into uniform time intervals, and a unique secret key is associated with each time interval. These secret keys are generated using a one-way key chain. In time interval i , the sender uses the key of the current interval, K_i , to compute the message authentication code (MAC) of the packets in that interval. The key K_i is revealed after a certain time delay. The received packets are guaranteed to be authentic as long as they were received before the corresponding key was disclosed and the key has the one-way property (i.e., future keys cannot be predicted given the present and past keys).

μ TESLA and its variations only rely on symmetric-key cryptosystems. Because of its efficiency and tolerance to packet loss, it is well suited for WSNs. However, this scheme is not an ideal solution for all WSN applications and is not suitable for large sensor networks. μ TESLA is not appropriate for large WSNs because of the following reasons:

- To “bootstrap” μ TESLA, each receiver needs to have at least one key from the one-way key chain generated by the sender. This key, along with other initial parameters, are sent to each receiver individually. In a large network, where the number of receivers is correspondingly large, this requires the sender to exhaust a great amount of energy in transmitting the initial parameters.
- In μ TESLA, the sender and the receivers need to be time synchronized. The validity of the MAC keys (and therefore the authenticity of the packets) is directly dependent on the correct time synchronization of the sender and the receivers. To synchronize a large WSN, broadcast synchronization schemes are preferred over pair-wise synchronization schemes because of their small communication overhead. However, for security reasons, μ TESLA cannot be used in conjunction with broadcast synchronization schemes.

Recent efforts to address the first problem have been somewhat successful (e.g., Liu & Ning, 2003). However, the solution to the second problem remains open.

Key Management

Recent key predistribution proposals (Wood & Stankovic, 2002; Du, Deng, Han, & Varshney, 2003; Zhu, Setia, & Jajodia, 2003; Wadaa, Olariu, Wilson, & Eltoweissy, 2004; Jolly, Kuşçu, & Kokate, 2002; Eschenauer & Gligor, 2002; Liu & Ning, 2003) provide techniques to securely set up pair-wise keys post-deployment while attempting to balance efficiency and tamper resistance. Eschenauer and Gligor (2002) proposed a distributed key establishment mechanism that relies on probabilistic key sharing among the nodes of a random graph and uses a shared-key discovery protocol for key establishment. Chan, Perrig, and Song (2003) presented several extensions to the mechanism and provided solutions for node authentication and key revocation. Jolly, Kuşçu, and Kokate (2002) proposed a hierarchical key management scheme for sensor networks. In this scheme, nodes only communicate with their gateway and each node shares a key with its corresponding gateway. Based on probabilistic key sharing and threshold secret sharing, Zhu, Setia, and Jajodia (2003) proposed a

scheme for enabling two nodes in a network to establish a pair-wise secret key exclusively known to these nodes with overwhelming probability. In this scheme, a node only needs to know another node’s id to be able to determine the keys it shares with that node. Under the scheme, all nodes are assumed to be trusted. Any node can generate the preloaded keys that any other node possesses. Thus, in principle a malicious node t , knowing the set of keys that a neighbor node x possess, need only receive and decrypt all messages destined to x to collect all shares for a pair-wise secret key that some other node y is establishing with x , and thus compromise the secret key that is being established, without any collusion. Du et al. (2003) and Liu and Ning (2003) proposed random key predistribution schemes that exploit deployment knowledge to avoid unnecessary key assignments. They have shown that the performance of WSNs can be substantially improved with the use of these schemes. However, the assumption of prior knowledge about deployment may not be applicable in many cases.

With the exception of LEAP in Zhu, Setia, and Jajodia (2003), in-network processing by a group of nodes has not been addressed. LEAP (localized encryption and authentication protocol) is a hybrid key agreement protocol implementing a suite of key agreement solutions using keys at four levels, namely network, neighborhood, node pair, and individual node levels, that are stored at the sensor node to accommodate the various communication models in WSNs. LEAP uses only the base station and the individual sensor nodes for all computation and communications. It also uses key translation from one hop to the next to ensure freshness of a network-level key.

Most existing solutions in security management in WSNs assume unique node identifiers and therefore do not address the case of anonymous nodes. Also, most schemes preload sensor nodes with individual (or small group) state information. Furthermore, most solutions do not address node rekeying or security at different levels of granularity. Quite recently, Wadaa, Olariu, Wilson, and Eltoweissy (2004) proposed a key management solution that assumes anonymous nodes and is applicable to members that are individual nodes or geographically affiliated subgroups of nodes. Also, their scheme preloads all nodes with identical states and supports both forward and backward secrecy as nodes are added or removed. The key management solution in Wadaa, Olariu, Wilson, and Eltoweissy (2004) is based on a combinatorial formulation of the key management problem and uses no communication to initialize nodes with their set of keys. The key management functions, however, are centralized in the base station.

NEW APPROACH TO SECURING SENSORS AND WSNs

WSN security research is in its infancy. There still is a need to provide new simple, energy-efficient solutions to securing sensors and WSNs. This section discusses an approach to satisfying the security goals subject to the myriad constraints imposed on sensors and WSNs. This chapter promotes a holistic security solution integrated within

and encompassing the different network layers. This may result in more effective solutions to mitigate security threats, especially in massive deployment of WSNs with anonymous nodes. The approach should enable managed network mission and tasks, communication anonymity and confidentiality, and protection against physical tampering, impersonation, and denial of service. The solution components of the new approach include the following:

- innovative use of “sensor’s genetic material” to affect randomized time and frequency hopping that limits traffic collision and avoids incorporating data keys;
- leveraging a location-based, color-coded virtual infrastructure as a common infrastructure supporting multi-tasking with reduced collision and lightweight WSN protocols including traffic anonymity, routing, authentication, and tamper proofing;
- a task-based operation model; and
- a lightweight, task-based synchronization protocol.

The result is a holistic lightweight adaptive security solution for large-scale WSNs that can securely operate unattended in hostile environment for an extended period of time. Subsequent sections describe the building blocks of the approach, and the final section discusses how these building blocks can be used to develop secure sensors and WSNs solutions.

Genetic Material

Sensors in our proposal are equipped with frequency-hopping communications capabilities. Also, sensors may have more than one sensing capability. The basic idea is to inject individual sensors prior to deployment with randomization capabilities that we refer to as *genetic material*. The genetic material of individual sensors enables behavioral parameters that can be tailored for group communication and cooperation, as well as for supporting a sophisticated task-based management scheme. In addition, the genetic material supports

- short-lived, group-oriented, and task-driven sensor synchronization;
- the use of a time-varying, parameterized frequency-hopping scheme;
- decentralized operation and management; and
- traffic anonymity.

Just prior to deployment (perhaps onboard the aircraft that drops them in the terrain), it is assumed that the sensors are injected with *genetic material* that includes

- a standard public domain, pseudorandom number generator;
- a set of tuples $(c_i, k(c_i))$, $(1 \leq i \leq p)$, where c_i is a color, and $k(c_i)$ is a *secret* associated with color c_i ;
- a perfect hash function ϕ ; and
- an initial time. At this point all the clocks are synchronous; later because of clock drift synchronization is lost.

Figure 4: (a) Illustrating the dynamic coordinate system; (b) Illustrating color sets.

The Virtual Infrastructure

Because flat architectures do not scale and present a problem for large-scale synchronization, it is important to endow the WSN with a virtual infrastructure that can be leveraged for efficient protocol design. The virtual infrastructure that is proposed in Wadaa et al. (2004) consists of

- a dynamic coordinate system,
- a cluster structure, and
- a communications structure that is described in some detail shortly.

To help with organizing the virtual infrastructure, it is assumed that a centrally placed training agent (TA) exists, equipped with a long-range radio that can communicate with both the base station and the sensors in the deployment area. More than one TA can coexist in a sensor field. For simplicity, only one TA is being considered in this chapter. The TA is assumed to have a steady power supply. Its precise role will become clear later. The dynamic coordinate system divides the deployment area into coronas and wedges (Figure 4) defined as follows:

Coronas. Using differential transmission power, the area is ruled into coronas determined by concentric circles of increasing radii centered at the TA. All coronas have the same width, slightly less than the sensor transmission range (the case for equal-width coronas was made in Wadaa et al., 2004).

Wedges. These are equiangular wedges centered at the TA obtained by using directional transmission.

The resulting coordinate system is dynamic because it can be reestablished in response to changing network conditions. By using signal strength readings obtained during the establishment of the coordinate system, each sensor selects one of the p colors, say c_i , and remembers the associated secret $k(c_i)$. All the other tuples in its memory are deleted at this point. The effect of this autonomous choice of colors by individual sensor nodes is that coronas are further subdivided into p color sets in an efficient way. In each corona, the color sets are numbered, in the same order, from 1 to p as shown in Figure 4b. As a result, the WSN is partitioned into p color graphs, where a color graph is the communication graph that has the

Figure 5: (a) Centralized communication structure; (b) Distributed communication structure.

sensors of the same color as vertices with two sensors connected by an edge whenever they are within transmission range of each other. This, in effect, establishes multiple networks, each with its own color code. It is worth noting that the assumed width of coronas combined with a massive deployment guarantee that the color graphs are (initially) connected with high probability. The optimum number of colors and dynamic merging/splitting of colors resulting from changing network dynamics are issues to be investigated.

The dynamic coordinate system suggests a simple clustering scheme, where a cluster is the locus of all sensors that have the same coordinates. It is important to note that clustering is obtained for free once the coordinate system is established. Also, our clustering scheme does not assume synchronization and accommodates sensor anonymity: sensors need not know the identity of the other sensors in their cluster. Depending on the way the information is collected in the WSN, two communication structures are contemplated. In the centralized structure illustrated in Figure 5 sensing data collected in a source cluster are routed, within the same wedge, along a virtual path to the TA, where the data are uploaded to the sink.

In the distributed structure illustrated in Figure 5 data collected in a source cluster are routed to a destination cluster from where the data are uploaded to the sink. Note that the routing illustrated in Figure 5 involves only sensors in the same color graph.

Task-Based Operation and Management

We take the view that the WSN performs tasks mandated by a remote end user. The task-based operation for WSN leverages the virtual infrastructure previously discussed. The task-based management system involves an *application layer* (high-level consumer of information produced by the WSN) and *middleware* (the interface between the WSN and the application layer).

To illustrate, the application issues A tasks, defined in terms of application-level abstractions, to be performed by the WSN. An A task takes the form of a tuple consisting of a high-level action and a desired level of QoS. As an example, the A task (Fire, q) requires that the occurrence of fire in the area of interest be correctly detected with

probability of at least q , where q specifies the requested QoS.

The middleware, running at the base station, provides the interface between the application layer and the WSN. It parses the A tasks from the application layer, considers the current capabilities of the WSN including the remaining energy budget, and negotiates a contract with the application layer before committing the network. After a contract had been agreed upon, the middleware translates the corresponding A task into primitive tasks (P tasks) assigned to individual clusters. The clusters must then perform these P tasks at the QoS level required and send the data back to the sink for consolidation. The suitably consolidated information is then passed on to the application layer. A P task is a tuple $T(A, c, S, D, \pi, Q)$, where

- A describes the action to be performed, say detecting the presence of smoke;
- c specifies the color graph to be used;
- S specifies the identity of the cluster tasked with data collection (sensing);
- D specifies the identity of the cluster tasked with storing the resulting information;
- π specifies the sequence of clusters along which the data is to be sent from S to D; and
- Q specifies the desired QoS.

In addition to the sensors in cluster S, a number of sensors are selected to act as routers, relaying the data collected to D. Collectively these sensors are the workforce $W(T)$ associated with T. Note that the path π is either explicitly stated by the base station, along with S and D, or else is determined in a distributed way by the sensors in $W(T)$. The process by which $W(T)$ is selected follows. During a time interval of length, the base station issues a call for work containing the parameters of T. The sensors that happen to wake up during the interval (and that satisfy the conditions specified (color, energy level, membership in S, D, or $()$) stay awake and constitute $W(T)$. It is intuitively clear that by knowing the number of sensors, the density of deployment, and the expected value of sleep periods, one can finetune (in such a way that $W(T)$ is commensurate with the desired QoS. It is extremely important to note that a by-product of the call for work is that all the

sensors in $W(T)$ are synchronized for the duration of the task.

Sensor Synchronization

It is clear that to leverage the virtual infrastructure and the task-based view, the sensors participating in a task must be synchronized. Because large-scale synchronization in a WSN is impossible (Moharum, Mukkamala, and Eltoweissy 2004) proposed a synchronization scheme that is both group-based and short-lived. The discussion begins with a generic protocol that will be later specialized to suit the stated needs.

Using the genetic material, each sensor can generate (pointers into) three sequences of random numbers as follows:

- a sequence t_1, t_2, \dots, t_i , of time epoch lengths;
- a sequence $n_1, n_2, \dots, n_i, \dots$ of frequency sets drawn from a huge universe, for example, the ISM band;
- for every i , ($i \geq 1$), a permutation f_{1i}, f_{2i}, \dots of frequencies from the set n_i .

The interpretation of these sequences is as follows. Time is ruled into epochs: during the i th time epoch, of length t_i , frequency set n_i is used, subject to the hopping sequence f_{1i}, f_{2i}, \dots . Thus, as long as a sensor is synchronous to the TA, it knows the current time epoch, the offset into the epoch, and the frequencies and the hopping pattern for that epoch. Suppose that the TA dwells τ microseconds on each frequency in the hopping sequence. For every i , ($i \geq 1$), let l_i stand for t_i/τ . Thus, epoch t_i involves a hopping sequence of length l_i . Think of epoch t_i as being partitioned into l_i slots, with each slot using its own frequency selected by the hopping pattern from the set n_i . It is clear that determining the epoch and the offset of the TA in the epoch is sufficient for synchronization.

Our synchronization protocol is predicated on the assumption that sensor clock drift is bounded. Specifically, assume that whenever a sensor wakes up and its local clock shows epoch t_i , the master clock at the TA is in one of the time epochs t_{i-1} , t_i , or t_{i+1} . Using its genetic information, the sensor knows the last frequencies λ_{i-1} , λ_i and λ_{i+1} on which the TA will dwell in the three times epochs t_{i-1} , t_i , and t_{i+1} , respectively. Its strategy, therefore, is to tune in, cyclically, to these frequencies, spending $\tau/3$ time units on each of them. It is clear that, eventually, the sensor meets the TA on one of these frequencies. Assume, without loss of generality, that the sensor meets the TA on frequency λ in some (unknown) slots of one of the epochs t_{i-1} , t_i , or t_{i+1} . To verify the synchronization, the sensor will attempt to meet the TA in slots $s+1$, $s+2$, and $s+3$ at the start of the next epoch. If a match is found, the sensor declares itself synchronized. Otherwise, the sensor will repeat this process. It is important to understand that the synchronization protocol outlined is probabilistic: even if a sensor declares itself synchronized, there is a slight chance that it is not. However, a missynchronization will be discovered quickly and the sensor will reattempt synchronization.

The generic synchronization protocol can be used as a building block for a more sophisticated task-based synchronization protocol. The motivation is that, because

several color sets are present in a cluster, it is possible for a cluster to perform several tasks in parallel. However, any attempt at synchronization using the generic synchronization protocol will result in all the concurrent tasks using exactly the same frequency set and the same hopping sequence, creating frequent collisions and the need for subsequent retransmission. Suppose that one wishes to synchronize the workforce $W(T)$ of a task T that uses some color graph c and that the generic synchronization protocol would show that the actual time epoch is t_i . The idea is to use the perfect hash function ϕ to compute a *virtual* time epoch t_j with $j = \phi(I, c, k(c))$ to be used by $W(T)$. Therefore, the sensors in $W(T)$ will act as if the real time were t_j , using the frequency set n_j and the frequency hopping sequence f_{1j}, f_{2j}, \dots . Thus different concurrent tasks will employ different frequency sets and hopping sequences, minimizing the occurrence of collisions.

Note that this task-based synchronization is, in fact, a very powerful and lightweight physical layer encryption device. Indeed, to an outside observer, successive epoch lengths, hopping sets, and hopping patterns appear as the product of an unknown random process. Given that techniques are known to discover a hopping sequence by monitoring transmissions, security can only be provided if the design modifies the hopping sequence in less time than is required to discover the sequence. The choice of frequency-hopping parameters determines the time required to discover the sequence (the magnitude of the challenge to an adversary).

Security Proposal for Sensors and WSNs: Applying the New Approach

Ways in which the previously mentioned building blocks can be leveraged to address several important issues are described. These include making sensors tamper resistant, helping authentication, and providing traffic anonymity in WSNs. The following analogy with biology inspires our approach for securing individual sensors and WSNs. At birth, a crab is vulnerable because its shell is soft. In time, the shell hardens, affording appropriate protection. Because sensors are anonymous, they rely on received power levels from their neighbors to establish a unique signature of their neighborhood that is difficult to forge. The “hardening shell” paradigm applies in our context in the following way: immediately after deployment, individual sensors have no information about their neighborhood. In time, they overhear the transmissions of other sensors. Every time a new power level is detected, a new entry is recorded in the Neighborhood Signature Array (NSA) that individual sensors maintain. It is important to recall that the NSA is the only data available to the sensor node. This array establishes, in the obvious way, a signature of the neighborhood of the node. As discussed in the following sections, the NSA confers tamper resistance to individual sensors and can also be used for authentication purposes. In fact, the hardening shell paradigm refers to the fact that the protection afforded by the NSA increases with the number of neighbors recorded and, therefore, with time. Consequently, the vulnerability of individual sensors decreases with time.

Securing Individual Sensors

Because sensors must function unattended, the potential for physical tampering is significant. It is worth noting that although predeployment tamper detection may be worthwhile, post-deployment tamper detection is of little use because, in the vast majority of applications, inspecting individual sensors is impossible or impractical.

The most obvious tamper resistance strategies are hardware-based and involve special hardware circuits within the sensor to protect sensitive data, special coatings, or tamper seals. However, these solutions require extra circuitry that increases the cost and hardware complexity of sensors. Thus, not surprisingly, tamper resistance or tamper protection for sensors is not found in present-day sensors (Carman, Kruus, & Matt, 2000). Probabilistic tamper resistance for WSNs has been proposed in Chan, Perrig, and Song (2003) using cryptographic keys that incur noticeable overhead. Our solution to endowing sensors with tamper resistance does not require additional or more sophisticated hardware. The tampering threat model assumes that the adversary is either trying to force open an individual sensor in situ or is attempting to physically remove the sensor from the deployment area. The assumption is that once removed, the genetic material can be learned and the sensor compromised. The proposal is to guard against the first threat by blanking out the memory, triggered by a simple switch. The remainder of this section shows how the NSA can be used to endow sensors with tamper resistance. If a sensor is removed from the deployment area, it will notice changes in the signals received when compared to its NSA and erase its own memory. Note also that tampering attempts that involve the removal of several sensor nodes simultaneously will also be defeated because some node in the set of removed nodes will notice changes in its NSA and can alert the others.

Yet another possible solution to the tampering problem solution is as follows: The TA sends out periodically a control signal covering the entire deployment area that allows individual sensors to reconfirm their distance to the TA. If the sensor is removed from the area of deployment, it will notice changes in the signal strength received (and thus, color) from the TA and will erase its own memory, preventing the tampering agent from gaining access to information secret to the WSN.

Sensor authentication is one of the key problems in securing WSNs (Akyildiz, Su, Sankarasubramaniam, & Cayirci, 2002; Chan, Perrig, & Song, 2003; Wood & Stankovic, 2002). Frequency hopping and the tamper proofing scheme may prevent sensors from being compromised. The security threat for the purpose of authentication is an external sensor attempting to masquerade as a legitimate one. In particular, it is conceivable, although extremely unlikely, that the intruder is able to guess the set of frequencies and the hopping sequence in the current epoch and is requesting information from one of its neighbors. However, neighboring sensors exchange color information, which is orthogonal to frequency hopping, adding yet another barrier for the intruder.

The sensor authentication problem can also be tackled using the NSA signature array. Here, using the frequency-

hopping scheme, neighboring sensors exchange and update periodically their NSA information (as well as color information). When sensor A wants to send data to B, the authentication procedure is to have A produce the proper NSA information. In fact, the NSA information is likely to change slowly over time as sensors deplete their energy. In this case, the authentication procedure may request, "Give me your next-to-last NSA reading."

Securing WSNs

Denial of service attacks that target key nodes in the communication network or compromise communications in some other way could undermine the functionality as well as the performance delivered by the WSN (Chan, Perrig, & Song, 2003; Wood & Stankovic, 2002). Particularly vulnerable are the components of the virtual infrastructure. Because knowledge of the virtual infrastructure can be instrumental for successfully compromising network security, maintaining the anonymity of the virtual infrastructure is a primary security concern. Somewhat surprisingly, in spite of its importance, the anonymity problem has not been addressed by prior work in WSNs. The aforementioned virtual infrastructure, developed by the authors, can be leveraged to provide traffic anonymity in WSNs. Solutions, leveraging the virtual infrastructure, define schemes for randomizing communications such that the cluster structure and coordinate system used remain undetectable and invisible to an observer of network traffic during both the setup and operation phases of the network. It is worth noting that traffic anonymity in wired networks is achieved by injecting spurious traffic into the network, essentially hiding the actual traffic. The associated cost in terms of energy makes this strategy impractical in WSNs. Two possible solutions can be contemplated. The *centralized* solution is by far the simplest and involves relying on traffic randomization specified by an entity external to the WSN. Consider a sequence T_1, T_2, \dots, T_n of P tasks to be performed by the WSN. Although the source cluster S_i of task T_i may be dictated by specific interests of the end user, the choice of the destination cluster D_i and the specific path π_i along with the information is sent to D_i can be chosen externally in such a way that the overall traffic is randomized.

The *distributed* solution is more complex and it relies on the genetic material available at individual sensors. To understand the idea behind the distributed solution to the traffic anonymity problem, imagine that in time epoch t_i a cut through the coordinate system of Figure 4a is performed as illustrated in Figure 6. Consider a task $T = (A, c, D, \pi, Q)$ issued during time epoch t_i . The idea is that both D and π are determined by individual sensors (using their genetic material) as a function of the location of S and need not be specified explicitly. In Figure 6, the dark circles denote destination clusters and data is routed along a predetermined path. Because the cut is different from epoch to epoch, the net effect of this approach is to randomize the traffic in the WSN, making it look chaotic to an external observer.

In time, as individual sensors deplete their energy, the functionality of the WSN is bound to decrease. One of the main goals of our research is to address not only the ideal

Figure 6: Illustrating the distributed solution.

case where all the sensors deployed function at their peak performance level, but, indeed, the point at which system performance decreases to a point where graceful degradation must be contemplated. One such situation, depicted in Figure 7, arises in the course of exploiting the WSN. Indeed, as the sensors exhaust their power budget more and more *gaps* will be formed in the communication structure. One proposal is to model the communication structure as a *circular arc graph* (Golombic, 1980) and tap into known algorithmic resources that can help with the design of secure protocols for sparse WSNs.

CONCLUSION AND DIRECTIONS FOR FUTURE RESEARCH

It is anticipated that in the near future wireless sensor networks will be employed in a wide variety of applications, establishing ubiquitous networks that will pervade

Figure 7: Illustrating sparsity in wireless sensor networks.

society. It is widely recognized that sensor network research is in its infancy (Akyildiz, Su, Sankarasubramanian, & Cayirci, 2002). In particular, there is precious little known about how WSNs self-organize in a way that maximizes the effectiveness and operational longevity of the network and that guarantees a high level of availability in the face of potential security attacks. Given the characteristics of WSNs, security protocols developed for wired, cellular, or ad hoc networks do not apply. Also, cryptographic key-based solutions generally are too expensive for the tiny sensors. This chapter presented a survey of key conceptual and technological security issues in WSN environments. It also reported on some research efforts and solution to the problem of securing WSNs.

An aim of this chapter is to motivate the development of a holistic solution for securing WSNs. It has been shown that a suitable enhancement to the classic frequency-hopping strategy may provide a lightweight and scalable mechanism for securing sensors and WSNs. At the network level, a generic virtual infrastructure and lightweight communications and tasking protocols can be used to ensure sensor collaboration in a coherent and authentic way while hiding the details of the network topology and the information flowing among nodes. Tamper proofing and authentication of (initially) anonymous nodes are provided through the concept of neighborhood context.

Issues currently (at the time of writing) under investigation in our research include (a) sensor circuitry, storage, types, attributes, and behavior of the genetic material; (b) The placement of the TA, having multiple TAs, and the distribution of the TA's functions; and (c) The granularity of synchronization and adaptation to varying network conditions. Finally, modifications to the UCB motes are needed to achieve security objectives addressed in this chapter without demanding a boost in the sensor's capabilities that is inconsistent with the small cost and size requirements.

A major open research direction is securing multitier WSNs. As far as we know, comprehensive security solutions covering the different tiers of WSNs (sensor nodes to sinks including subsink layers) do not exist. Multitier architectures where different tiers may employ different security solutions is an area that warrants investigation. Although asymmetric cryptography is generally dismissed for WSNs, a multitier WSN may employ powerful nodes at higher tiers that may be capable of performing asymmetric cryptography. We envision the emergence of solutions that employ frequency hopping, symmetric cryptography, and asymmetric cryptography in a common framework.

Another area of research is context-aware privacy and security in WSNs. Because WSNs will present an essential component of the emerging pervasive computing environments and because these new environments must be sensitive to users' resources and environmental contexts, it is imperative that privacy and security solutions for WSNs are devised, taking into account context semantics and dynamics. For example, higher levels of security may be needed in an unfriendly context, whereas security may be relatively relaxed in friendlier contexts. Context definition and representation; agile security, services, and protocols; and privacy preservation in a changing environment are some of the open research problems.

GLOSSARY

Administrative Keys Cryptographic keys used to distribute session keys and other administrative keys.

Frequency Hopping A scheme where communications hop from one channel frequency to another in a pseudorandom fashion.

Key Management This refers to session and administrative key assignment, generation, and distribution.

Sensor Network A network where sensor nodes communicate with each other and with one or more base stations.

Sensor Node A device with computing, communication, and sensing capabilities.

Session Keys Cryptographic keys used in secure data communications.

Sink (or Base Station) A computing node charged with tasking sensor nodes and collecting data from them.

Training Agent A base station, or subbase station node, tasked to do WSN training.

Wireless Sensor Networks (WSNs) A sensor network with wireless links and no physical communications infrastructure.

WSN Security This refers to the protection of confidentiality, availability, integrity, and authenticity of data in WSNs.

WSN Training The process of bootstrapping a WSN and endowing it with a virtual infrastructure.

WSN Virtual Infrastructure A logical infrastructure that is built to help render the WSN functional by providing means for sensor node identification and communications.

Evolution of Cellular Networks	660		

INTRODUCTION

Cellular communications has experienced explosive growth in the past two decades. Today millions of people around the world use cellular phones. Cellular phones allow a person to make or receive a call from almost anywhere. Likewise, a person is allowed to continue the phone conversation while on the move. Cellular communications is supported by an infrastructure called a cellular network, which integrates cellular phones into the public switched telephone network.

The cellular network has gone through three generations. The first generation of cellular networks is analog in nature. To accommodate more cellular phone subscribers, digital TDMA (time division multiple access) and CDMA (code division multiple access) technologies are used in the second generation (2G) to increase the network capacity. With digital technologies, digitized voice can be coded and encrypted. Therefore, the 2G cellular network is also more secure. The third generation (3G) integrates cellular phones into the Internet world by providing high-speed packet-switching data transmission in addition to circuit-switching voice transmission. The 3G cellular networks have been deployed in some parts of Asia, Europe, and the United States since 2002 and will be widely deployed in the coming years.

This chapter gives an introduction to cellular networks. The rest of this chapter is organized as follows: the second section introduces basic cellular concepts, and the third section describes how the air interface is shared by multiple users. The fourth and fifth sections discuss how to track mobile users and how to assign channels to hand-off calls and new calls, respectively. The sixth section discusses the relevant security issues. The seventh section describes the evolution of cellular networks. The eighth section presents alternatives to cellular networks. The final section gives a summary.

BASIC CONCEPTS

A cellular network provides cell phones or mobile stations (MSs), to use a more general term, with wireless access to the public switched telephone network (PSTN). The service coverage area of a cellular network is divided into

many smaller areas, referred to as cells, each of which is served by a base station (BS). The BS is fixed, and it is connected to the mobile telephone switching office (MTSO), also known as the mobile switching center. An MTSO is in charge of a cluster of BSs and it is, in turn, connected to the PSTN. With the wireless link between the BS and MS, MSs such as cell phones are able to communicate with wireline phones in the PSTN. Both BSs and MSs are equipped with a transceiver. Figure 1 illustrates a typical cellular network, in which a cell is represented by a hexagon and a BS is represented by a triangle.

The frequency spectrum allocated for cellular communications is very limited. The success of today's cellular network is mainly due to the frequency reuse concept. This is why the coverage area is divided into cells, each of which is served by a BS. Each BS (or cell) is assigned a group of frequency bands or channels. To avoid radio co-channel interference, the group of channels assigned to one cell must be different from the group of channels assigned to its neighboring cells. However, the same group of channels can be assigned to the two cells that are far enough apart such that the radio co-channel interference between them is within a tolerable limit. Typically, seven neighboring cells are grouped together to form a cluster, as shown in Figure 2. The total available channels are divided into seven groups, each of which is assigned to a cell. In Figure 2, the cells marked with the same number have the same group of channels assigned to them. Furthermore, the cells marked with different numbers must be assigned different groups of channels.

If there are a total of M channels allocated for cellular communications and if the coverage area consists of N cells, there are a total of $MN/7$ channels available in the coverage area for concurrent use based on the seven-cell reuse pattern. That is the network capacity of this coverage area. Because of explosive growth of mobile phone subscribers, the current network capacity may not be enough. Cell splitting is one technique that used to increase the network capacity without new frequency spectrum allocation (Black, 1996; Rappaport, 2002). In this technique, the cell size is reduced by lowering antenna

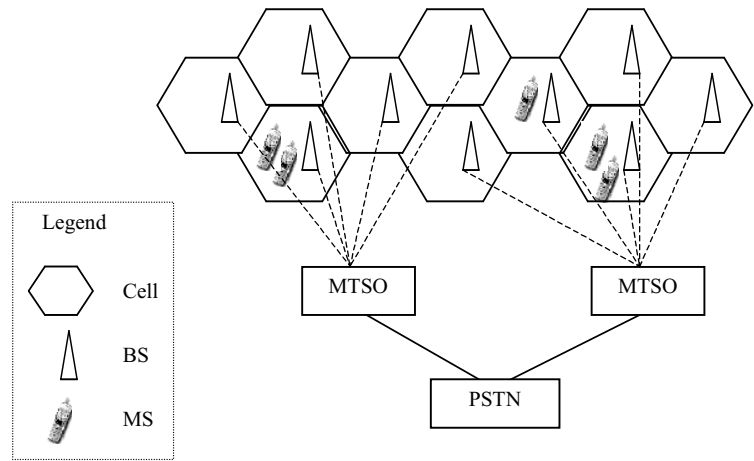

Figure 1: Typical cellular network.

height and transmitter power. Specifically, an original cell is divided into four smaller cells. After cell-splitting, the coverage area with N cells originally will be covered by $4N$ smaller cells. Therefore, the new network capacity is $4MN/7$, which is four times the original network capacity. In reality, bigger cells are not completely replaced by smaller cells. Therefore, cells of different sizes (e.g., pico, micro, and macro cells) may coexist in one area. This allows high-speed subscribers to use bigger cells, which reduces the number of hand-offs (to be explained later).

Sectoring is another technique to increase the network capacity (Black, 1996; Rappaport, 2002). In sectoring, the cell size remains the same, but a cell is divided into several sectors by using several directional antennas at the BS instead of a single omnidirectional antenna. Typically, a cell is divided into three 120° sectors or six 60° sectors. The radio co-channel interference will be reduced by dividing a cell into sectors, which reduces the number of cells in a cluster. Therefore, the network capacity is increased.

Digital technology can also be used to increase the network capacity. Transmission of digitized voice goes through three steps before the actual transmission: speech

coding, channel coding, and modulation. Speech coding is to compress voice. For example, a short voice segment can be analyzed and represented by a few parameter values. These values cannot be transmitted directly because wireless transmission is error prone, and a small change in these values may translate into a big change in voice. Therefore, data representing compressed voice should be arranged carefully, and redundancy should be introduced such that a transmission error can be corrected or at least detected. This process is called channel coding. Finally, the output data from channel coding are modulated for transmission. The detailed information on speech coding, channel coding, and modulation can be found in three corresponding chapters in Rappaport (2002). A good speech-coding scheme combined with a good channel-coding scheme will greatly reduce the amount of bandwidth needed by each phone user and therefore increase the network capacity while keeping the quality of voice unchanged.

The channels assigned to a cell are used either for voice or for control. A voice channel is used for an actual conversation, whereas a control channel is used to help set up conversations. Both voice and control channels are further divided into forward (or downlink) and reverse (or uplink). A forward channel is used to carry traffic from the BS to the MS, and a reverse channel is used to carry traffic from the MS to the BS. The channels assigned to a cell are shared by MSs located in the cell. Multiple access methods are used to share the channels in a cell.

Each MS has a home MTSO, which is the MTSO where the mobile user originally subscribed for wireless services. If an MS moves out of the home MTSO area, it is roaming. A roaming MS needs to register in the visited MTSO. An MS needs to be authenticated against the information kept in its home MTSO before any service can be rendered by the network. The services include making a call, receiving a call, registering the location, and so forth. These services are possible because of a widely used global, common channel-signaling standard named SS7 (Signaling System No. 7) (Modarressi & Skoog, 1992; Rappaport, 2002).

To make a call from an MS, the MS first needs to make a request using a reverse control channel in the current cell.

Figure 2: Frequency reuse.

If the request is granted by MTSO, a pair of voice channels (one for transmitting and the other for receiving) is assigned for the call. Making a call to an MS is more complicated. The call is first routed to its home MTSO or its visited MTSO if it is roaming. The MTSO needs to know the cell in which the MS is currently located. Finding the residing cell of an MS is the subject of location management. Once the MTSO knows the residing cell of the MS, a pair of voice channels is assigned in the cell for the call.

If a call is in progress when the MS moves into a neighboring cell, the MS needs to get a new pair of voice channels from the BS of the neighboring cell so the call can continue. This process is called hand-off. A BS usually adopts a channel assignment strategy that prioritizes hand-off calls from neighboring cells over the new calls initiated in the current cell.

MULTIPLE ACCESS METHODS

Within a cell covered by a BS, there are multiple MSs that need to communicate with the BS. Those mobile stations must share the air interface in an orderly manner so that no MSs within the cell interfere with each other. The methods for MSs to share the air interface in an orderly manner are referred to as multiple access methods. The popular multiple access methods include (frequency division multiple access) FDMA, TDMA, and CDMA.

FDMA divides the frequency spectrum assigned to the BS into several frequency bands, also known as channels, as shown in Figure 3. These channels are well separated and do not interfere with each other. An MS can use the assigned channel(s) exclusively. FDMA is used in the Advanced Mobile Phone System (AMPS) (Black, 1996, 1999). AMPS uses a total of 40 MHz in the 800-MHz spectrum, 825–845 MHz and 870–890 MHz, to be exact. (For ease of clarification, the additional 10 MHz added later is not considered here.) In AMPS, each channel has a bandwidth of 30 kHz, and the 40-MHz bandwidth translates into about 1332 channels. In the United States, it is required that two cellular communication providers be present in every market to encourage competition.

Figure 3: FDMA (frequency division multiple access).

Figure 4: TDMA (time division multiple access).

Therefore, each cellular communication provider has 666 channels. AMPS uses FDD (frequency division multiplexing). That is, 333 channels are for communication from the BS to MSs and the other 333 channels are for communication from MSs to the BS. Among these 333 channels, only 312 channels are for voice traffic because 21 of them need to be used for control. Based on the seven-cell reuse pattern, only about 45 MSs within a cell can communicate with the BS simultaneously.

TDMA usually builds on FDMA and allows multiple MSs to share the same channel. In TDMA, time is slotted. In each time slot, only one MS is allowed to use the shared channel to transmit or receive. MSs take their turn transmitting or receiving in their allocated slots in a round-robin fashion. Although the channel is shared, no interference can arise among those sharing MSs because only one MS can use the channel at one time. Figure 4 illustrates the concept of TDMA.

Because an MS is not able to use the channel all the time, it is challenging to deliver voice, which is supposed to be continuous. Fortunately, an ordinary human can tolerate a delay of 20 milliseconds (ms). In D-AMPS (D for digital), a speech segment consists of 20-ms durations of speech. The speech segment is first digitized and then compared with the VSELP (vector sum excited linear predictive) Cookbook (Black, 1999). The index to the entry in the VSELP Cookbook that is closest to the digitized voice is transmitted instead of the digitized voice. The index is 159 bits long. At the receiving end, the digitized voice that is very close to the original voice can be retrieved based on the 159-bit index. In D-AMPS, which uses the same 30-kHz channel as AMPS, 159 bits (along with overhead bits for a total of 260 bits) can be transmitted in two of six time slots in a frame. At 25 frames per second, D-AMPS has three times the capacity of AMPS using the same number of channels. TDMA can operate in either the 800-MHz cellular spectrum (IS-54/D-AMPS; EIA/TIA, 1990) or the 1900-MHz PCS spectrum (IS-136; EIA/TIA, 1995).

CDMA takes an entirely different approach from TDMA. In CDMA, multiple MSs share the same wideband of spectrum. Instead of being assigned to time slots as in TDMA, each MS is assigned a unique sequence code. Each

Figure 5: CDMA (code division multiple access).

MS's signal is spread over the entire bandwidth by the unique sequence code. At the receiver, that same unique code is used to recover the signal. Although the radio spectrum is shared, no interference can arise because the sequence codes used by the sharing MSs are basically orthogonal. Figure 5 illustrates the concept of CDMA. An excellent illustration of how CDMA encodes and decodes can be found in Stallings' text (2002). In principle, for CDMA to work, the signals received by the BS from different MSs must be at the same power level. To achieve this, a few bits in the forward control channel are set aside for power control. Specifically, the BS uses these bits to instruct each MS to increase or decrease its output power level such that all signals received at the BS have the same strength.

LOCATION MANAGEMENT

This section describes how to track an MS. How to keep track of an MS is the subject of location management in cellular networks. Because the exact location of an MS must be known to the cellular network when a call is in progress, location management tracks an active MS that is not in a call. (An MS is active when it is powered on.) Specifically, the cellular network needs to find out the exact cell in which an MS is located when an incoming call arrives for the MS.

An extreme case, known as "Never-Update" in Bar-Noy, Kessler, and Sidi (1995), is that an MS never tells the cellular network its location when it moves around. When an incoming phone call arrives for the MS, the cellular network needs to page all cells in the service area to find out the cell in which the MS is currently located so the incoming call can be routed to the BS of that cell. It will cost a great deal to page all cells in the service area. The other extreme case is known as "Always-Update," in which an MS needs to update its location whenever it moves into a new cell. When an incoming phone call arrives for the MS, the cellular network can just route the incoming call to the cell that is last reported by the MS. Obviously, there

is no paging cost involved. However, the MS needs to tell the cellular network its location when it moves from cell to cell, which can also be very expensive.

There are two basic operations involved with location management: location update and paging. The paging operation is performed by the cellular network. When an incoming call arrives for an MS, the cellular network will page the MS in all possible cells to find out the cell in which the MS is located so the incoming call can be routed to the corresponding BS. The number of all possible cells to be paged is dependent on how frequent the location update operation is performed. The location update operation is performed by an MS. Both operations consume wireless bandwidth: location update uses reverse control channels, whereas paging utilizes forward control channels. Although the cost of location management involves both the wireline portion and the wireless portion of the cellular network, only the wireless portion is usually considered. This is mainly because the radio-frequency bandwidth is limited, whereas the bandwidth of the wireline network is easily expandable. Therefore, the location management cost is measured by the total wireless bandwidth consumed by both location update and paging operations, that is, the location update cost and the paging cost. There is a trade-off between the location update cost and the paging cost. For example, if an MS updates its location more frequently, the network knows the location of the MS better. It incurs a higher location update cost, but the paging cost will be lower when an incoming call arrives for the MS.

The location-areas scheme is used in current cellular networks. In the location-areas scheme, the whole service coverage area is partitioned into location areas, each of which consists of several contiguous cells. The BS of each cell broadcasts the ID of the location area to which the cell belongs. An MS knows the location area it is in by listening to the broadcasting from the BS. An MS updates its location (i.e., location area) whenever it moves into a cell that belongs to a new location area. When an incoming call arrives for an MS, the cellular network pages all the cells of the location area that was last reported by the MS. Figure 6 illustrates a coverage area with three location

Figure 6: A service area with three location areas.

areas separated by wide lines. When an MS moves from cell A to cell B in the figure, it will report its new location area because cell A and cell B are in different location areas. No location update is necessary if the MS moves from cell A to cell C because cell A and cell C are in the same location area.

The location-areas scheme is a generalization of both Never-Update and Always-Update extreme cases. In Never-Update, all the cells in the coverage area belong to the same location area, and in Always-Update, each cell forms a location area. How to divide the whole coverage area into location areas greatly affects the location management cost. In reality, a location area consists of all the cells under the control of an MTSO. Each MTSO consists of two main databases: HLR (Home Location Register) and VLR (Visitor Location Register). HLR contains information for each MS that considers the location area covered by the MTSO as its home. Each MS can subscribe to one MTSO as its home. VLR records a list of the MSs that are currently located in the location area covered by the MTSO but do not consider the MTSO as their home. When an MS moves out of its home MTSO and visits another MTSO, the MS needs to register with the visited MTSO. The visited MTSO contacts the home MTSO about the MS. The home MTSO records the visited MTSO of the MS in its HLR. The visited MTSO updates its VLR about the MS. When a call is made to the MS, it is first addressed to the home MTSO of the MS. By checking the information stored in HLR about the MS, the call can eventually be routed to the visited MTSO. Finally, the visited MTSO pages the MS in the cells of its covered location area.

The location-areas scheme is global in the sense that all MSs transmit their location updates in the same set of cells, and it is static in the sense that the location areas are fixed. A location-update scheme can be classified as either global or local (Bar-Noy, Kessler, & Sidi, 1995; Ramanathan & Steenstrup, 1996). A location-update scheme is global if all MSs update their locations at the same set of cells, and a scheme is local (or individualized) if an individual MS is allowed to decide where to perform location update. From another point of view, a location-update scheme can be classified as either static or dynamic (Bar-Noy, Kessler, & Sidi, 1995; Ramanathan & Steenstrup, 1996). A location-update scheme is static if there is a pre-determined set of cells at which location updates must be generated by an MS regardless of its mobility. A scheme is dynamic if a location update can be generated by an MS in any cell depending on its mobility. Recently there was a swarm of research on location management, especially how to reduce the cost of location management. For detailed information on recent research on location management, please refer to the survey in Zhang (2002).

HAND-OFF STRATEGIES AND CHANNEL ASSIGNMENT

The previous section described how to track the movement of an MS when it is not in a call. This section deals with the movement of an MS when it is in a call. When an MS is in a call, it has acquired two channels (one for transmitting and the other for receiving) from the current

cell for communication with the BS. When the MS moves out of the current cell and enters a neighboring cell, the MS needs to acquire two channels from the neighboring cell in order for the call to continue. The process of transferring a call from the current cell to a neighboring cell is called hand-off. To a cell, a hand-off call is a call that is in progress in a neighboring cell and needs to be continued in the cell because of the movement of an MS. In contrast, a new call is a call that is started in the cell. As mentioned earlier, the number of channels assigned to each cell is limited. Channel assignment deals with how to assign available channels to new calls as well as hand-off calls.

The simplest channel assignment scheme is the fully shared scheme (FSS), in which all available channels are shared by hand-off calls and new calls. No distinction is made between a hand-off call and a new call. FSS is widely used in the current cellular networks because of its simplicity. In addition, FSS has the advantage of maximizing the utilization of wireless channels. The disadvantage is the increased dropping rate of hand-off calls. In general, it is less desirable to drop a hand-off call than to block a new call. The dropping probability of hand-off calls is considered as one of major metrics that measure the quality of service of calls.

Recently intensive research on channel-assignment schemes has been conducted to decrease the dropping probability of hand-off calls. One such scheme is the hand-off queuing scheme (HQS; Tekinay & Jabbari, 1991). When an MS detects that the received signal strength from the current BS is below a certain level, called the hand-off threshold, a hand-off operation is initiated. The hand-off operation first identifies the new BS into which the call is moving. If the new BS has unused channels, the call will be transferred to the new BS. If there is no unused channel available, the hand-off call will be queued until a channel is released by another call. The HQS scheme is feasible because there is a difference between the signal strength at the hand-off threshold and the minimum acceptable signal strength for voice communication. This gives an MS some time to wait for a channel at the new BS to become available. A new call will be blocked in the new cell until all the hand-off calls in the queue are served. Therefore, the HQS scheme decreases the dropping probability of hand-off calls while increasing the blocking probability of new calls because the scheme gives higher priority to hand-off calls.

The scheme proposed by Li, Shroff, and Chong (1999) goes one step further. When a hand-off call is not able to acquire the necessary channels in the new cell, the call is allowed to carry the channels in the current cell to the new cell, a concept the authors called channel carrying. However, carrying the channels from the current cell to the new cell may reduce the reuse distance of the channels and violate the minimum reuse distance requirement. To ensure the minimum reuse distance requirement is not violated, an $(r + 1)$ -channel assignment scheme is used. That is, the same channels are reused exactly $(r + 1)$ cells apart. Here r is the minimum reuse distance. In this scheme, a channel can only be carried from the assigned cell to a neighboring cell, and the carried channel will be returned as soon as a local channel is available. By using channel

carrying, a hand-off call can continue, even if there is no channel available in the new cell. Therefore, the dropping probability of hand-off calls will be reduced. However, the capacity of the cellular network is reduced because the $(r + 1)$ -channel assignment scheme is used instead of r -channel assignment.

Another channel assignment scheme that prioritizes the hand-off call is referred to as the guard channel scheme (GCS; Tekinay & Jabbari, 1991). In GCS, each BS reserves a fraction of wireless channels exclusively for hand-off calls, and the remaining channels, called normal channels, are shared between hand-off calls and new calls. Both hand-off calls and new calls use the normal channels first. When the normal channels are used up, a new call will be blocked, but a hand-off call can still use the reserved channels. In this way, the dropping probability of hand-off calls will be reduced. The improvement in the dropping probability of hand-off calls is dependent on the number of channels reserved. However, a new call is blocked if there are only reserved channels left even though no hand-off calls exist. Therefore, the total utilization of wireless channels is decreased. There is a trade-off between decreasing the blocking probability of hand-off calls and increasing the total channel utilization. The number of channels that should be set aside for hand-off calls depends on a lot of factors such as the mobility of MSs, the call duration, and so forth.

Kim et al. (1999) propose a dynamic channel reservation scheme (DCRS) based on mobility. Their goal is to guarantee the required dropping probability of hand-off calls while minimizing the blocking probability of new calls. As in GCS, the normal channels of DCRS are shared by both hand-off calls and new calls, and the guard channels are reserved for hand-off calls. However, the guard channels can also be used by new calls whose request probability is a function of the mobility of calls. The mobility of calls in a cell is defined as the ratio of the hand-off call arrival rate to the new call arrival rate. If there is no arrival of hand-off calls, the request probability will be one, and the guard channels will be used by new calls. If there is no arrival of new calls, the request probability will be zero, and the guard channels will be used by hand-off calls. When the arrival rate of hand-off calls is larger than that of new calls, the request probability is decreased quickly so the hand-off calls can use the guard channels. In this way, the dropping probability of hand-off calls is guaranteed. When the arrival rate of hand-off calls is lower than that of new calls, the request probability is decreased slowly so new calls have a chance to use available guard channels. This decreases the blocking rate of new calls without sacrificing the dropping probability of hand-off calls, which increases the total channel utilization.

AUTHENTICATION AND ENCRYPTION

Because cellular communication is carried out over the air interface, it is more vulnerable to fraud and eavesdropping. It is essential to have cell phone users authenticated and voice or data traffic encrypted. Authentication verifies whether a user is who he or she claims to be. Encryption is to use a key to scramble a message such that the

message cannot be read by anyone but the holder of the correct key. There are two popular encryption methods, private key encryption and public key encryption. Both encryption methods can also be used for authentication. For more information on how these two encryption methods work and how they can be used for authentication, the reader is referred to Stallings' text (2003) or the corresponding chapters in this book. This section discusses how authentication and encryption are performed in cellular networks, including global system for mobile communications (GSM) and IS-41.

Every GSM mobile subscriber has an SIM (subscriber identity module) card that can be inserted into a mobile phone (Black, 1999; Mouly & Pautet, 1992). A phone with an SIM card inserted can be activated by entering the four-digit PIN (personal identification number) correctly. The SIM stores identity- and security-related information such as the IMSI (international mobile subscriber identity), the authentication key (K_i), the A_3 authentication algorithm, and the A_8 ciphering key generating algorithm. The authentication in GSM checks if the SIM is genuine, and it is based on a challenge-and-response method. A 128-bit random number is sent by the network to the MS as the challenge. The MS inputs the challenge and the authentication key (K_i) to the A_3 algorithm to generate the signed response (SRES), which is sent back to the network. The network compares the received SRES with the SRES provided by the authentication center. If they match, the mobile user is authenticated; otherwise, the user is not. Once the mobile user is authenticated, the A_8 algorithm uses the random number and the authentication key (K_i) to generate a ciphering key (K_c) at both ends of the air interface. The ciphering key (K_c) is used by the A_5 ciphering algorithm of the MS to encrypt and decrypt data.

To make GSM secure, all security specifications such as the A_3 and A_8 algorithms are kept secret. However, it is claimed a secret encryption algorithm prevents the brightest minds in the world from identifying flaws in them. Recently a group of researchers discovered that the method used for authentication in GSM was not strong enough to resist attack (GSM Cloning, n.d.). An attacker can repeatedly send the challenges and collect the responses. By analyzing the responses, the secret key can be determined. However, despite its security vulnerability, GSM is still the most secure public wireless system in the world.

For the cellular systems in North America including IS-54, IS-136, and IS-95, IS-41 is used for security (Black, 1999; EIA/TIA, 1993; Mohan, 1996). There are five authentication and privacy operations defined in IS-41: authentication of mobile station registration, authentication of mobile station originating a call, authentication of a call to a terminating mobile station, unique challenge-response procedure, and updating the shared secret data. The idea used for authentication in IS-41 is similar to that used in GSM. Both the authentication center and the MS share a secret key, referred to as SSD (shared secret data). SSD consists of two parts: SSD-A and SSD-B, each of 64 bits. SSD-A is used for authentication, and SSD-B is used for encryption. A BS periodically broadcasts a 32-bit random number, that is, the authentication challenge. At request of the network, an MS inputs the received authentication challenge, SSD-A, its ESN (electronic serial number), and

its last six digits of the phone number to the CAVE (cellular authentication and voice encryption) algorithm to obtain the 18-bit response to the authentication challenge, which is sent back to the network. If the response matches the one calculated by the authentication center, the MS is authenticated. Once authenticated, the MS will receive two values, the signaling message encryption key for message encryption and the voice privacy mask for voice encryption.

EVOLUTION OF CELLULAR NETWORKS

Cellular systems became popular because of radio-frequency reuse, which allows more cell phone users to be supported. The cellular concept was first used in the AMPS in the United States. As a first generation of cellular systems, AMPS is a FDMA-based analog system. The 2G of cellular systems uses digital technologies. Two interim standards, IS-95 (CDMA-based) and IS-136 (TDMA-based), are used in the United States, and TDMA-based GSM is used in European countries. It is clear that the 3G of cellular systems will be CDMA-based. However, the GSM community is developing WCDMA to be backward compatible with GSM while the CDMA community tries to evolve CDMA into CDMA2000. Currently researchers are studying technologies for Beyond 3G (B3G) or fourth-generation (4G) networks.

In the late 1970s and early 1980s, AT & T Bell Laboratories developed the AMPS, which was the first-generation cellular system used in the United States (Rappaport, 2002; Young, 1979). It was first deployed in Chicago and Washington, DC, then in all the major U.S. cities. Currently it is still used in many rural areas. The Federal Communications Commission (FCC) initially allocated a 40-MHz spectrum in the 800-MHz band for the AMPS in 1983, and later in 1989 added an additional 10 MHz to accommodate the increasing demand for cellular phone services. AMPS is FDMA-based, with each channel occupying a narrow band of 30 kHz. AMPS is an analog system. It transmits 3-kHz voice signal over the 30-kHz channel using frequency modulation. IS-41 was originally developed to support the operations with AMPS. However, as an analog system, AMPS does not support voice encryption.

To overcome the limited capacity of AMPS, especially in large cities, D-AMPS (IS-54) was developed in the early 1990s (EIA/TIA, 1990). D-AMPS inherited a lot of features from AMPS. Specifically, in D-AMPS, the same AMPS allocation of frequency spectrum is used, and each channel is still 30 kHz wide. However, in D-AMPS, a 30-kHz channel can be shared by three users through the 2G TDMA digital technology. In a typical D-AMPS cell, some of the 30-kHz channels are assigned for analog AMPS traffic, whereas the others are for digital TDMA traffic. It means that D-AMPS allows a service provider to migrate from the first-generation analog technology to the 2G digital technology on a gradual basis. In a less densely populated area, all the channels can be assigned for AMPS traffic. When the demand increases, some channels will be converted from analog to digital. In a densely populated area, all the channels need to be assigned for TDMA traffic to meet the demand.

IS-136, another prominent TDMA-based cellular system in the United States, is built on D-AMPS. Whereas D-AMPS provides dual-mode operations (both analog and digital), IS-136 provide pure digital operations. All the 30-kHz channels are shared by three users via TDMA digital technology. In addition, unlike D-AMPS, IS-136 also uses the digital control channels. IS-136 was initially developed on the 800-MHz cellular spectrum. It can be adopted onto the 1900-MHz PCS spectrum.

GSM is a 2G system developed to solve the incompatibility problem of different first-generation systems in Europe (Black, 1999; Mouly & Pautet, 1992; Rahnema, 1993). It is now widely deployed around the world including in the United States. GSM was first developed for Europe in the 900-MHz band (GSM 900), then expanded to the 1800-MHz band (1710–1880 MHz), which is named DCS 1800, and later renamed to GSM 1800. The North America version of GSM is called PCS 1900 because of its use of the 1900-MHz PCS spectrum. GSM uses the TDMA digital technology. The allocated spectrum is divided into multiple channels of 200 kHz using FDMA, and each 200-kHz channel is shared by as many as eight users using TDMA. One feature of GSM worth mentioning is the SIM card that can be inserted into a cellular phone to provide the owner's identity information. A cell phone without a SIM card inserted does not work. A SIM card can be inserted into any cell phone to make the phone usable.

Whereas IS-54, IS-136, and GSM are all TDMA-based, IS-95 is CDMA-based (EIA/TIA, 1995). As mentioned earlier, each user in CDMA is assigned a unique code to encode the data to be transmitted. Knowing the code of the transmitter, the receiver is able to recover the original data from the received data. CDMA is a very new 2G digital technology. Since its first launch in 1995, CDMA quickly became one of the world's fastest-growing wireless technologies. CDMA uses channels that are 1.25 MHz wide, and it is able to support up to 64 users with orthogonal codes. With CDMA, the same channel can be reused in a neighboring cell. CDMA is superior to FDMA and TDMA. In fact, CDMA provides roughly 10 times more capacity than analog systems, whereas TDMA provides 3 to 4 times more capacity than analog systems. In 1999, CDMA was selected by the International Telecommunications Union as the industry standard for new 3G cellular systems.

The goal of a 3G cellular system is to provide all kinds of services: voice, high-speed data, audio/video, and so forth. The high-speed data transmission is the main development focus. The CDMA and GSM communities are two major players in this effort. The 3G path adopted by the GSM community is first to GPRS, then to EDGE, and ultimately to WCDMA (Qualcomm CDMA Technologies, n.d.). Currently GSM provides data services of 9.6 Kbps using a single TDMA channel. Although multiple TDMA channels can be combined to provide high-speed data service, it is circuit switched. A service called general packet radio service (GPRS) is first developed to allow users to connect to packet-switched data networks via a different connection from the voice network. With GPRS, the raw data rate increases to approximately 170 Kbps. The next step is enhanced data rates for global evolution (EDGE). EDGE provides practical raw data rates of up to 384 Kbps using a new high-speed physical layer. Finally, WCDMA

is used for the 3G version of the GSM community. In WCDMA, CDMA is used instead of TDMA, and the carrier bandwidth jumps from 200 kHz to 5 MHz to provide data rates of up to 2 Mbps. However, new frequency allocations, BSs, and MSs are required because of the change from TDMA to WCDMA.

The 3G path adopted by the CDMA community is first to CDMA2000 1x, then to 1xEV, and ultimately to 3x (Qualcomm CDMA Technologies, n.d.). The first step is to use one 1.25-MHz carrier to support packet data. In fact, CDMA phones and networks are already capable of handling packet data. The CDMA2000 1xEV consists of two phases. In Phase 1, one carrier (1.25 MHz) is dedicated to high-speed packet data, and one or more additional carriers are used for voice. In Phase 2, packet data and voice can be combined in the same carrier. Finally, CDMA2000 3x can use up to three 1.25-MHz carriers. When CDMA2000 uses three 1.25-MHz carriers, its total bandwidth approaches that of WCDMA. However, 3x is more flexible because three channels can be used independently or together as a single 3.75-MHz channel. The main advantage of the 3x approach is that it can be implemented in existing frequency allocations in CDMA, which also uses 1.25-MHz carriers.

Now researchers are developing technologies for B3G or 4G networks (Technologies Beyond 3G, n.d.). It is expected all the 4G network elements are digital and the entire network is packet-switched. 4G networks will integrate wireless local area networks (LANs) such as IEEE 802.11 and Bluetooth with wide area cellular networks. The data transmission rate of 4G communications will be much higher than 3G, at 20 to 100 Mbps in mobile mode.

ALTERNATIVES TO CELLULAR NETWORKS

This section describes alternatives to cellular networks. Although cellular networks use either the 800-MHz cellular spectrum or the 1900-MHz PCS spectrum, most of the alternatives use the license-free 2.4-GHz industrial, scientific, and medical (ISM) band. The alternatives introduced here include IEEE 802.11 wireless LAN, IEEE 802.16 wireless MAN (metropolitan area network), mobile ad hoc networks, and multihop cellular networks.

IEEE 802.11 wireless LAN is an infrastructure wireless network, similar to a cellular network (Crow, Widjaja, Kim, & Sakai, 1997; IEEE P802.11, n.d.). (IEEE 802.11 also supports peer-to-peer communication that is not frequently used.) Access points (APs) that are analogous to BSs in cellular networks are established to provide an extension to the wired network. The area covered by an AP is called the basic service area, which is analogous to a cell in cellular networks. The nodes in a basic service area form the basic service set. Any node in the basic service set can communicate with the AP directly. Their radio communication uses the license-free ISM band with direct sequence spread spectrum. Under 802.11b (a variation of the IEEE 802.11), the communication is kept at a maximum speed of 11 Mbps whenever possible. It drops back to 5.5 Mbps, then 2 Mbps, and finally down to 1 Mbps if signal strength or interference is corrupting data. New

IEEE 802.11g extends the data rate to 54 Mbps from 11 Mbps of IEEE 802.11b. With IEEE 802.11 wireless LAN, a node is connected to the Internet world, and it is able to get any service the Internet provides.

IEEE 802.11 works well for wireless access in a local area. To use it for wireless access in a metropolitan area, its bandwidth is often insufficient, and it can experience interference from competitors because they use the same license-free ISM band. IEEE 802.16 standards are for broadband wireless access in a metropolitan area, and they use licensed bands (IEEE 802.16 Task Group e, n.d.). IEEE 802.16a is just for fixed broadband wireless access. IEEE 802.16e supports both fixed and mobile broadband wireless access. Therefore, hand-off between two towers is allowed in IEEE 802.16e.

Unlike cellular networks, mobile ad hoc networks (MANET for short) are infrastructureless. All nodes within the network can be mobile, and there is no fixed BS or centralized control (Macker & Corson, 1998). A mobile node can communicate with another one directly if one is within the transmission range of the other. Because the network topology for a MANET can dynamically change as a result of node mobility, a MANET is usually modeled by a dynamically changing graph. A MANET finds its applications in an environment where it may not be economically practical or physically possible to provide the necessary infrastructure, or the expediency of the situation may not permit its installation. For example, in a battlefield, it is not possible to install an infrastructure wireless network in the enemy's territory. In such a situation, a MANET is a good solution. Unlike in the cellular network, the route for communication between two nodes is not fixed in MANET. To send a message from one mobile node (the source) to another mobile node (the destination), a route between the source and the destination must be found. Designing a good routing protocol in a dynamically changing network is very challenging. For more information on routing protocols, please refer to routing surveys in Royer and Toh (1999) and Stojmenovic (2002).

The traditional cellular network is called a single-hop cellular network (SCN) because an MS in a cell can reach the corresponding BS with a single wireless hop, and a MANET is considered a multihop wireless network because intermediate nodes are required for communication between two nodes that are not within the transmission range of each other. Lin and Hsu (2000) proposed a new architecture, referred to as multihop cellular network (MCN), which combines the features of SCN and MANETs. MCN has many advantages over SCN. In SCN, two MSs communicate only via a BS even though they are in the same cell and mutually reachable. In MCN, these two MSs can communicate directly. In MCN, if a MS is not reachable from a BS in one hop, the BS will seek intermediate nodes to forward, which is not feasible in SCN.

SUMMARY

Cellular networks are based on the frequency reuse concept. In a cellular network, a service coverage area is divided into cells, each of which is served by a BS. Each BS is assigned a group of channels. The same set of channels can be assigned to the two cells that are far apart such that

the radio co-channel interference between them is within a tolerable limit. Within a cell covered by a BS, multiple MSs want to communicate with the BS. Multiple access methods deal with how to share the channels assigned to a BS by the MSs located within the cell. FDMA, TDMA, and CDMA are three popular multiple access methods.

When an incoming call arrives for a MS, the cellular network needs to find out the exact cell in which a MS is located. How to track the movement of a MS is the subject of location management. Location management for cellular networks was discussed in this chapter. When a MS is in a call and moves from the current cell to a neighboring cell, the cellular network needs to transfer the call from the current cell to the neighboring cell. This process is called hand-off. A hand-off call is usually prioritized over a new call. Several channel assignment schemes that deal with new calls and hand-off calls were presented in this chapter.

Because wireless communication is carried out over the air interface, it is more vulnerable to fraud and eavesdropping. Therefore, authentication and encryption are two important issues in cellular networks. This chapter discussed authentication and encryption in GSM and IS-41. A cellular network integrates cell phones into the public switched telephone network. Whereas the first generation of cellular networks was analog, the 2G is digital. The 3G integrates cell phones into the Internet world by providing high-speed packet-switching data transmission. The evolution of cellular networks from the first generation to the 3G was presented. Technologies for B3G or 4G networks are being studied currently. Finally, this chapter discussed alternatives to cellular networks, including IEEE 802.11 wireless LAN, IEEE 802.16 wireless MAN, MANETs and MCNs. For further reading on cellular networks, please refer to these three excellent books: Agrawal and Zeng (2002), Black (1999), and Rappaport (2002).

ACKNOWLEDGMENTS

The authors thank Professor Hossein Bidgoli and five anonymous referees for their constructive comments and suggestions that greatly improved the quality of this chapter. The authors also thank Professor Phillip Bradford for many helpful discussions and his time to proofread the manuscript, and Mr. Zhijun Wang for drawing the figures in this chapter.

GLOSSARY

AMPS (Advanced Mobile Phone System) The first-generation analog cellular network developed in the United States.

BS (Base Station) A fixed station in the cellular network that connects mobile stations to the land telephone network by communicating with mobile stations via radio.

CDMA (Code Division Multiple Access) A digital cellular technology that allows multiple users to share a channel using different orthogonal codes.

Cell The area covered by a base station.

Cell Splitting A technique that divides a cell into multiple smaller cells to increase the capacity of a cellular network.

Cellular Network A network that divides a geographic area into cells such that the same radio frequency can be reused in two cells that are a certain distance apart.

FDMA (Frequency Division Multiple Access) An analog cellular technology that divides a wide band into multiple narrow bands to be used by multiple users.

GSM (Global System for Mobile Communications) A second-generation TDMA cellular network developed in Europe to achieve compatibility among European countries.

Hand-Off Channel switching for a call to continue when the mobile station involved in the call moves from one cell to another.

HLR (Home Location Register) An MSC database that stores information about the users who consider the area covered by the MSC as their home.

IS-54 A second-generation TDMA cellular network in the United States that uses the same cellular spectrum (800 MHz) as AMPS. It is also known as Digital-AMPS.

IS-95 A second-generation CDMA cellular network in the United States for both the cellular and PCS spectrums.

IS-136 A second-generation TDMA cellular network in the United States for both the cellular (800 MHz) and PCS (1900 MHz) spectrums.

Location Management A subject that deals with how to track an active mobile station.

MS (Mobile Station) A station in the cellular network that can communicate with base stations via radio even when it is in motion. Examples include cellular phones and wireless-capable laptops.

MTSO (Mobile Telephone Switching Office) The switching center that interconnects cellular phones with the land telephone network. It is also known as MSC (mobile switching center).

Multiple Access Method A method that allows multiple users in a cell to share the air interface in an orderly manner. Multiple access methods include FDMA, TDMA, and CDMA.

PSTN (Public Switched Telephone Network) The regular wireline telephone network.

TDMA (Time Division Multiple Access) A digital cellular technology that allows multiple users to share a channel using different time slots.

VLR (Visitor Location Register) An MSC database to temporarily store information about the users who are visiting the area covered by the MSC.

INTRODUCTION

Mobile networking is becoming increasingly important as portable devices such as personal digital assistants (PDAs) and laptops become more powerful and less expensive, and as users need to be connected whenever and wherever they are. Mobile Internet protocol (IP) allows portable devices called *mobile nodes* to roam from one IP subnet to another while maintaining the communication sessions.

An IP address identifies a node (end point) as well as the subnet to which it is connected. The dual usage of IP addresses thus causes problems when a mobile node changes its point of attachment (indicated by a different *subnet prefix*) to the Internet. Packets destined to the mobile node would not be able to reach it while it is away from its home IP subnet because routing is based on the network prefix in a packet's destination IP address. To continue communication in spite of its mobility, a mobile node could change its IP address each time it moves to a new IP subnet. However, both ends of a TCP session need to keep the same IP address for the life of the session. Otherwise, existing sessions stop working and new sessions need to be started when a mobile node moves to another subnet.

Mobile IP allows the mobile node to use two IP addresses. Each mobile node is assigned a (permanent) IP address in the same way as any other node, and this IP address is known as the mobile node's *home address*. A mobile node's home address remains unchanged regardless of where the node is attached to the Internet. The IP subnet indicated by this home address is the mobile node's *home network*, and standard IP routing mechanisms will deliver packets destined to a mobile node's home address only to its home network. When away from its home network, a *care-of address* is associated with the mobile node and reflects the mobile node's current point of attachment to the *foreign network* that it is visiting.

The outline of this chapter is as follows: It begins with an overview of mobile IP in Internet protocol version 4

(Ipv4) environment (mobile Ipv4). The protocol mechanisms enabling operation of mobile Ipv4 are discussed next. Internet protocol version 6 (Ipv6), with its many advantages, provides a more integrated and efficient implementation in the form of mobile Ipv6. After a review of security threats in mobile IP environment, security design of mobile Ipv4 is covered. This is followed with an extensive discussion of protocol mechanisms designed to make mobile Ipv6 as secure as Ipv4.

OVERVIEW OF MOBILE Ipv4

The design of mobile IP has been guided by the need to provide mobility support on the top of existing IP infrastructure, *without requiring* any modifications to the routers, the applications, or the stationary end hosts (called *correspondent nodes*). This requirement implies that a mobile node must continuously use its permanent IP address even as it roams to another area. The mobile node basically works like any other node in its home network when it is at home. The packets destined to it are routed using traditional IP routing protocols. To provide support for mobility, Mobile IP requires the existence of two types of agents: one on the mobile node's home network, known as its *home agent*, and the other on the foreign network, known as its *foreign agent*. Typically, one or more routers on a network will implement the roles of both the home and foreign agents. Figure 1 shows mobile Ipv4 operational environment.

The home and foreign agents make themselves known by sending agent advertisement messages. After receiving an agent advertisement, the mobile node determines whether it is in its home network or in a foreign network. Whenever the mobile node moves to a foreign network, it obtains a care-of address from the foreign agent and then *registers* this new care-of address with its home agent, by way of the foreign agent. The association between a mobile node's home address and its care-of address, along

Figure 1: Mobile IP operation.

with the remaining lifetime of that association, is known as *binding*. While away from its home subnet, the mobile node's home agent maintains a record of the current binding of the mobile node. The home agent intercepts any packets on the home subnet addressed to the mobile node's home address using the proxy (Postel, 1984) and gratuitous (Stevens, 1994) *address resolution protocol* (ARP) mechanisms and tunnels them to the mobile node at its current care-of address. This tunneling uses IPv4 encapsulation and the path followed by a packet while it is encapsulated is called a *tunnel*. Thus, the mobile node is reachable at any location in the Internet using its care-of address and its movement is transparent to the higher-layer applications that use the home address.

Mobile IPv4 allows another kind of care-of address, called *collocated care-of address*, which is an IP address temporarily assigned to an interface of the mobile node itself. The subnet prefix of a collocated care-of address must equal the subnet prefix that has been assigned to the foreign link being visited by the mobile node. The collocated care-of address, acquired by an IP address-assignment procedure, such as *dynamic host configuration protocol* (DHCP; Stevens, 1994), might be used by the mobile node in situations where no foreign agents are available on a foreign link. A collocated care-of address can be used by only one mobile node at a time.

Packets transmitted by the mobile node (MN) to the correspondent (CN) node use normal IP packet format

with the mobile node's address as the source IP address and the correspondent node's address as the destination IP address. These packets follow the default route

$$MN \rightarrow CN.$$

Note that *all* packets sent to a mobile node from a correspondent node must be routed first to the mobile node's home network and then forwarded to the mobile node at its current location by its home agent (HA), leading to this *triangle routing*:

$$CN \rightarrow HA,$$

$$HA \rightarrow MN.$$

Mobile IPv4 protocol with triangle routing is not optimal, especially in cases when the correspondent node is very close to the mobile node. It is, however, simple, because the number of control messages to be exchanged is limited and the address bindings are highly consistent, because they are kept at one single point (the home agent) for a given mobile node. One of the drawbacks of triangle routing is that the home agent is a fixed redirection point for the exchange of every IP packet, even if a shorter route is available between the correspondent and mobile nodes. This can lead to unnecessarily large end-to-end packet delay. The other drawback is that the network links connecting a home agent to the network can easily be overloaded.

MOBILE Ipv4 PROTOCOL OVERVIEW

Mobile Ipv4 includes the following extensions to support mobility in the Ipv4 environment (Perkins, 1997; 1998; 2002):

Agent discovery. A mobile node uses a discovery procedure to identify prospective home agents and foreign agents.

Registration. A mobile node uses an authenticated registration procedure to inform its home agent of its care-of address.

Tunneling. Tunneling is used to forward IP datagrams from a home address to a care-of address.

The registration protocol is an application-layer protocol that uses the *user datagram protocol (UDP)* as transport protocol to exchange registration request-reply messages at the well-known port number 434. For agent discovery, mobile IP modifies the existing *router advertisement* and *router solicitation* messages defined by the *Internet control message protocol (ICMP)*; Stevens, 1994) by adding the appropriate extensions to the ICMP header. ICMP is a connectionless protocol well suited for the agent discovery operation. Finally, tunneling is performed at the IP level.

Agent Discovery

Agent discovery is a process by which a mobile node detects its change of location and identifies whether it is currently connected to its home network or a foreign network. The mobile node determines whether it is connected to the home or foreign link from agent advertisements sent periodically by agents (home, foreign, or both) as multicasts or broadcasts to the link. In case a mobile node does not receive any agent advertisement, or it does not have the patience to wait for the next agent advertisement, the mobile node can send an agent solicitation to request an agent advertisement from the agent to which it is attached. When a mobile node detects that it has moved by comparing the network prefix portions of the router IP address with its home IP address, it acquires a care-of address by reading it directly from the agent advertisement or by contacting a DHCP server.

The *agent advertisement extension* (Perkins, 2002) follows the ICMP router advertisement message fields and consists of the following fields as shown in Figure 2.

Type: 16 indicates that this is an agent advertisement extension.

Length: $(6 + 4N)$, where N is the number of care-of addresses advertised.

Sequence number: The count of agent advertisement messages sent since the agent was initialized.

Lifetime: The longest lifetime, in seconds, that this agent is willing to accept in any registration request from a mobile node.

The flags (R, B, H, F, M, G, r, and T) inform mobile nodes of special features of the advertisement:

R: Registration required. Registration with this foreign agent (or another foreign agent on this link) is required even when using a collocated care-of address.

B: Busy. The foreign agent will not accept registrations from additional mobile nodes.

H: This agent offers services as a home agent on this network.

F: This agent offers services as a foreign agent on this network.

M: This agent can receive tunneled IP datagrams that use minimal encapsulation (Perkins, 1996b).

G: This agent can receive tunneled IP datagrams that use *generic routing encapsulation (GRE)* (Perkins, 1996a).

r: Sent as zero; ignored on reception.

T: Foreign agent supports reverse tunneling (Montenegro, 2001).

Care-of address: The care-of address or addresses supported by this agent on this network. There must be at least one such address if the F bit is set. There may be multiple care-of addresses.

Registration

When a mobile node recognizes that it is on a foreign network and has acquired a care-of address, it needs to alert a home agent on its home network and request that the home agent forward its IP traffic. The registration process involves four steps as shown in Figure 3.

If the mobile node is using a collocated care-of address, then it registers directly with its home agent, rather than going through a foreign agent. The registration process uses two types of messages, carried in UDP segments.

The *registration request message* format is shown in Figure 4.

An explanation of the fields follows:

Type: 1 indicates that this is a registration request.

Lifetime: The number of seconds remaining before the registration is considered expired. A value of zero is a request for deregistration.

Figure 2: Agent advertisement extension format.

Figure 5: Registration reply format.

Lifetime: If the Code field indicates that the registration was accepted, the Lifetime field is set to the number of seconds remaining before the registration is considered expired. A value of zero indicates that the mobile node has been deregistered.

Identification: A 64-bit number used for matching registration replies to registration requests.

Tunneling

Tunneling is defined as the encapsulation of a certain data packet (the original or *inner* packet) into another data packet (the encapsulating or *outer* packet) so that the inner packet is opaque to the network via which the packet is routed (Leon-Garcia & Widjaja, 2004; Yuan & Strayer, 2001). The tunnel between two nodes across the network (e.g., global Internet), as shown in Figure 6,

appears as a *single* link. The need for tunneling arises when it is not appropriate for the inner IP packet (in our case with the destination address as the original home IP address of the mobile node) to be handled directly by intermediate routers while traveling across the network. Mobile IP solves the problem by providing a *tunnel* between the home and the foreign agents. Two components uniquely determine a network tunnel: the end points of the tunnel and the encapsulation protocol used to transport the original data packet within the tunnel. In most cases, a tunnel has two end points: one where the tunnel starts (encapsulation) and one where the tunnel ends (decapsulation).

Two options for encapsulation are supported in mobile IP:

IP-in-IP encapsulation (Perkins, 1996a). This is implemented, as shown in Figure 7, by encapsulating each IP

Figure 6: (a) Tunneling from Home Agent to Foreign Agent; (b) Virtual link between them.

Figure 7: IP-in-IP encapsulation.

packet at the home agent with an outer IP header containing the home agent’s address as the source IP address and the care-of address as the destination IP address. When the foreign agent receives the packet, it decapsulates the original IP packet with the correspondent node’s address as the source IP address and the mobile node’s home address as the destination IP address. The foreign agent now examines the header of the original inner IP packet and determines that the mobile node is connected to the same IP subnet. It can thus deliver the packet directly to the mobile node.

The original IP header is unchanged, as shown in Figure 8, except to decrement *time to live* (TTL) by 1. The outer header is a full IP header. The presence of the encapsulated IP packet is indicated by using protocol number 4 in the outer IP header. In the original IP header, the source address refers to the correspondent node that is sending the original datagram, and the destination address is the home address of the mobile node. In the outer IP header, the source and destination addresses refer to the entry and exit points of the tunnel. Thus, the source address

typically is the IP address of the home agent, and the destination address is the care-of address for the intended destination.

Minimal encapsulation (Perkins, 1996b). This approach can be used if the mobile node, home agent, and foreign agent all agree to do so. With minimal encapsulation, the new header is inserted between the original IP header and the original IP payload as shown in Figure 9a. The presence of the minimal encapsulation is indicated by using protocol number 55 in the original IP header. The source and destination IP address fields are replaced by IP addresses of the tunnel end points. The home agent prepares the encapsulated datagram in the format of Figure 9a. This datagram is now suitable for tunneling and is delivered across the Internet to the care-of address. Figure 9b shows the fields of the minimal encapsulation header. At the care-of address, the fields in the minimal encapsulation header are restored to the original IP header and the former is removed from the datagram. The original IP datagram is now delivered to the mobile node using link-layer mechanisms.

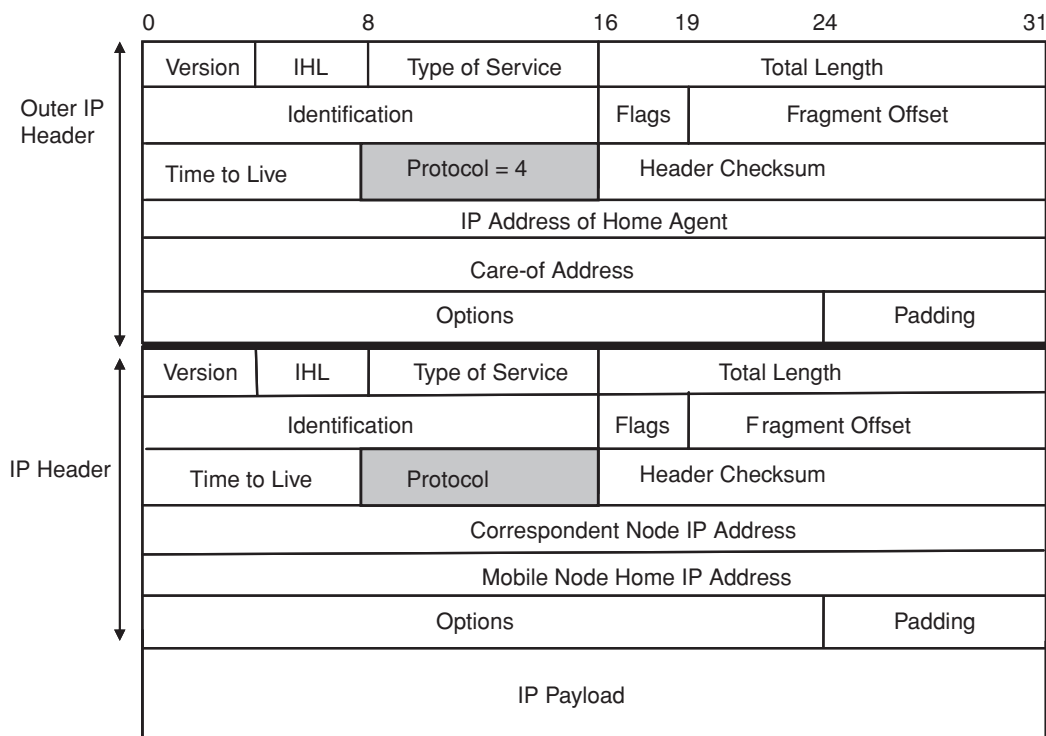

Figure 8: IPv4-in-IPv4 Encapsulation: Contents of outer IP header and IP header.

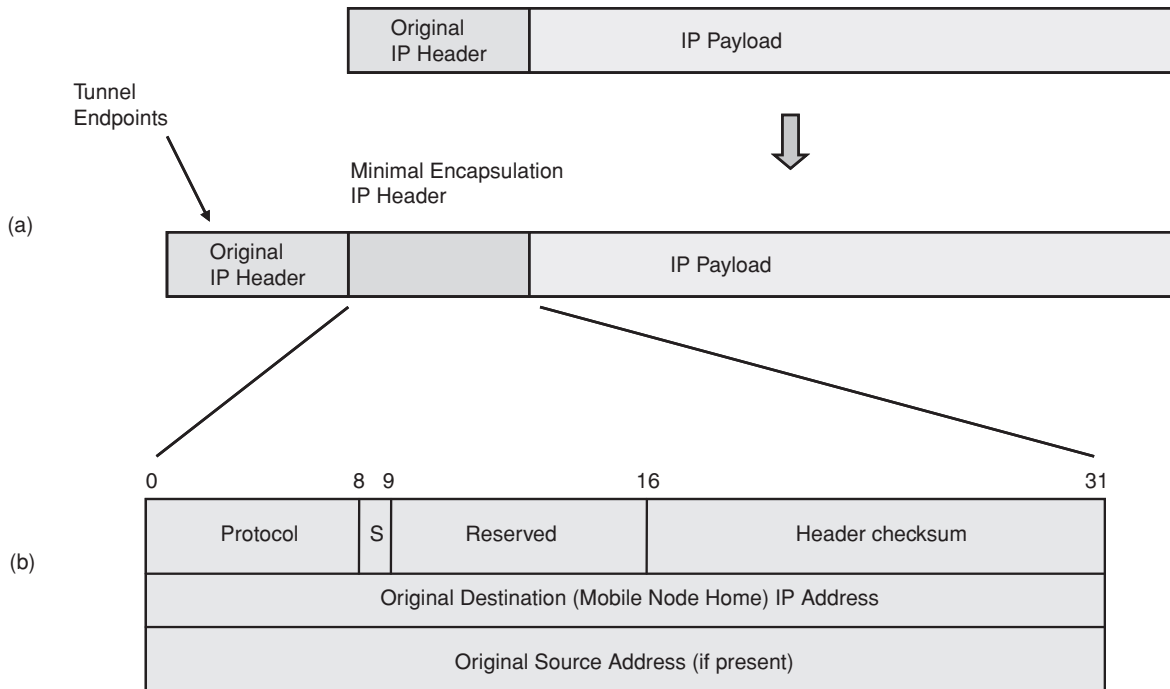

Figure 9: Minimal encapsulation.

ADVANTAGES OF Ipv6 FOR MOBILE IP

The design of mobile IP support in Ipv6 (mobile Ipv6) benefits both from the experiences gained from the development of mobile Ipv4 and from the opportunities provided by Ipv6. Mobile Ipv6 thus shares many features with mobile Ipv4 but is integrated into Ipv6 and offers many other improvements. The important features of base Ipv6 protocol (Huitema, 1998) that facilitate mobility to be built into the protocol include the following:

Enough addresses. Ipv6 allows for about 2^{128} (340 undecillion) addresses needed for billions of IP-addressable wireless devices that are forecasted for the next two decades.

Address autoconfiguration for getting care-of addresses. In Ipv6, unlike Ipv4, multiple IP addresses are allocated to each network interface of a node. An Ipv6 node can automatically obtain a valid global Ipv6 address by either using either *stateless* or *stateful* autoconfiguration (explained later).

Advanced network management support. *Internet control message protocol for Ipv6 (ICMPv6)* is an integral part of Ipv6 and supports advanced network management functions. ICMPv6 (Conta & Deering, 1998b) not only comprises three Ipv4 support protocols (ICMP, ARP, and *Internet group management protocol [IGMP]*), but also provides support for address autoconfiguration and mobility in Ipv6. ICMPv6 messages used for *neighbor discovery (ND)*, which implements address autoconfiguration and address resolution functions, include router solicitation, router advertisement, *neighbor solicitation*, and *neighbor advertisement*.

Embedded security. *Internet security protocol suite (IPSec)* (Kent & Atkinson, 1998c; Stallings, 2002; Yuan & Strayer, 2001) is a specification of mechanisms at the

network (IP) layer that provide a set of security services. These services are enabled through the use of two security protocols—the *authentication header (AH)* (Kent & Atkinson, 1998a) and the *encapsulating security payload (ESP)* (Kent & Atkinson, 1998b) protocols—and through the use of cryptographic key management procedures and protocols, including Internet security association and key management protocol (ISAKMP; Maughan, Schertler, & Turner, 1998) and the Internet key exchange (IKE) protocol (Harkins & Carrel, 1998). Although the use of IPsec is optional in Ipv4, IPsec is mandatory in Ipv6 and is part of the Ipv6 protocol suite.

Address Autoconfiguration in Ipv6

Stateless address autoconfiguration (Thomson & Narten, 1998) allows an Ipv6 node to obtain a valid global Ipv6 address on every link by discovering the subnet prefix of the link through router solicitations and combining it with its own *interface ID*. The steps involved include the following:

1. The node builds up a *link local address* by concatenating the well-known *link local prefix* (FE80::/64) with its own interface ID as shown in Figure 10a. The interface ID is unique to each network interface of the node and is a EUI-64 number, which can be derived from an 8-byte Ethernet media access control (MAC) address. Link local addresses can only be used on the local link and are not routable.
2. The mobile node listens to router advertisements, which are transmitted periodically. Alternatively, the mobile node sends a router solicitation message on the network to request router advertisement using the link local address. The node can now construct the global

Figure 10: Stateless address autoconfiguration.

IPv6 address by changing link local prefix to subnet prefix received via a router advertisement as shown in Figure 10b.

In **stateful address autoconfiguration** mode, the mobile node can obtain a new IPv6 address by using the service of a protocol such as DHCPv6 (Droms et al., 2003). It is called stateful because a server manages which address is allocated to whom and maintains that state. This is the most widely used method in IPv4.

By using either stateless or stateful address autoconfiguration mode, a mobile node can obtain a new care-of address on every link that it attaches to in the Internet. Therefore, *there are no foreign agents in mobile IPv6*.

MOBILE IPv6 OVERVIEW

Mobile IPv6 optimizes the mobility support of the IPv6 protocol by providing the following extensions (Johnson, Perkins, & Arkko, 2004):

1. A new extension header, called the *mobility header*, is used by mobile nodes, correspondent nodes, and home agents in all datagrams related to the creation and management of bindings.
2. A new option in the IPv6 destination options extension header, the *home address destination option*, is used for route optimization.
3. A new type of IPv6 routing header (*type 2 routing header*) is used for route optimization.
4. New IPv6 ICMP messages are used to detect movement, to receive network prefixes, and in the dynamic home agent address discovery mechanism.

The basic operation of mobile IPv6 is similar to mobile IPv4 as shown in Figure 11. While a mobile node is attached to some foreign link away from home, it is addressable at one or more care-of addresses. The mobile node can acquire its care-of address through conventional IPv6 mechanisms, and as such there are no foreign agents in mobile IPv6. As long as the mobile node stays in this location, packets addressed to this care-of address will be routed to the mobile node. The mobile node may also accept packets from several care-of addresses, such as when it is moving but still reachable at the previous link.

While away from home, a mobile node registers its primary care-of address with a home agent in its home network. The mobile node performs this binding registration by sending a *binding update (BU)* message to the home agent (Perkins & Johnson, 1996; Johnson, Perkins, & Arkko, 2004). The home agent replies to the mobile node

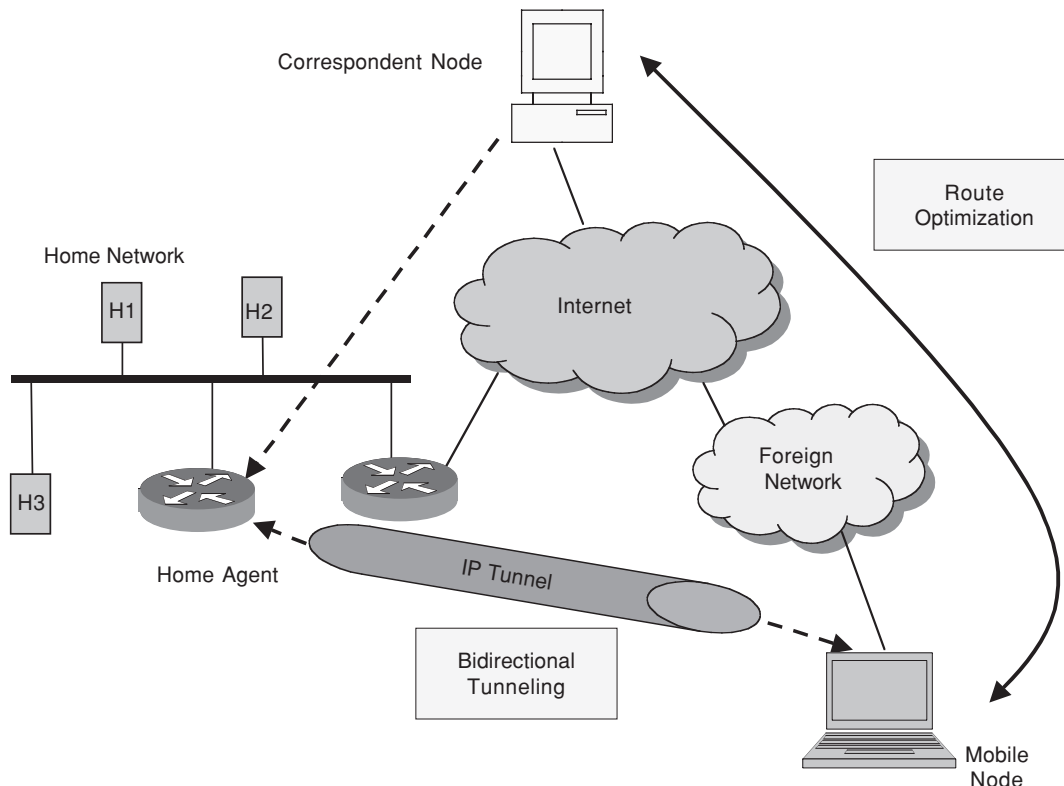

Figure 11: Mobile IPv6 operation.

Figure 12: Type 2 Routing header.

by returning a *binding acknowledgement (BA)* message. Mobile nodes can provide information about their current location to correspondent nodes. This happens through the correspondent registration. As a part of this procedure, a *return routability test* (Nikander et al., 2003; Johnson, Perkins, & Arkko, 2004) is performed to authorize the establishment of the binding.

There are two possible modes for communications between the mobile node and a correspondent node. The first mode, *bidirectional tunneling*, does not require mobile Ipv6 support from the correspondent node and is available even if the mobile node has not registered its current binding with the correspondent node. Packets from the correspondent node are routed to the home agent and then tunneled to the mobile node as in mobile Ipv4. In this mode, the home agent uses *proxy neighbor discovery* (Narten, Nordmark, & Simpson, 1998) to intercept any Ipv6 packets addressed to the mobile node's home address on the home link. Each intercepted packet is tunneled to the mobile node's primary care-of address. Packets from the mobile node to the correspondent node are tunneled to the home agent (*reverse tunneled*) and then routed normally from the home network to the correspondent node. This tunneling is performed using Ipv6 encapsulation (Conta & Deering, 1998a). The second mode, *route optimization*, requires the mobile node to register its current binding at the correspondent node.

Route Optimization

The basic idea underlying route optimization (Perkins & Johnson, 1996; Johnson, Perkins, & Arkko, 2004) involves providing the correspondent node an up-to-date BU for the mobile node to eliminate the inefficient triangle routing. Ipv6 allows other Ipv6 nodes to receive BUs from a mobile node so that they will know how to deliver datagrams directly to the mobile node. Packets from the correspondent node can thus be routed directly to the care-of address of the mobile node. When sending a packet to any Ipv6 destination, the correspondent node checks its cached bindings for an entry for the packet's destination address. If a cached binding for this destination address is

found, the correspondent node sets the destination IP address in the Ipv6 header to the care-of address of the mobile node. The type 2 routing header, as shown in Figure 12, is also added to the packet to carry the desired home address. Once the packet arrives at the care-of address, the mobile node retrieves its home address from the new routing header, and this is used as the final destination address for the packet (to allow transparency at higher layers for ongoing sessions).

Similarly, the mobile node sets the source address in the packet's Ipv6 header to its current care-of address. The mobile node adds its permanent Ipv6 home address in the home address option carried by the destination options extension header in Ipv6 as shown in Figure 13. The inclusion of home addresses in these packets makes the use of the care-of address transparent above the network layer (e.g., at the transport layer).

Routing packets directly to the mobile node's care-of address allows the shortest communications path to be used. It also eliminates congestion at the mobile node's home agent and home link. In addition, the effect of any possible failure of the home agent or networks on the path to or from it is reduced.

Mobile Ipv6 also provides support for multiple home agents and a limited support for the reconfiguration of the home network. In these cases, the mobile node may not know the IP address of its own home agent, and even the home subnet prefixes may change over time. A mechanism, known as *dynamic home agent address discovery* (Johnson, Perkins, & Arkko, 2004), allows a mobile node to dynamically discover the IP address of a home agent on its home link, even when the mobile node is away from home. Mobile nodes can also learn new information about home subnet prefixes through the *mobile prefix discovery* mechanism (Johnson, Perkins, & Arkko, 2004).

Binding Management Messages

Mobile nodes, correspondent nodes, and home agents use the new mobility header in all messages related to the creation and management of bindings. The format of the

Figure 13: Destination options extension header: Home address option.

Figure 14: Mobility header format.

mobility header is shown in Figure 14. An explanation of the fields follows:

Payload protocol: Identifies the type of header immediately following the mobility header. Uses the same values as the Ipv6 next header field (Huitema, 1998).

Header len: Represents the length of the mobility header in units of eight octets, excluding the first eight octets.

MH type: Identifies the particular mobile Ipv6 binding management message type.

Message data: A variable-length field containing the data relevant to the indicated binding management message type.

A description of different binding management messages follows:

Binding update (BU): Used by a mobile node to notify other nodes of a new care-of address for itself. The BU uses the MH type value 5 in the mobility header.

Binding acknowledgement (BA): Used to acknowledge receipt of a BU. The BA has the MH type value 6 in the mobility header.

Binding refresh request: Used by correspondent nodes to request a mobile node to update its mobility binding. This message is typically used when the cached binding is in active use but the binding's lifetime is close to expiration. The correspondent node may use, for instance, recent traffic and open transport layer connections as an indication of active use. The binding refresh request message uses the MH type value 0 in the mobility header.

Binding error: Used by the correspondent node to signal an error related to mobility, such as an inappropriate attempt to use the home address destination option without an existing binding. The binding error message uses the MH type value 7 in the mobility header.

SECURITY THREATS IN MOBILE IP

Any mobility solution must protect itself against misuses of the mobility features and mechanisms. Unauthenticated or malicious BUs (registration messages) in mobile Ipv6 (mobile Ipv4) open the door for many types of attacks, a few of which are discussed here (Nikander et al., 2003; Johnson, Perkins, & Arkko, 2004).

Theft of Address

The most obvious danger in mobile Ipv6 is theft of address, that is, an attacker illegitimately claiming to be a given node at a given address and then trying to “steal”

traffic destined to that address. Some basic forms of this attack include the following:

Hijacking. By means of false BUs, an attacker can redirect traffic to itself or another node and prevent the original node from receiving traffic destined to it. For instance, let us say node A and node B in Figure 15 have been communicating with each other. Then, an attacker, node C, sends a spoofed BU packet to node A, claiming to be node B with a care-of address of node C. This would cause node A to create a binding for node B's care-of address and subsequently send further traffic to node C, believing it to be node B's new care-of address. Node B would not receive the data it was intended to receive, and, if the data in the packets is not protected cryptographically, node C will be able to see all of the sensitive information from node A to node B.

Man-in-the-middle attack. The attacker sends spoofed BUs to both nodes A and B and inserts itself in the middle as shown in Figure 16. Consequently, the attacker would be able to see and modify the packets sent between node A and node B.

Replay Attacks

An attacker might also attempt to disrupt a mobile node's communications by *replaying* a BU that the node had sent earlier. If the old BU was accepted, packets destined for the mobile node would be sent to its old location and not its current location.

Denial of Service Attacks

As the name suggests, a denial of service attack renders a network, host, or other piece of network infrastructure unusable by legitimate users. Typically, a denial of service

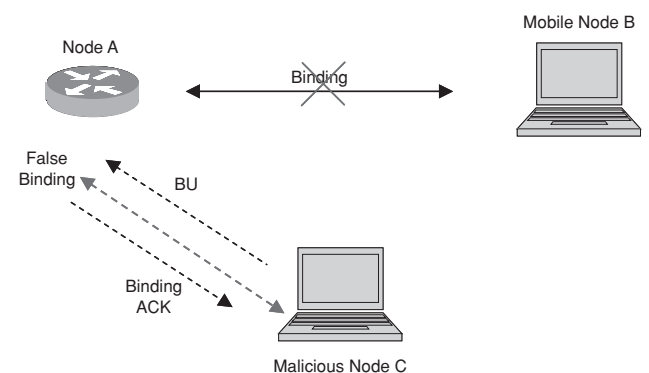

Figure 15: Theft of address: Hijacking.

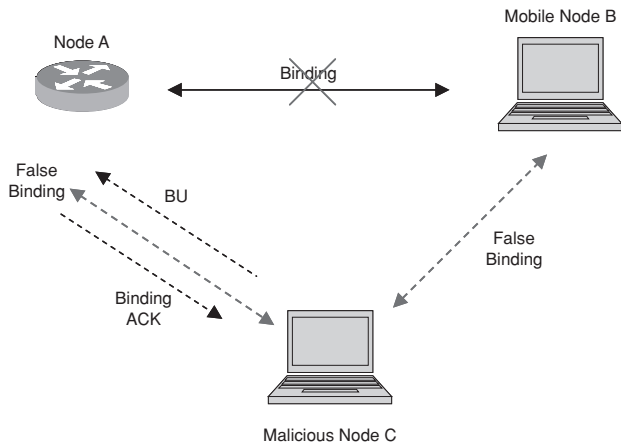

Figure 16: Theft of Address: Man-in-the-middle attack.

attack works by creating so much unnecessary work for the network node or server that legitimate work can not be performed. In mobile IP, a denial of service attack occurs when a malicious (mobile) node sends BUs in which the care-of address is set to the address of a victim node. If such BUs were accepted, the malicious node could lure the correspondent node (e.g., a server) into sending potentially large amounts of data to the victim; the correspondent node's replies to messages sent by the malicious mobile node will be sent to the victim host or network. For example, the correspondent node might be a video stream server that will send a high-bandwidth stream of video to anyone who asks for it. Note that the use of flow-control protocols such as *transmission control protocol (TCP)* does not necessarily defend against this type of attack, because the attacker can fake the acknowledgments. Even keeping *TCP initial sequence numbers (ISN)* secret does not help, because the attacker can receive the first few segments (including the ISN) at its own address and then redirect the stream to the victim's address. These types of attacks may also be directed to networks instead of nodes (e.g., TCP SYN flooding attack).

MOBILE Ipv4 SECURITY MECHANISMS

In mobile Ipv4, most of the potential threats are concerned with false registrations sent to home agents.

Mobile Ipv4 prevents malicious nodes from being able to do bogus registrations by requiring strong authentication on all registration messages that are exchanged during the registration process. For purposes of authentication, each registration request and reply message contains an *authentication extension* (Perkins, 1997; 1998; 2002) as shown in Figure 17 with the following fields:

Type: Used to designate the type of this authentication extension.

Length: 4 plus the number of bytes in the authenticator field.

Security parameter index (SPI): Unique ID for security association.

Authenticator (authentication data): Contains 128-bit message digest of the registration message computed by using the keyed HMAC-MD5 (Krawczyk, Bellare, & Canetti, 1997; Stallings, 2002) authentication algorithm. The authenticator protects the entire registration request or reply message (UDP payload), any extensions prior to this extension, and the type, length, and SPI fields of this extension.

Three types of authentication extensions are defined:

Mobile-home: This extension must be present and provides for authentication of the registration messages between the mobile node and the home agent.

Mobile-foreign: The extension may be present when a security association exists between the mobile node and the foreign agent. The agent will strip this extension off before relaying a request message to the home agent and add this extension to a reply message coming from a home agent.

Foreign-home: The extension may be present when a security association exists between the foreign agent and the home agent.

The SPI within any of the authentication extensions defines the security context, which is used to compute the authenticator value and which must be used by the receiver to check that value. In particular, the SPI selects the authentication algorithm and mode and a secret (a shared key or appropriate public-private key pair) used in computing the authenticator.

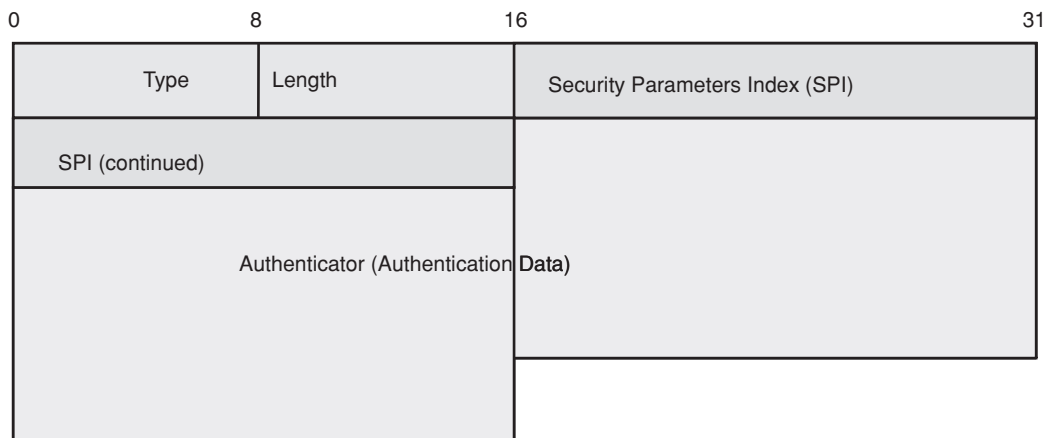

Figure 17: Authentication extension.

Note that the authenticator protects the identification field in the request and reply messages. As a result, the identification value can be used to thwart replay types of attacks. The identification value enables the mobile node to match a reply to a request. Furthermore, if the mobile node and the home agent maintain synchronization so that the home agent can distinguish a reasonable identification value from a suspicious one, then the home agent can reject suspicious messages. One way to do this is to use a time stamp value. As long as the mobile node and home agent have reasonably synchronized values of time, the time stamp will serve the purpose. Alternatively, the mobile node could generate values using a pseudorandom number generator. If the home agent knows the algorithm, then it knows what identification value to expect next.

MOBILE IPv6 SECURITY MECHANISMS

Mobile IPv6 introduces several additional security vulnerabilities into IPv6. In mobile IPv6, most of the potential threats are concerned with false bindings sent to home agents and correspondent nodes. As discussed earlier, mobile IPv6's route optimization is built into the IPv6 protocol rather than added as an extension to the protocol as with mobile IPv4 and it greatly improves the efficiency of routing by eliminating triangle routing. However, route optimization also greatly increases the number of BUs sent by a mobile node to its correspondent nodes, and in doing so, it also greatly increases the security risk of mobile IPv6. Mobile IPv6 provides a number of security features that provide protection against many of the threats posed to mobile IPv6 as a result of its new features.

Protection of Binding Updates to the Home Agent

The mobile node and the home agent use an IPsec *security association* (SA; Kent & Atkinson, 1998; Stallings,

2002; Yuan & Strayer, 2001) to protect the integrity and authenticity of the BUs and BAs. An SA creates a network-layer logical simplex connection to enable transfer of secure datagrams from source to destination hosts. That is, two SAs are needed to protect bidirectional traffic between two nodes, one for each direction. It is uniquely defined by the following three parameters:

Security parameter index (SPI): A 32-bit connection identifier, usually chosen by the destination end point of the SA, uniquely identifies the logical connection (SA).

Destination IP address: This is the address of the destination end point of the SA.

Security protocol identifier: This indicates whether the association is an AH (51) or ESP (50) security association.

SAs between the mobile nodes and the home agents use the ESP protocol in transport mode and use a non-null payload authentication algorithm (Arkko, Devarapalli, & Dupont, 2004) to provide data origin authentication, connectionless integrity, and optional antireplay protection. The formats of BU and BA messages between the mobile node and the home agent are shown in Figure 18.

To prevent the mobile node from sending a BU for another mobile node, the home agent checks that the given home address has been used with the right SA. Such a check is provided in the IPsec processing by having the security policy database entries unequivocally identify a single SA for protecting BUs between any given home address and home agent. To make this possible, it is necessary that the home address of the mobile node is visible in the BUs and BAs. The home address used in these packets is contained in either the source IP address field of the packet or in the home address destination option (in the destination options extension header) or the type 2 routing header.

Figure 18: Security mechanisms for exchange of mobility messages between mobile nodes and home agents.

Figure 19: Return Routability Procedure (RRP): Message flow.

IPsec can provide antireplay protection only if dynamic keying is used (which may not always be the case).

Protection of Binding Updates to Correspondent Nodes

The protection of BUs sent to correspondent nodes does not require the configuration of security associations or the existence of an authentication infrastructure between the mobile nodes and correspondent nodes. Instead, a method called the *return routability procedure (RRP)* (Nikander et al., 2003; Johnson, Perkins, & Arkko, 2004) is used to assure that the right mobile node is sending the message.

The RRP enables the correspondent node to obtain some reasonable assurance that the mobile node is in fact addressable at its claimed care-of address as well as at its home address. Only with this assurance is the correspondent node able to accept BUs from the mobile node, which

would then instruct the correspondent node to direct that mobile node’s data traffic to its claimed care-of address. This is done by testing whether packets addressed to the two claimed addresses are routed to the mobile node. The mobile node can pass the test only if it is able to supply proof that it received certain data (the *keygen tokens*) that the correspondent node sends to those addresses. These data are combined by the mobile node into a binding management key, denoted K_{bm}. Figure 19 shows the message flow for the RRP.

The RRP consists of two tests, a *home (address) test* and a *care-of (address) test*. These tests are triggered by sending *home test init* and *care-of test init* packets. The RRP uses cookies and keygen tokens as opaque values within the test init and test messages, respectively.

The home and care-of test init messages, shown in Figure 20, are sent at the same time by the mobile node to the correspondent node, and they verify that the mobile node is reachable at its home and care-of addresses and request

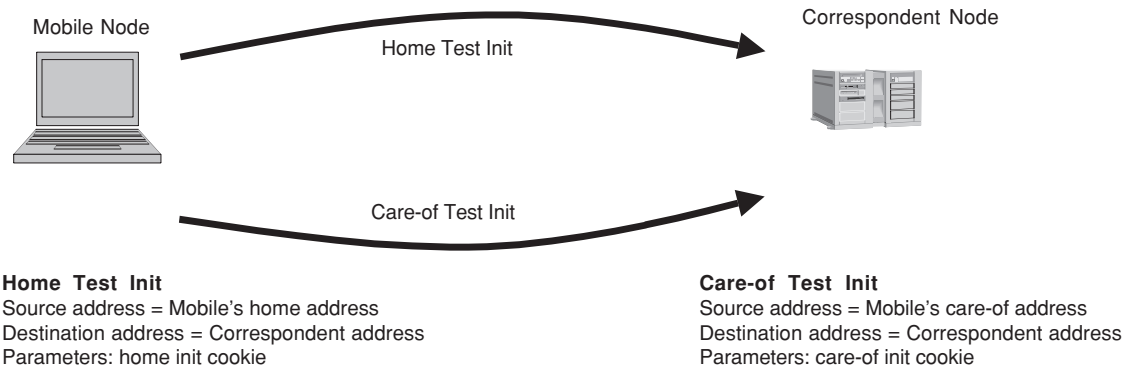

Figure 20: RRP: Test init messages from the mobile to correspondent node.

Figure 21: RRP: Test messages from the correspondent to mobile node.

keygen tokens to be sent from the correspondent node. The home test init message is reverse tunneled through the home agent. Each message also contains an *init cookie*, a 64-bit random value, which must be returned by the correspondent in the next step to verify the identity of the correspondent node. The mobile node remembers these cookie values to obtain some assurance that its protocol messages are being processed by the desired correspondent node.

The correspondent node, upon receiving the home test init message from the mobile node, generates a *home keygen token* from a hash function using the first 64 bits of the message authentication code (MAC) (Johnson, Perkins, & Arkko, 2004):

$$\text{home keygen token} = \text{First}(64, \text{HMAC_SHA1}(\text{Kcn}, (\text{home address} \mid \text{nonce} \mid 0)))$$

where \mid denotes concatenation and $\text{HMAC_SHA1}(\text{Kcn}, m)$ denotes a MAC computed on message m with key Kcn using HMAC_SHA1 (Krawczyk, Bellare, & Canetti, 1997; Stallings, 2002) function. The final “0” inside the HMAC_SHA1 function is a single zero octet, used to distinguish home and care-of cookies from each other. Each correspondent node generates nonces at regular intervals. The home keygen token tests that the mobile node can receive messages sent to its home address.

Next the correspondent node, upon receiving the care-of test init message from the mobile node, generates a *care-of keygen token* from a hash function using the first 64 bits of the message authentication code (MAC) (Johnson, Perkins, & Arkko, 2004):

$$\text{care-of keygen token} = \text{First}(64, \text{HMAC_SHA1}(\text{Kcn}, (\text{care-of address} \mid \text{nonce} \mid 1)))$$

Here, the final “1” inside the HMAC_SHA1 function is a single octet containing the hex value 01 and is used to distinguish home and care-of cookies from each other. The care-of keygen token tests that the mobile node can receive messages sent to its care-of address.

Next, the home and care-of test messages containing keygen tokens are sent simultaneously, as shown in

Figure 21, from the correspondent node to the mobile node, in response to the mobile node's test init messages. Included in both messages are the init cookies, which verify for the mobile node that the test messages are being received from the correspondent node, or at least by a node in the path to the correspondent node. The home test message is sent to the mobile node via the home network, where it is presumed that the home agent will send the message to the mobile node inside the IPsec tunnel. This means that the mobile node needs to already have sent a BU to the home agent, so that the home agent will have received and authorized the new care-of address for the mobile node before the RRP.

When the mobile node has received both the home and care-of test messages, the RRP is complete. The mobile node now hashes the keygen tokens together to form a 20-octet binding management key Kbm (Johnson, Perkins, & Arkko, 2004):

$$\text{Kbm} = \text{SHA1}(\text{home keygen token} \mid \text{care-of keygen token})$$

The integrity and authenticity of the BU's messages to correspondent nodes is protected by using the Kbm to key the hash algorithm for this purpose. As a result of the procedure, the mobile node now has the security mechanism in place to send a verifiable BU to the correspondent node as shown in Figure 22.

When sending the BU, the mobile node includes its home address, the nonce indexes, sequence number, and the MAC. This new value of the MAC is calculated by hashing the Kbm with a concatenation of the care-of address, the correspondent node address, and the entire BU message itself. Once the correspondent node has verified the MAC, it can create a binding cache entry for the mobile. A BA is optionally sent by the correspondent node if the mobile node requests it. The BA contains the same sequence number as in the BU and also contains a MAC, which is calculated similar to the BU, by hashing the Kbm with a concatenation of the care-of address, correspondent node address, and the entire BA message itself.

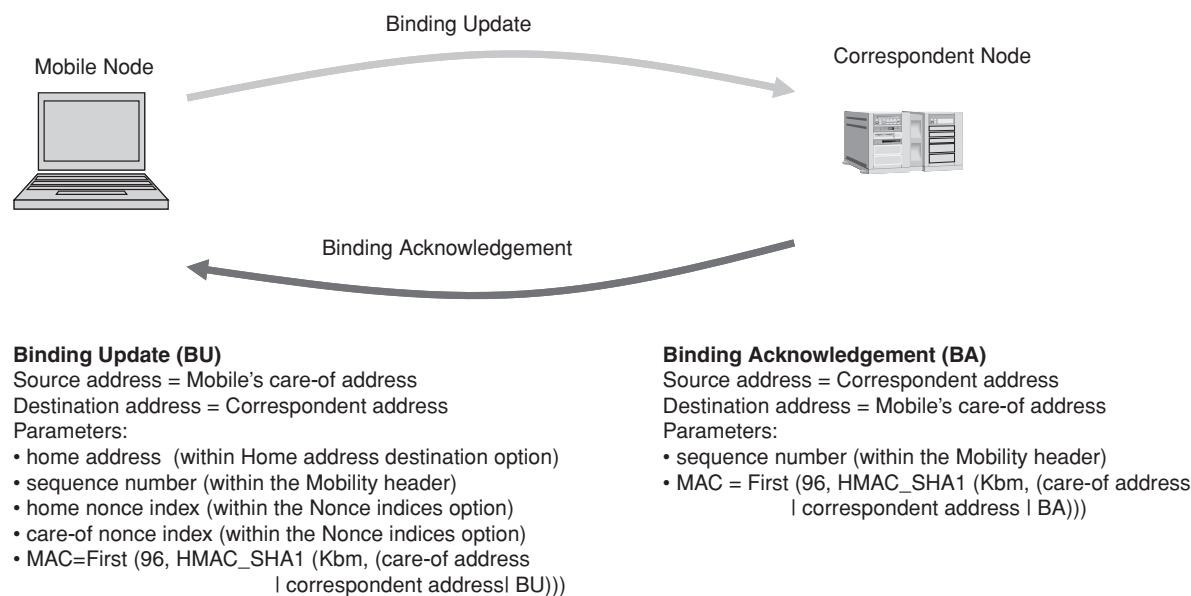

Figure 22: Binding update and acknowledgement messages.

CONCLUSION

Mobile Ipv4 provides protocol enhancements required for mobility support in networks based on current Ipv4. Much of the interest in mobile IP has shifted to Ipv6 in recent years, driven by the proposals to make the new IP protocol a mandatory part of the next generation of wireless networks. Mobile Ipv6 uses the same basic network entities as mobile Ipv4, except that there is no need for the foreign agent. Route optimization, which greatly improves the routing efficiency in mobile Ipv6, also enhances its security vulnerabilities by increasing the likelihood of false binding updates. The security design of mobile Ipv6 deals with this threat and provides the necessary mechanisms to make mobile Ipv6 as secure as Ipv4.

GLOSSARY

Agent Solicitation The message sent by a mobile node to request agent advertisement.

Binding The association of the home address of a mobile node with a care-of address for that mobile node, along with the remaining lifetime of that association.

Binding Management Key (Kbm) A key used for authorizing a binding cache management message (e.g., BU or BA). The return routability procedure provides a way to create a binding management key.

Care-Of Address The address associated with a mobile node while visiting a foreign link; the subnet prefix of this IP address is a foreign subnet prefix.

Collocated Care-Of Address An externally obtained local IP address temporarily assigned to an interface of the mobile node.

Cookie A random number used by a mobile node to prevent spoofing by a bogus correspondent node in the return routability procedure.

Correspondent Node A peer host with which a mobile node communicates. The correspondent node may be either mobile or stationary.

Foreign Agent A router with an interface on a mobile node's visiting network, which assists the mobile node in informing its home agent of its current care-of address.

Foreign Network A network other than a mobile node's home network to which the mobile node is currently connected.

Gratuitous ARP An ARP packet sent by a node to spontaneously cause other nodes to update an entry in their ARP cache.

Home Address An IP address that is assigned for an extended period of time to a mobile node. It remains unchanged regardless of where the node resides in the Internet. Standard IP routing mechanisms will deliver packets destined for a mobile node's home address to its home link.

Home Agent A router with an interface on the mobile node's home network link, which the mobile node keeps informing of its current location, the care-of address, as the mobile node moves from link to link. While the mobile node is away from home, the home agent intercepts packets on the home link destined to the mobile node's home address, encapsulates them, and tunnels them to the mobile node's registered care-of address.

Home Network A network having a network prefix matching that of a mobile node's home address.

IPSec Security Association A cooperative relationship formed by the sharing of cryptographic keying material and associated context. Security associations are simplex.

Keygen Token A number supplied by a correspondent node in the return routability procedure to enable the mobile node to compute the necessary binding management key for authorizing a BU.

Link A facility or medium via which nodes can communicate at the link layer.

Link-Layer Address An address that identifies the physical end point of a link. Usually, the link-layer

address is the interface's medium access control (MAC) address.

Mobile Node A host or a router that can change its point of attachment from one link to another, while still being reachable via its home address.

Mobile Node's Foreign Link The link that the mobile node is visiting, which has been assigned the same subnet prefix as the subnet prefix of the mobile node's care-of address.

Mobile Node's Home Link The link that has been assigned the same subnet prefix as the subnet prefix of the mobile node's home address.

Nonce A random number used internally by the correspondent node in the creation of keygen tokens related to the return routability procedure. The nonces are not specific to a mobile node and are kept secret within the correspondent node. They are updated at regular intervals.

Nonce Index An index associated with each nonce to help the correspondent node identify which nonce, the current one or one of a previous few, was used with a particular message.

Subnet Prefix Specifies routing information to an IP subnet (link). In Ipv6, it is followed by an *interface identifier*, which specifies a node (host) attached to the link.

Tunnel The path followed by a datagram while it is encapsulated.

INTRODUCTION

IP multicast is an internetwork service that provides efficient delivery of data from one or more sources to a set of recipients, commonly known as a group (Deering, 1989). Examples of services that could take great advantage of multicast communication are live video/audio distribution (for example, videoconferencing and collaborative groupware), periodic data distribution (for example, software updates, newspaper/magazine distribution, and sport or stock quotes), Web server updates, pay-per-view services (for example, video on demand), and distributed videogames.

The goal of multicast is to reduce sender transmission overhead, network bandwidth usage, and the latency observed by receivers. If only one IP multicast datagram, or packet as we interchangeably call it, containing, for example, video information, can be sent to multiple teleconference sites instead of one packet per site, network bandwidth is saved and time synchronization is closer to optimal. For this to be possible, special addresses and routing schemes must be devised. Group management protocols that define how a host may join or leave a multicast group are also necessary.

The first experiments with multicast were performed in the early 1990s on the MBone research network (Almeroth & Ammar, 1997), a virtual network obtained by encapsulating multicast traffic in traditional unicast datagrams. General-purpose UNIX machines executing user-space ad hoc daemons were in charge of routing. Moving from MBone through a variety of protocols proposed by the networking community, multicast communication is now available by default in the TCP/IP stack. Research and standardization efforts are still ongoing, however, because some areas have not reached a final development stage or still can be improved (see, e.g., IETF, n.d.a; n.d.b; n.d.c; n.d.d). Group-based services may require secure communication, that is, that data traffic be protected from disclosure to unauthorized receivers or from unauthorized modifications and that group members be authenticated. Further restrictions on the receiver and/or sender group may be in place, for example, keeping their identity private

while guaranteeing their membership. In general, it is implicitly assumed that the multicast primitive satisfies some basic security requirements, such as the confidentiality and the integrity of the information transmitted and the authenticity of the group members. Yet, IP multicast was not designed with integrated security services: data is sent in the clear and groups are open, and thus are vulnerable to a variety of threats (Ballardie & Crowcroft, 1995; Pinkas & Canetti, 1999; Canetti et al., 1999). This has sparked a wealth of research to propose efficient protocols to add security features to multicast primitives. An Internet Research Task Force (IRTF) on group security at large, GSEC, originally part of the initial secure multicast research group (SMug), was formed “to discuss issues related to multicast security.” GSEC is actively working on various areas such as group policy management, group key management, and security technologies for open and closed groups (IETF, n.d.d). In parallel, a working group of the IETF on multicast security (MSEC) is active with the goal of “standardizing protocols for securing group communication over internets, and in particular over the global Internet” (IETF, n.d.d).

A secure multicast protocol must ensure that only authorized group members access, and possibly distribute, the information circulating in the group and that members join and leave the group in a controlled fashion. Cryptographic systems for traffic encryption and party authentication can be designed to satisfy such requirements. This requires, in turn, protocols for managing cryptographic key distribution and updates. Therefore, key management is the critical issue characterizing the problem of secure IP multicast and has been the subject of extensive research efforts in the past 15 years (see, for example, (Banerjee & Bhattacharjee, 2002; Balenson, McGrew, & Sherman, 2000; Ballardie, 1996; Ballardie & Crowcroft, 1995; Briscoe, 1999; Burmester & Desmedt, 1996; Canetti et al., 2000; Canetti et al., 1999; Caronni, Lubich, Aziz, Markson, & Skrenta, 1996; Chang, Engel, Kandlur, Pendarakis, & Saha, 1999; Chiou & Chen, 1989; Chu, Qiao, & Nahrstedt, 2002; Fiat & Naor, 1993; Hardjono & Cain, 2000; Harney & Harder, 1999; Harney & Muckenhirn, 1997a; Harney & Muckenhirn, 1997b; Huang & Mishra,

2003; Judge & Ammar, 2002; Matsumoto & Imai, 1988; Maugham, Schertler, Schneider, & Turner, 1998; Mitra, 1997; Molva & Pannerat, 2000; Moyer, Rao, & Rohatgi, 1999; Perrig, Song, & Tygar, 2001; Pinkas & Canetti, 1999; Setia, Koussih, & Jajodia, 2000; Setia, Zhu, & Jajodia, 2002; Steiner, Tsudik, & Waidner, 2000; Waldvogel, Caronni, Sun, Weiler, & Plattner, 1999; Wallner, Harder, & Agee, 1999; Wong, Gouda, & Lam, 1998; Yang, Li, Zhang, & Lam, 2001; Zhang, Lam, Lee, & Yang, 2001; Zhu, Setia, & Jajodia, 2003). Because groups are likely to become larger and highly dynamic as multicast usage becomes widespread, membership changes will occur frequently. Therefore, the design of efficient and scalable key management protocols is crucial for the deployment of secure multicast services in real scenarios.

In this chapter, we review the basic concepts of IP multicast for Ipv4 with particular attention to addressing, routing, group management, and reliability. We discuss the security issues of such a communication service and present the main features of the most relevant key management schemes proposed in the literature to secure IP multicast communication.

This chapter is organized as follows: the second section reviews IP multicast, the third section illustrates the security issues in IP multicast and the requirements of a secure multicast protocol, the fourth section describes a selection of key management protocols, and the fifth section summarizes our contributions and concludes the paper.

IP MULTICAST

In this section, we illustrate the basic concepts of IP multicast within the Ipv4 context. IP multicasting is the ability to send IP datagrams to multiple nodes in a logical group, in such a way as to minimize the number of packets. An addressing scheme to efficiently identify the nodes in the group, a protocol to distribute the datagrams and thereby minimize their replication, and a protocol to manage nodes joining and leaving are the components of IP multicasting.

In the original service model (Deering, 1989), groups are open and public. Any node can send traffic to any multicast group, even if it is not a member of the destination group. Any node can be a receiver, that is, a group member. Routers ignore members' and sources' identities. As we discuss, such a general service model makes the design of efficient protocols for routing traffic, managing groups, and assigning addresses quite challenging.

In what follows, we review the addressing scheme and multicast routing protocols. We then describe how group management is performed and discuss the issues of reliable multicast communication.

Addressing

A multicast group is identified by a particular address, which allows a source to send a message simultaneously to all the hosts in the group without listing their individual IP addresses. Special addresses are necessary to distinguish groups from unicast addresses so that routers can handle multicast packets more efficiently. For this purpose, in Ipv4 the Internet Assigned Number Authority

Table 1 Current Statically Reserved Multicast Addresses

Address Range	Usage
224.0.0.0–224.0.0.225	Local network control
224.0.1.0–224.0.1.255	Internetwork control
224.1.0.0–224.1.255.255	ST multicast groups
232.0.0.0–232.255.255.255	Source-specific multicast
233.0.0.0–233.255.255.255	GLOP
239.0.0.0–239.255.255.255	Administrative scoping

(IANA) reserved class D address space, that is, addresses with the four high-order bits equal to 1110, covering the range 224.0.0.0–239.255.255.255 (Reynolds & Postel, 1994). The remaining 28 bits of the address identify the group, for a total of about 268 million groups.

Some of the addresses of the class range are reserved for particular uses and may be assigned statically, whereas the rest are assigned dynamically to different multicast groups on a per-session basis and reclaimed when the session is terminated. Examples of statically assigned addresses are the 224.0.0.0–224.255.255.255 range, used for routing protocols, and the 233.0.0.0–233.255.255.255 range, known as the GLOP range, which is reserved for organizations that already have a reserved autonomous systems number (Meyer & Lotheberg, 2001). Among the set of dynamically assigned addresses, the range 232.0.0.0–232.255.255.255 is reserved for source-specific multicast (SSM) (Bhattacharya, 2003), that is, one-to-many groups. This service model has been gaining popularity because it is simpler than the many-to-many or any-source multicast (ASM) of the original proposal and the majority of commercially viable applications are one-to-many, for example, video on demand, news casting, and Web updates. To support ASM, the network must discover all sources for a given group and deliver the traffic to the group members, which accounts for the greater complexity of this model. With SSM, it is the user that typically specifies the source. When the receiver contacts its router to join a group, it specifies both the group and the sender, thus lifting the burden of source discovery from the network and simplifying multicast delivery. Table 1 reports a summary of the current address assignment (Albanna, Almeroth, Meyer, & Schipper, 2001).

To limit address space consumption and to allow routers to confine packets within an administrative domain, the higher end of the address space is reserved for administratively scoped applications (Meyer, 1998). Because such applications are not Internet-wide, they have no need for uniquely assigned addresses and the routers do not have to propagate the packets outside the network boundaries. Scope limitation used to be achieved by using specific values in the time-to-live (TTL) field of the IP header. This is an inheritance of Mbone but is now deprecated because overloading the TTL with both packet lifetime and scope limitation semantic may result in ambiguity and cause difficulty when reconfiguring a distribution tree.

In IP multicast, no central authority exists that allocates addresses upon request. Because addresses are allocated in a distributed uncoordinated fashion, clashes are

possible. Another issue is the exhaustion of the limited address space, as multicast becomes more popular, which calls for address reuse when sessions terminate. The multicast address allocation architecture proposed by the Malloc working group of the IETF copes with these issues by defining a three-layer hierarchical approach to address allocation (IETF, n.d.b; Thaler, Handley, & Estrin, 2000). A host dynamically requests an address to a multicast address allocation server (MAAS) using MADCAP, multicast address dynamic client allocation protocol (Hanna, Patel, & Shah, 1999). The server provides an address that is unique within its allocation domain, but not necessarily globally unique. Because there is no central authority enforcing address uniqueness, such an approach provides for scalability and locality of group members and low probability of address duplication across the Internet. To minimize clashes, routers claim sets of addresses at interdomain level for the MAASs in their domain using the multicast address-set claim (MASC) protocol (Kumar et al., 1998; Radoslavov et al., 2000), although domains do not have to allocate an address set for hosts in the domain to be able to allocate group addresses. A module for managing multicast address allocation in a protocol-independent manner, as well as for managing specific protocols used in allocating multicast addresses, has also been defined (Thaler, 2003). The module provides the ability to configure and monitor the status of multicast address allocation within the local domain, answering questions regarding how full a given scope is and who filled it up, who allocated a given address, and whether requests are being met.

Routing

Routing multicast traffic requires ad hoc protocols in order to deliver packets in a more efficient way than simply broadcasting them to the entire network or individually sending them as unicast messages to each receiver. The source sends only a single datagram and the routers replicate the datagram along the branches of a distribution tree. When the final router is reached, it delivers the packet to its local network. Because groups are open and sources do not have to be part of the group, routers do not necessarily know where the sender is or who the receivers are. How the distribution tree is built and what information a router stores and/or computes distinguishes the various routing protocols. This determines the “density” or “sparseness” of the routing protocols, that is, whether they are more efficient with densely or sparsely populated groups, respectively. Finally, multicast routing protocols may be suitable for intradomain or interdomain routing.

The simplest approach consists in building the spanning tree rooted at the source that connects all the group member networks, by using the “broadcast and prune” strategy. A packet is initially broadcast to the entire network. Each router that receives a packet performs a reverse path-forwarding check to identify the interface on the most efficient path to the source. All packets received on the other interfaces will be discarded. Routers that have group members in their domain forward the packets on the subnet. Otherwise, they return a “prune” message

on the interface to the source. When a router receives prune messages on all interfaces but the one to the source, it sends a prune message back to the source. Otherwise, only the interfaces that have received a prune message are pruned. Protocols that adopt this paradigm are usually called “dense mode” protocols. The distance vector multicast routing protocol (DVMRP; Waitzman, Partridge, & Deering, 1988) and the protocol-independent multicast dense mode (PIM-DM; see Adams, Nicholas, & Siadak, 2003 for the latest specification) follow this approach. The former builds and maintains its own unicast routing table whereas the latter uses the existing one, independent of the protocol used to build it. With both protocols, a new tree rooted at the source must be built for each source in the group and state information is kept for each source at every router in the network, regardless of whether there are group members downstream.

An alternative to dense mode protocols, “sparse mode” protocols aim at optimizing multicast routing when members are widely distributed. They are also known as explicit join protocols, because group members send explicit join messages to a designated router acting as a rendezvous point (RP), or core. This allows for a better network bandwidth usage, because multicast traffic only flows through links that have been explicitly added to the tree. Sources and receivers in a group share a single tree rooted at the RP. Only routers along the distribution tree need to maintain state for each group, thus providing for better scalability with respect to dense mode protocols. Sources send packets to the RP, which forwards them to the registered members. As it is easy to understand, this is the critical aspect of sparse mode protocols. The RP can be a single point of failure and can easily become a performance bottleneck. Furthermore, it may force the use of less-than-optimal routes between the source and the receivers. The two popular sparse mode protocols, namely core based tree (CBT; Ballardie, 1997) and PIM sparse mode (PIM-SM; Estrin et al., 1998), address these issues differently. Robustness is achieved via the bootstrap router protocol that performs RP discovery and selects a backup RP if the primary one fails. CBT uses bidirectional trees to limit the hot spot effect on the RP, whereas PIM-SM allows the RP to switch forwarding from the shared tree to the shortest path tree to a given leaf router whenever traffic exceeds a given threshold.

A different type of protocol is MOSPF, multicast extensions to OSPF (Moy, 1994), which relies on the link-state routing paradigm of the OSPF unicast routing protocol to deliver multicast packets. Each MOSPF router floods its domain with information about the receivers in each group so that all routers can have the same view of group membership and build the correct tree. However, data is sent only to receivers that explicitly requested it, thus reducing the protocol overhead. Thus, while MOSPF is considered a dense protocol with respect to control information, it is a sparse one with respect to data.

The routing protocols presented so far are typically employed at intradomain level. Features such as the RP router of sparse mode protocols or the waste of resources to maintain state in routers not on the multicast distribution tree make them unsuitable for global deployment. Hierarchical interdomain routing has been proposed to

address such an issue. The multiprotocol extensions to BGP (MBGP; Bates, Rekhter, Chandra, & Katz, 2000) and the border gateway multicast protocol (BGMP; Kumar et al., 1998; IETF, n.d.a; Thaler, 2004) are examples of interdomain protocols. MBGP was the initial response to the need for interdomain routing. It extends BGP-4 with the ability to provide next-hop information between domains, to provide reachability and policy control for multicast routing, and to route various types of network traffic. BGMP was proposed as the long-term solution to wide-scale interdomain routing, in association with the multicast address-set claim (MASC) protocol for hierarchical address space allocation. It strongly relies on the existence of a domain-oriented address allocation scheme to avoid collisions. BGMP is independent of the intradomain multicast routing protocol. It builds a bidirectional, shared tree of domains using a domain as global root for the distribution tree. Unlike the intradomain case, choosing the root domain is a delicate operation in the interdomain case because of administrative issues regarding the ownership of the root domain and the effect on performance that the location of the root may have. BGMP selects the domain of the group initiator as the root domain, hoping that this domain will be the source of most of the traffic.

The complexity of the general nature of the ASM model, that is, any source sending traffic to any group of receivers without any previous notification, the inadequacy of the unicast financial charging scheme, the lack of access control, and its limited scalability are behind the proposal of the source-specific multicast model. As mentioned in a previous section, SSM captures the single-source nature of most commercially viable applications, such as file distribution and Internet TV. It simplifies routing significantly because sources are unique and well known, and allows for a new addressing scheme. With the EXPRESS multicast protocol (Holbrook & Cheriton, 1999) groups are replaced by “channels,” or <source, express destination address> pairs. This solves the problem of address collisions and address space scarcity. Nodes explicitly subscribe to channels, possibly also in an authenticated manner. This allows service providers to guarantee the channel owner exclusive use of the channel and subscribers to receive traffic only from a given channel. A single protocol supports both channel subscription and efficient collection of channel information such as subscriber count. Another proposal in this direction is represented by the simple multicast protocol (Perlman et al., 1999). SM builds on the bidimensional address space proposed by EXPRESS and the shared bidirectional trees of CBT. It identifies groups with <core, multicast address> pairs, which are sent by an end node to the router, thus eliminating the need for core router advertisements. Thanks to its simplicity and scalability, SM is suitable both for intra- and interdomain routing.

Group Management

In Deering (1989), multicast groups are public and open. Any node can be a source for any group, regardless of its being a member of the group. Any node can join any group. Group members do not know each other. Routers

filter the traffic for a given group and then forward it on their LAN. How nodes join, leave, and interact with their local multicast router was first defined in the Internet Group Management Protocol (IGMPv1; Deering, 1989).

According to IGMPv1, routers periodically query their attached networks to determine which groups have members on them. They send an IGMP message to the reserved address 224.0.0.1, which identifies the “all hosts” group. Hosts reply with a membership report only if they are interested in any of the advertised groups, with a separate reply for each group in which they are interested. When no reports are received, the query times out and is discarded. A host that wants to join a group sends a membership report without waiting for the router query message. The router then adds the group to the membership list for the interface that received the report, unless it is already present. After joining, the router begins forwarding the multicast traffic onto the network segment. Note that sources do not have to join the group to be able to send traffic. If a host wants to leave a group, it simply does not reply to the router membership query and lets it time out. This makes the latency to leave a group longer than the one to join it, as a time-out must expire before the router detects the leave. Leave messages were added in the second version of the protocol.

The service model envisioned in the first two versions of the protocol has some drawbacks. Because there is no control on sources nor is their location known, flooding multicast groups is easy but establishing a distribution tree is hard. Furthermore, address uniqueness is not guaranteed, as we saw in the previous section. IGMPv3 (Cain, Deering, Kouvelas, Fenner, & Thyagarajan, 2002) addresses these issues by allowing hosts to specify the list of sources from which they are willing to receive traffic and the list of sources from which they do not want any traffic. This way unwanted traffic can be discarded at the network level, rather than blocked by the application, which wastes system resources. The service model converges toward a source-specific paradigm, making distribution tree establishment, source identification, and address collision avoidance easier.

Reliable Multicast

IP multicast is an unreliable service, as it is based on the IP protocol. Because multicast applications typically use UDP as a transport protocol, which is also unreliable, either the applications themselves implement the necessary services to add reliability or ad hoc reliable multicast protocols are adopted. To make multicast reliable, functionalities that implement error control and possibly congestion control must be added. Error control provides a solution to packet loss, whereas congestion control allows the system to maintain a smooth traffic flow. Error control can be performed reactively, that is, by retransmitting packets when a packet loss is detected, or proactively, that is, by sending redundant data as part of the normal traffic flow. Although the former is more efficient when packets are lost, the latter is better suited for slightly lossy links, that is, links where packets are corrupted rather than lost. Because in this case parity checks and other error correcting codes are adopted, proactive or forward error correc-

tion has been considered as an add-on to reliable multicast protocol of the reactive type. Various reliable multicast protocols, such as the scalable reliable multicast (SRM; Floyd, Jacobson, Liu, McCanne, & Zhang, 1995), the reliable multicast transport protocol (RMTP; Lin & Paul, 1996), the pragmatic general multicast (PGM; Speakman et al., 2001), or the light-weight multicast service (LMS; Papadopoulos, Parulkar, & Varghese, 1998), have been proposed that follow the retransmission approach. Error detection and recovery distinguish the various protocols. The nature of the applications that use them determines which one is more suitable.

An error is detected when the source receives a negative acknowledgement, or NACK, meaning that at least one node lost a packet, or when the source does not receive all of the expected ACKs confirming the reception of traffic from the receivers. SRM, PGM, and LMS are NACK-based protocols, whereas RMTP is ACK based. Protocols differ on how control messages are propagated from a receiver to the source, regardless of their type. This affects the amount of state the source or the multicast routers may have to maintain, hence the protocol scalability, and the amount of bandwidth consumed. Suppression mechanisms are usually in place that eliminate redundant control messages in entire subtrees, to avoid flooding the sender (implosion).

Once errors have been detected, retransmission is required. The issues to be considered in this case are which nodes resend the lost packet and how they resend it. In particular, it can be the source that unicasts the lost packet to the requesting receivers, or nodes in the distribution tree, whether routers or end hosts, that multicast the lost packet to an entire subtree. The goal is to minimize traffic retransmission to nodes that did not request it (exposure). The error detection and recovery strategies affect the recovery latency, that is, the average amount of time it takes to receive a reply after detecting a loss, and the adaptability of the protocol to dynamic membership changes.

Whereas in SRM the source waits for the NACKs and every member may perform retransmission with retransmission suppression in place to minimize traffic duplication, RMTP channels ACKs through a hierarchy of statically designated "ACK processor" nodes. Such nodes merge ACKs from their subtrees and unicast a single ACK up to their parents. They are also in charge of retransmission, using unicast or multicast depending on the percentage of nodes requesting it. In PGM, each router along the distribution tree forwards only one NACK for every packet loss up to the source, thus reducing the NACK traffic at the source. Routers also selectively retransmit traffic only to the nodes that sent NACKs. In LMS, routers select a receiver in their subtree as their substitute and forward all the control messages to it and redistribute messages from it to the subtree. Thus, the burden that in PGM was on the router in LMS has been shifted to a receiver, thus maintaining the router load light.

SECURE MULTICAST

Given the type of applications where multicast can be most useful, it would be beneficial from a security point of view if traffic were accessible only to a restricted set

of users, and hosts joined and left a group in a controlled fashion. Based on these simple requirements, the main security issues in multicast communication can be divided into traffic-related and group-related issues. They are discussed in what follows and the requirements of a secure multicast protocol are derived.

Traffic Security

Limiting traffic access to a set of nodes means being able to control which nodes generate, read, and modify traffic. That is, confidentiality, integrity, and authenticity are the properties a secure multicast service should satisfy.

Confidentiality, that is, the requirement that all the traffic within a group may be read only by group members, may be satisfied in a soft way or in a strong, or long term, way. A soft requirement on confidentiality means that it is sufficient to delay access to traffic to nonmembers for a limited amount of time. This applies to cases where the value of the transmitted information depends on its timely and private distribution, because the information is bound to become public access anyway, for example, stock quotes or news feeds. Long-term secrecy implies that the traffic may not be accessible to nonmembers for long periods of time, thus requiring backward and forward secrecy. The former means that new members should not be able to read past traffic and the latter that former members should not be able to read present and future traffic. Long-term secrecy may be too strong for multicast, but cases such as corporate videoconferencing could still require it. Integrity guarantees that only authorized members may modify the traffic whereas authenticity allows the receiver to verify that a message was sent by a group member (group authenticity) or by a particular sender (source authenticity).

Cryptography is the mechanism to guarantee these three properties. Efficient schemes must be adopted to deal with large volumes of traffic, constraints on latency, bursty traffic, or a combination thereof. By combining cryptography with traffic padding, reordering, and delaying, protection from traffic analysis may also be achieved.

Group Security

Group security issues regard group member authentication and authorization, group control, member dynamics, damage containment, member collusion, and possibly anonymity. Group member authentication may take the weaker form where a host is only able to prove it belongs to the group, that is, membership authentication, or the stronger one where each host can prove both that it is a member and its declared identity. The latter could contrast with the possible requirement of anonymity, that is, keeping the identity of group members secret to nonmembers or to other members or keeping the identity of message senders secret. Anonymity could also conflict with the possible requirement of nonrepudiation, that is, the impossibility of denying to a third party that an action was performed, for example, sending or receiving a message. Such a requirement could be present in commercial systems to prevent disputes or frauds.

Group member authorization defines what a member is allowed to do, for example, receive only or receive and

send, and possibly for how long, for example, whether the permitted activities can change during the lifetime of the group. Furthermore, a group may be open to receiving messages from nonmembers but may not be allowed to forward internal traffic outside.

Group control refers to the information the system maintains about group members, who has access to such information, and how. This implies, for instance, that group authentication could be mediated by a group controller or be distributed among all members. The same would apply to member subscription or revocation.

Member dynamics refers to whether the group is static, that is, members are defined at group creation time, or dynamic, that is, members can join at any time and possibly leave as they please. It also specifies how subscriptions and voluntary cancellations and/or revocations are dealt with. Membership changes should be secure, that is, they should not affect the security of the traffic before or after the change.

In case of restricted group access, making sure that the compromise of a subgroup or a single member would not jeopardize the privacy of the rest of the group or of other subgroups becomes an important factor. Damage containment indicates that a breach in a subgroup has limited effects on the rest of the group. Similarly, resisting member collusion, that is, members that cooperate to gain additional privileges, provides containment of the damage such malicious members can do.

A factor that should not be overlooked when designing a secure multicast service is group size. The cryptographic systems that guarantee traffic security may also provide for group security. Because large groups are expected to become prevalent in the future, scalability is a critical aspect of any acceptable solution. Additionally, the heterogeneous nature of the member of such large groups in terms of computational power, connectivity, and mobility, imposes further constraints and calls for ad hoc protocols, which are beyond the scope of this chapter.

Security Requirements

A solution for secure multicast should provide

- data confidentiality, integrity, and authenticity;
- group control, authentication, and authorization;
- secure leave and join;
- collusion resistance;
- compromise containment; and
- scalability.

The use of cryptographic techniques is the way to satisfy these requirements. Traffic is encrypted and digitally signed or MACed for confidentiality, integrity, and authentication. Membership is granted upon adequate electronic credentials, usually based on key certificates or analogous cryptographic identification tools. Joins and leaves trigger encryption key changes. Therefore, the core of secure multicast is the generation, distribution, updating, and revocation of cryptographic keys or the key management protocol. As we discuss in the next section, keys are used to encrypt/decrypt data traffic, the so-called traffic encryption keys (TEK), and to encrypt/decrypt the TEKs

for their distribution, the so-called key encryption keys (KEK).

KEY MANAGEMENT FOR SECURE MULTICAST

Key management schemes define the key agreement mechanism at the beginning of a multicast session and the successive key exchanges during a session without rebuilding the group, that is, rekeying. The rekeying operation characterizes a key management protocol. Rekeying is required upon membership changes, that is, whenever a new member joins the group or a current member leaves it or is evicted, and to refresh the TEK to protect it from cryptanalytic attacks. Key refresh can be performed efficiently and in a totally distributed fashion. The GM multicasts an “update” message for the target key, possibly encrypted with the current TEK, which triggers the computation of a commonly agreed-upon one-way hash function applied to the current target key at each node. Keeping the nodes synchronized on the current version is critical for nodes to be able to access traffic. This form of key update is possible regardless of the specific key management scheme adopted.

Therefore, the focus is on the rekeying operation upon membership changes. Its efficiency in terms of the number of nodes affected by the key change, the number and size of messages exchanged, and the time required to the group members to compute the new key is critical for the actual deployment of the protocol. It depends upon the way keys are organized from a logical point of view and the potential dependency on each other. Scalability requires that the amount of processing be independent of the group size and the number of affected nodes be small. The amount of storage required for storing the keys each group member handles is also important for protocol scalability and applicability to environments with heterogeneous nodes, where some may have limited resources. Furthermore, security breaches in a subgroup should not expose the rest of the group.

Two main classifications have been proposed for key management protocols. In one case, protocols are classified based on the logical organization of the key set, that is, as a flat set, a collection of subgroups, or a tree-based hierarchy. In the other case, protocols are classified based on the relation between the keys in consecutive distribution rounds, namely as stateful or stateless protocols. Stateful protocols tie the keys distributed in a round to those distributed in the previous ones, so not receiving one key prevents a member from decrypting the traffic multicast afterward. With stateless protocols, keys in successive rounds are independent, so missing one key only introduces a temporary glitch in a member service. Independent keys also provide for containment in case of security breaches.

In the following sections, we present the most significant contributions, grouped according to the logical organization of the key set. We use GM to refer to the group manager that controls group membership and key distribution. Data distribution and key management are kept separate from a logical point of view, although the same node might perform them both.

Flat Schemes

In the simplest solution, each of the n group members shares a personal secret key with the GM, set up when the group is created either via the Diffie–Hellman key establishment algorithm or via the GM sending it to the member encrypted with its public key, if a public key cryptosystem is in place. Such key is used as the KEK for that member for the entire duration of its subscription.

When a member leaves the group or is evicted, the GM computes a new TEK and sends it to each member encrypted with its own personal key in a unicast message. As a performance improvement, the content of the n unicast messages can be combined in a single multicast message, n times the size of each unicast message. Assuming n members are left, the GM sends to the entire group G :

$$GM \Rightarrow G : [E_{K_1}(TEK'), E_{K_2}(TEK'), \dots, E_{K_n}(TEK')]$$

where \Rightarrow indicates the multicast communication primitive, K_i is the personal secret key the GM shares with member i , and $E_{K_i}(TEK')$ is the new group key TEK' encrypted with key K_i . Each member retrieves its key based on the id (i) the GM assigned to it at join time. When a new member joins, either the GM distributes a new key as just described or the old members update the current TEK as if in a refresh and the new member receives the new TEK in a unicast message from the GM. In the first case, TEKs are independent of each other, containing the damages of key compromise between successive rounds. In the other case, key dependency is the price paid for a more efficient key update, but the use of one-way hash functions protects the sequence from cryptanalysis. Note that, if backward secrecy is not an issue, there is no need to “forward” the current key before sending it to a new member, thus reducing the amount of computation at each node for key update.

The group key management protocol (GKMP; Harney & Muckenhirn, 1997a; 1997b) and the scalable multicast key distribution scheme (Ballardie, 1996), which is an improvement of GKMP in terms of scalability, have been designed along this approach. Chu, Qiao, and Nahrstedt (2002) add copyright protection and the ability to identify possible infringers. Data with different watermarks is distributed to the members, thus allowing the system to single out the leaker(s) with a certain error probability.

The communication complexity of flat schemes is $O(n)$ if unicast messages are sent, but it is $O(1)$ if the key updates are multicast to the group. In this case, however, the message size may become prohibitively large in case of large groups, as it is proportional to the group size. On the other hand, only one cryptographic operation is required to compute the new key, either to decrypt the key extracted from the message or to compute a one-way hash function. In both cases, it does not depend on any group feature. Similarly, member storage occupation is very efficient, because two keys only must be stored: the one shared with the GM and the current TEK. On the contrary, GM storage is proportional to the group size. All the overhead of group management is on the GM, and minimum effort is required from the group members.

Although attractive for their simplicity, flat schemes are not scalable, because they quickly lead to the GM saturation. As the group size increases, the number of messages for key update, or the size of the single multicast message,

becomes quickly excessive, especially with highly dynamic groups. Another limitation of such protocols is the central group manager, which might jeopardize the security of the entire group and become a performance bottleneck. Furthermore, because a common TEK is used for all the nodes, the compromise of a single node may lead to the compromise of the entire group. On the other hand, because in case of eviction successive TEKs are independent from each other, it is easy to isolate a compromised node by not sending it the new TEK.

Clustered Schemes

Clustered schemes were introduced to overcome the scalability limitations inherent in the flat schemes. According to Iolus (Mittra, 1997), the first clustered scheme, a group is partitioned into independent subgroups along the distribution tree. Each subgroup operates as a multicast group with its own address and is assigned to a subgroup controller, a trusted intermediary that operates locally on behalf of the GM. Subgroup controllers relay data to and from their subgroup and are the manager of the local secure multicast group. They establish a local TEK for their subgroup for each session and share a secret key with each member of their subgroup, established at member join and used for unicast communication. Subgroup controllers are organized into a virtual secure multicast group, possibly following a different protocol from the subgroups, with a group key and individual secret keys each subgroup controller shares with the GM. Figure 1 illustrates a multicast group organized in four subgroups, SG0, SG1, SG2, and SG3, with subgroup controllers SGC0, which happens to coincide with GM, SGC1, SGC2, and SGC3, forming the virtual secure multicast group.

The sender, which does not necessarily coincide with the GM or the local subgroup controller, multicasts traffic encrypted with a session key. The session key is piggybacked on traffic, encrypted with the local TEK of the subgroup. The subgroup controller remulticasts the encrypted traffic after decrypting and reencrypting the session key with the virtual group key. This provides for better performance than using the local TEK or the sender private key to encrypt traffic, as in both cases the subgroup

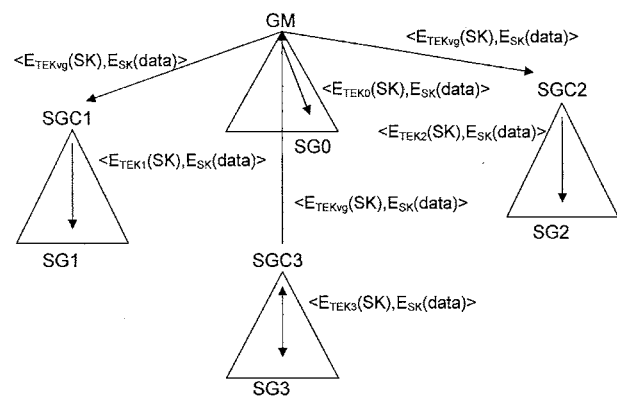

Figure 1: A simple multicast group organized in four subgroups, SG0, SG1, SG2, and SG3, with respective subgroup controllers GM, SGC1, SGC2, and SGC3. Arrows represent multicast communication and are labeled with the data multicast in the subnetwork.

controller would have to decrypt and encrypt the data packets rather than the few bytes of the session key. The process is illustrated in Figure 1. TEK_i is the local TEK of subgroup SG_i and TEK_{vg} is the TEK of the subgroup controllers virtual secure multicast group. S , a node in subgroup SG_3 , generates traffic and multicasts packets to its subgroup comprising the encrypted data and the encrypted session key, that is, $\langle E_{TEK_3}(SK), E_{SK}(data) \rangle$. The local subgroup SGC_3 decrypts the session key and reencrypts it with TEK_{vg} , thus multicasting $\langle E_{TEK_{vg}}(SK), E_{SK}(data) \rangle$ to the secure virtual group. When a subgroup controller SG_i receives a packet, it transforms it into $\langle E_{TEK_i}(SK), E_{SK}(data) \rangle$ by decrypting the session key and reencrypting it with its local TEK, and multicasts it to its local subgroup.

As the example shows, in clustered schemes multicasting is computation intensive, because of the cryptographic operations required at the subgroup controllers. This is the price paid for the group management locality the two-level node organization provides. Group membership changes are handled at subgroup level and do not affect any other subgroup. A new member sends its join request to the local subgroup controller, and if the request is accepted, a private key is established between the two. This key will then be used for all the unicast communications, such as the first local TEK distribution to the new member. When a member leaves, only the TEK of its subgroup must be updated. A rekeying on TEK_{vg} is triggered also at the subgroup controller level only if the leaving member leaves behind an empty group. Containment of security breaches is a direct consequence of subgroup organization, because damages resulting from key compromise are limited to the victim subgroup.

Within each subgroup, the subgroup controller may adopt a flat scheme to distribute the local TEK, or any other scheme among those described in the next sections, based on the size of the subgroup and the nature of the members; see, for example, Huang and Mishra (2003). The same applies to the virtual secure multicast group comprising the subgroup controllers. Scalability is achieved by creating new subgroups when the size of the existing ones exceeds a given threshold. There is, however, a trade-off between the number of subgroups and their size. Few large subgroups improve the communication complexity in the virtual group whereas several small subgroups improve performance at subgroup level. In the worst case scenario, each subgroup comprises a single element, hence the virtual group comprises n nodes, and the communication complexity is $O(n)$. At the other extreme, only one group exists that contains all of the nodes and the clustered scheme reduces to whatever scheme is used at local level. In general, the number of subgroups is smaller than the size of each subgroup.

Similar considerations apply to the amount of storage each node uses. Because the GM multicasts traffic and keys to the subgroup controllers only, it stores an encryption key for each subgroup controller and the TEK_{vg} . Subgroup controllers perform most of the work for traffic relay and key updates upon joins and leaves. They store keys for the group to which they belong, that is, the shared key with the GM, the TEK_{vg} , and any control key the protocol at this level may require. They also store keys for the group they manage, that is, the local TEK, the

individual keys shared with each member, and any control key the protocol they adopt may require. Members only store the local TEK, the key they share with their subgroup controller, and the possible control keys. The total number of keys in the system depends upon the actual protocols.

Clustered schemes strongly rely on the trust in dedicated nodes, that is, the subgroup controllers, because they access the data traffic to relay it. This could result in a serious weakness of the system in case of subgroup controller compromise. In this case, the damages affect the entire system.

The most famous clustered solution is Iolus (Mittra, 1997). Several other solutions were proposed that adopt the same divide-and-conquer approach, for example, IGKMP (Hardjono, Cain, & Monga, 1998), Kronos (Setia, Koussih, & Jajodia, 2000), and Molva and Pannerat (2000), Zhang, Lam, Lee, and Yang (2001), and Yang, Li, Zhang, and Lam (2001). In particular, Yang, Li, Zhang, and Lam (2001) focus on the reliability of aspect of secure key distribution, which is also addressed by some of the tree-based protocols. They are the first to make the case for batch rekeying as an effective and efficient way to deal with large dynamic groups. In this case, security is traded for performance, because former members might be able to access traffic until the next rekeying is performed after they left, and new members might be able to access all the traffic distributed with the current TEK at the moment they subscribed. Kronos introduces periodic rekeying in an IGKMP-like scheme, where subgroup controllers periodically generate the same key in an independent fashion, rather than receiving it from the GM. Because key generation does not depend upon the frequency of joins and leaves in the group, and it is performed locally rather than centrally at the GM, such a scheme provides excellent scalability. It also resists network partitioning, like all clustered schemes, as long as there is a sender in each of the partitions.

Tree-Based Schemes

Tree-based schemes, also generically referred to as LKH (logical key hierarchy) or keygraphs, were suggested in Wallner, Harder, and Agee (1999) and independently in Wong, Gouda, and Lam (1998). They address the problem of minimizing the communication complexity of the rekeying operation, without relying on secure third parties, such as the subgroup controllers. They introduce a hierarchy of control keys that allows the GM to efficiently multicast group key updates.

All the keying material is organized in a balanced tree of degree d maintained at the GM. Recent work has shown that unbalanced trees might be beneficial as they may lead to a considerable performance improvement in the rekeying process (Banerjee & Bhattacharjee, 2002; Zhu, Setia, & Jajodia, 2003). The key hierarchy is independent of the distribution tree. Keys in a subtree may, however, be assigned to members in a distribution subtree to keep into account their relative physical position, the expected duration of their membership, link loss probability, for the purpose of exploiting locality and/or different rekeying rates. The leaves are the keys established at join time, which each group member shares with the GM. The key at the root of the tree is the TEK. The keys along the

Figure 2: A balanced binary key tree for an eight-node multicast group. Keys K1 through K8 are the private keys each member shares with the GM for unicast communications. The keys along the path from the root to a leaf are the control keys.

internal nodes are the control keys used to distribute the TEK. Each group member stores all the keys along the path from its leaf node to the root. Figure 2 depicts a balanced binary key tree for a simple group comprising eight nodes. Keys K1 through K8 are the individual keys each node shares with the GM for unicast communication. K12, K34, K56, K78, K14, and K58 are the control keys.

During a rekeying operation, the group manager uses the hierarchy of KEKs to distribute the new TEK. Thus, as an example, the new TEK can be distributed to all nodes in Figure 2 by multicasting it separately encrypted with keys K14 and K58. Note that all the members in a subtree can decrypt any data encrypted with the key at the root of their subtree. The closer to a leaf the key used to encrypt data is, the fewer members can decrypt that data. Thus, by encrypting the TEK with a subset of keys in a subtree, it is possible to exclude a single participant or a group of participants from receiving the next TEK.

If node 7 in Figure 2 were evicted, or left voluntarily, all the keys node 7 has must be changed, that is, the TEK, K58, and K78. The new TEK can be distributed to the rest of the group by separately encrypting it with K14, K56, and K8. Note that none of the KEKs node 7 has is used to distribute the new TEK. Then $E_{K56}(K58')$ and $E_{K8}(K58', K78')$ are distributed. All the compromised KEKs and the TEK are replaced during a rekeying operation.

In case of a member joining, a new leaf is added to the tree, the KEKs between the new leaf and the root are recomputed to guarantee backward secrecy, and in case the tree requires adjustments for balancing purposes. The GM then distributes the KEKs between the leaf and the root to the new member using the shared key (K1 in Figure 2). The intermediate keys that were changed because of the

addition of the new member are also transmitted to the members in the subtree where the new leaf was added. A new version of the TEK is then distributed or derived by each member by applying a one-way hash function to the current one. In case of a member leaving, the TEK must be updated and the KEKs along the path to the leaving member must be updated.

Because there is a single common key used to encrypt traffic, tree-based protocols do not provide containment. The compromise of a node exposes data traffic to unauthorized access along the entire multicast tree. Furthermore, although the key tree is significantly more efficient than flat key distribution, the key update requested upon each leaf affects the entire group, thus affecting scalability when the group is highly dynamic.

When this scheme is applied to a group of n users, it requires each group member to store $O(\log_d n)$ keys, that is, all the keys along the path from the node to the root, whereas the GM must store $O(n)$ keys, because it also stores the individual keys shared with each member (K1 in Figure 2). The number of messages is on the order of $O(\log_d n)$. Later work improved the original scheme with respect to various aspects (Canetti et al., 1999; Banerjee & Bhattacharjee, 2002; Waldvogel, Caronni, Sun, Weiler, & Plattner, 1999; Chang, Engel, Kandlur, Pendarakis, & Saha, 1999; Balenson, McGrew, & Sherman, 2000; Burmester & Desmedt, 1996; Harney & Harder, 1999; Perrig, Song, & Tygar, 2001; Moyer, Rao, & Rohatgi, 1999; Zhu, Setia, & Jajodia, 2003). In some cases, attention is placed on the unreliable nature of IP multicast and provisions are made to guarantee keys will be received even in case of unreliable transmission (Setia, Zhu, & Jajodia, 2002; Perrig, Song, & Tygar, 2001). By organizing the key tree so as to concentrate members with high loss probability in one subtree and retransmitting key distribution messages to such subtree, reliable secure multicast is achieved.

Table 2 summarizes the main characteristics of the flat, clustered, and tree-based schemes, assuming a group of size n . In the case of clustered schemes, the group is organized in g subgroups, which we assume to have n/g members each, for the sake of simplicity. In the case of tree-based schemes, the keys are organized in a balanced tree of degree d and height $\log_d n$. The parameters considered for the comparison are the type of TEK, whether it is global for the entire group or not, the number of keys stored at the GM and at each member, the number of keys to be changed upon a join or a leave, and the number of cryptographic operations required when a multicast packet is transmitted. Note that for clustered

Table 2 A comparison of key management schemes with respect to type of TEK, number of keys stored at the GM and at each member, number of new keys to be distributed upon a join and a leave, number of cryptographic operations required by a multicast transmission, for a group of size n and organized in g subgroups in the case of the clustered scheme. For the clustered scheme, ranges are reported for some of the parameters because they depend upon the scheme adopted within each subgroup

Approach	TEK	No. Keys GM	No. Keys Member	Join	Leave	Crypto-Op
Flat	global	$N + 1$	2	1	1	1
Clustered	local	$[g + 1, \log_d g + 1]$	$[2, \log_d n/g + 1]$	$[1, \log_d n/g + 1]$	$[1, \log_d n/g + 1]$	$2g + 1$
Tree-based	global	$\sum d^i \quad i=0,h$	$\log_d n + 1$	$\log_d n + 1$	$\log_d n + 1$	1

schemes some of the parameters are given as ranges, because they depend upon the specific key management scheme adopted at each subgroup. So, for instance, the number of keys at a member can be as small as two in case of a flat scheme or as large as $\log_d n/g + 1$, in case of a tree-based solution.

As the table shows, the TEK is local only in clustered schemes. Although this provides for containment in case of compromise of the subgroup TEKs, it does not help if the group key of the virtual group, TEK_{vg}, is compromised. Another aspect that should not be forgotten is that the apparent simplicity of the join and leave operations in the case of the flat scheme is paid in terms of the size of the message required to distribute the single key that must be changed, namely the TEK (see the fourth section). Note that in all cases, the join operation can be performed in a more efficient way by simply multicasting an “update” message to all the old members, which will generate a new local version of the current TEK by applying the same one-way function. When a tree-based scheme is adopted, such an update must be applied also to the KEKs along the path from the new node to the root, for a total of $\log_d n + 1$ key changes involving the n/d nodes in the subtree where the new node is added.

Other Schemes

In the approaches outlined, the goal is to improve the protocol communication complexity by balancing the distribution of keying material to the members and possible intermediate nodes so as to avoid sending the new key to each group member individually. Different approaches have been taken by Chiou and Chen (1989), Steiner, Tsudik, and Waidner (2000), Briscoe (1999), and Judge and Ammar (2002).

Chiou and Chen (1989) propose a solution based on the Chinese remainder theorem and that uses public key technology, thus trading communication complexity for computation. Securelock has communication complexity $O(1)$ but it requires that each group member perform $O(n)$ exponentiations to “unlock” the message, thus becoming prohibitively expensive for large groups.

Cliques, the solution proposed by Steiner, Tsudik, and Waidner (2000), generalize the Diffie–Hellman key agreement algorithm to a group of n users. In the so-called up-flow, each member raises the value it receives from another member to its own secret number and forwards the result to the next member. The last member starts the down-flow by multicasting the value it computed in the up-flow phase. Each member can calculate the key. Because the control messages and the number of exponentiations are linear in the group size, this solution does not scale.

In MARKS (Briscoe, 1999), a multicast session is divided in sets of time slices. During each one of such sets, different keys are distributed and used to encrypt data traffic. Binary hash trees are used to generate the encryption keys, which are the leaves of such trees. Intermediate nodes are the seeds needed to generate the keys. A new member admitted to the group for a certain subset of time slices receives the seeds necessary to generate the keys for the specific time range. Leaves are permitted only at join

times, because they would otherwise require change the key tree.

In Gothic (Judge & Ammar, 2002), it is observed that, unlike what happens on the Internet with open multicast groups, with group access control in place, a host cannot receive the encrypted traffic of a multicast group before being a member. Therefore, there is no need to rekey the group either at joins or at leaves, except in the case where new (former) members belong to the same broadcast link as current group members. An architecture implementing a group policy management system and a group authorization system that control access to the group is proposed. It is shown that existing key management protocols may benefit dramatically from deployment in a system implementing group access control.

CONCLUSION

IP multicast is a fundamental tool for efficient communication of one-to-many and many-to-many services, such as videoconferencing, collaborative work, and periodic data distribution. Address allocation, routing, and group management are the key components of the multicast service. The original service model focusing on many-to-many communication makes address allocation and routing complex and heavy for the underlying network. The current trend is to shift the service paradigm toward easier-to-manage source-specific multicast, as one-to-many communication better suits commercially viable applications, such as video on demand or file distribution. Group management is also being adjusted to fit the less-general service model.

The open nature of IP multicast groups makes it impossible to provide added value services, for example, services based on fee payment or that require guarantees of the party identity. Secure multicast protocols provide for restricted access to traffic, group member authentication, and secure membership changes by employing cryptographic systems. At their core are key management schemes that provide the necessary keying material. The efficiency of such schemes, their ability to resist collusion of malicious members and to contain security breaches resulting from member compromise, the level of trust required in the participating nodes, their scalability to large group sizes, and their ability to deal with groups where members may join and leave at any time during a multicast session are critical parameters for secure multicast protocols evaluation.

GLOSSARY

Access Control The collection of policies and mechanisms used to restrict access to and usage of system resources to authorized users only.

Authentication The process by which a user verifies the declared identity of the other party in a communication.

Confidentiality Ensuring that information is accessible only to those authorized to have access.

Diffie–Hellman A cryptographic protocol that allows two communication parties to establish a shared key over an insecure channel.

- Group Management** The practice of managing multicast group membership.
- Hash Function** A function that maps values from a large domain into a smaller codomain.
- Integrity** Ensuring that information is modifiable only by authorized users.
- Key Management** The generation, distribution, and updating of cryptographic keying material.
- MAC (Message Authentication Code)** A one-way hash function that accepts a cryptographic key, used to generate a message digest for integrity check and authentication purposes.
- Multicast** Delivery of information to multiple destinations simultaneously.
- One-Way Function** A function that is easy to compute but difficult, that is, computationally hard, to reverse.
- Routing** The means of forwarding logically addressed packets from their local subnetwork toward their final destination.
- Scalability** The ability of a system to maintain quality performance or service under an increased system load.
- Spanning Tree** In graph theory, the tree that includes all the vertices of the graph.

INTRODUCTION

The transport layer is the basic end-to-end building block of the Internet (TCP/IP) architecture and communications. Protocols above the transport layer concentrate on distributed applications processing, and protocols below the transport layer concentrate on the transmission, routing, and forwarding of application data. The transmission control protocol is a connection-oriented, reliable, byte stream service that provides data transfer that is reliable, ordered, fully duplex, robust, and flow controlled (Network Sorcery, n.d.; Rey, 1981)

Each TCP segment (shown in Figure 1) contains the source and destination *port number* to identify the sending and receiving application. A socket is a pair (IP address and port number); the ends of a connection are each sockets. The *socket pair* (client IP address, client port number, server IP address, and server port number) specifies the two end points that uniquely identify each TCP connection in an Internet and the port number.

There are six flag bits in the TCP header. One or more of them can be turned on at the same time:

U (URG) Urgent pointer field significant (the urgent flag is set).

A (ACK) Acknowledgment field significant.

P (PSH) Push function.

R (RST) Reset the connection.

S (SYN) Synchronize sequence numbers.

F (FIN) No more data from sender.

Because TCP is a connection-oriented protocol, before sending and receiving data, a connection must be established between the sender and receiver. TCP connection establishment is a three-way handshake procedure as shown in Figure 2. The initiating end (client) sends a SYN

segment (a segment in which the SYN bit is set) specifying the port number of the server to which that the client wants to connect and the client's initial sequence number (198990 in this example). The server responds with its own SYN segment containing the server's initial sequence number (segment 2). The server also acknowledges the client's SYN by ACKing (acknowledging) the client's initial sequence number (ISN) plus one. The client must now acknowledge this SYN from the server by sending an ACK with the server's ISN plus one (segment 3).

The host that sends the first SYN is said to perform an *active open*. The other host, which receives this SYN and sends the next SYN, performs a *passive open*. When each end sends its SYN to establish the connection, it chooses an initial sequence number for that connection. The ISN should change over time, so that each connection has a different ISN. The purpose of these sequence numbers is to prevent packets that get delayed in the network from being delivered later and then misinterpreted as part of an existing connection.

Once the TCP connection is established, the data transfer can begin. Data are transferred over a TCP connection in TCP segments; however, TCP views the data as streams of octets. When the application has sent all its data and wishes to close the connection, it sends a CLOSE primitive to TCP, which sends a segment with the FIN flag set. Because a TCP connection is full duplex, each direction must be shut down independently when it is done sending data. When a TCP receives a FIN, the application is not notified explicitly (but the next read returns 0) that the other end has terminated that direction of data flow. The receipt of a FIN means there will be no more data flowing in that direction. However, the user can still send data after receiving a FIN. This is called a half-close.

Figure 3 shows TCP connection termination procedure. The end that first issues the close (sends the first

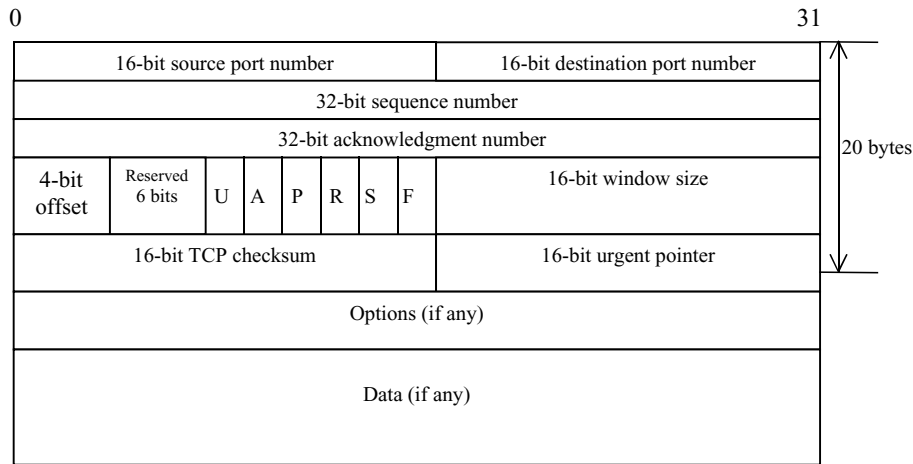

Figure 1: TCP segment format.

FIN) performs the *active close*, and the other end performs the *passive close*. The connection termination requires four TCP segments and is called a four-way handshake.

CONGESTION AVOIDANCE AND CONTROL

Modern implementations of TCP contain four intertwined algorithms: slow start, congestion avoidance, fast retransmit, and fast recovery (Stevens, 1997).

Slow Start

The slow start algorithm is used to control the transmission rate injected into the network. It operates by observing that the rate at which new packets should be injected into the network is the rate at which the acknowledgments are returned by the other end. Slow start adds another window called the congestion window (*cwnd*). When a new connection is established with a host on another network, the congestion window is initialized to one segment (current standard allows 1–4 segments). Each time an ACK is received, the congestion window is increased by one segment. The sender can transmit up to the minimum of the congestion window and the advertised window. The congestion window is based on the sender’s assessment of perceived network congestion. The advertised window is related to the amount of available buffer space at the receiver for this connection.

Figure 2: TCP connection establishment.

Figure 4 illustrates the working of slow start algorithm. The horizontal direction is time. The continuous time line has been chopped into *round-trip time* (RTT) pieces stacked vertically with increasing time going down the page. The white, numbered boxes represent segments. The shadowed, numbered boxes represent the corresponding ACKs. The sender starts by transmitting one segment and waiting for its ACK. When the ACK is received, the congestion window is incremented from one to two, and two segments are sent. When both of those two segments are acknowledged, the congestion window is increased to four. This provides exponential growth in the size of the congestion window. From Figure 4, we see that the window size doubles in every RTT. This implies that the time to reach a window size of W is $RTT \times \log_2 W$.

However, this growth can be moderated by sending one ACK for every two segments received. At some point, the capacity of the connection can be reached, and an intermediate router will start discarding packets. This informs the sender that its congestion window has become too large and induces to reduce the size of the window.

Congestion Avoidance

Congestion avoidance is also used to control the data injected into the network. The algorithm works based on the assumption that packet loss is mainly due to congestion

Figure 3: TCP connection termination.

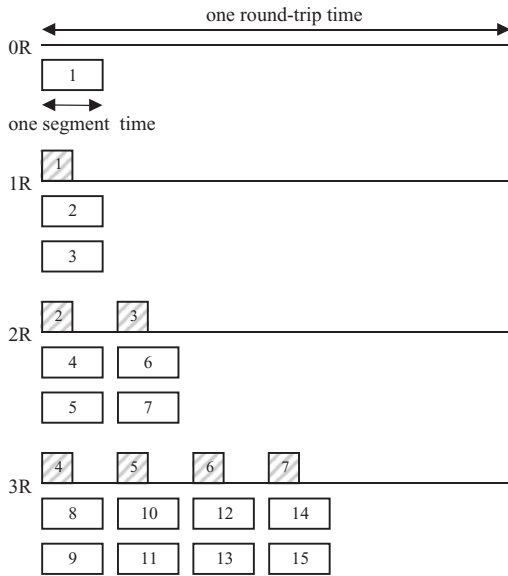

Figure 4: Slow start example.

in the network, somewhere between the source and destination. In congestion avoidance, on receipt of an ACK the *cwnd* is increased by $1/cwnd$ and if congestion occurs ($cwnd = W$) then *cwnd* is set to $0.5W$. This avoids the exponential queue build-up. The packet loss is indicated by a time-out or by the receipt of duplicate ACKs.

Congestion avoidance and slow start are independent algorithms with different objectives. In practice, they are implemented together. Congestion avoidance and slow start require two variables to be maintained for each connection: a *cwnd* and a slow start threshold size (*ssthresh*). The combined algorithm operates as follows:

1. Initially set *cwnd* to one segment and *ssthresh* to infinity.
2. The TCP output routine never sends more than the minimum of *cwnd* and the receiver's advertised window.
3. When congestion occurs, one half of the current window size (*W*) is saved in *ssthresh*. Additionally, if the

congestion is indicated by a time-out, *cwnd* is set to one segment (i.e., slow start).

4. When new data are acknowledged by the other end, increase *cwnd*, but the way it increases depends on whether TCP is performing slow start or congestion avoidance.

If *cwnd* is less than or equal to *ssthresh*, TCP is in slow start; otherwise, TCP is performing congestion avoidance. Slow start continues until TCP is halfway to where it was when congestion occurred, and then congestion avoidance takes over.

Congestion avoidance allows a linear growth of *cwnd*, compared to slow start's exponential growth. In congestion avoidance, the increase in *cwnd* should be at most one segment each RTT, whereas in slow start the increase in *cwnd* is equal to the number of ACKs received in each RTT.

Fast Retransmit

Fast retransmit detects lost segments (resulting from congestion) based on the duplicate ACKs received and retransmits them as quickly as possible. However, TCP cannot identify whether a received duplicate ACK is due to a lost segment or due to a reordering of segments. In fast retransmit, it is assumed that three or more *duplicate ACKs* (dupack) received in a row is a strong indication of a lost segment. TCP then performs a retransmission of the missing segment, without waiting for a retransmission timer to expire. During the retransmission, TCP enters slow start.

In Figure 5, segment 6 is lost during transmission. After receiving three dupacks *ssthresh* is set to $8/2 = 4$ (i.e., $W/2$), *cwnd* is set to 1, and the segment 6 is retransmitted. Because the receiver cached the received segments (7-14), an ACK is sent for segment 14. As in slow start, for every ACK received, the *cwnd* is incremented by 1.

Fast Recovery

The fast recovery algorithm is an improvement of fast retransmit that allows high throughput under moderate

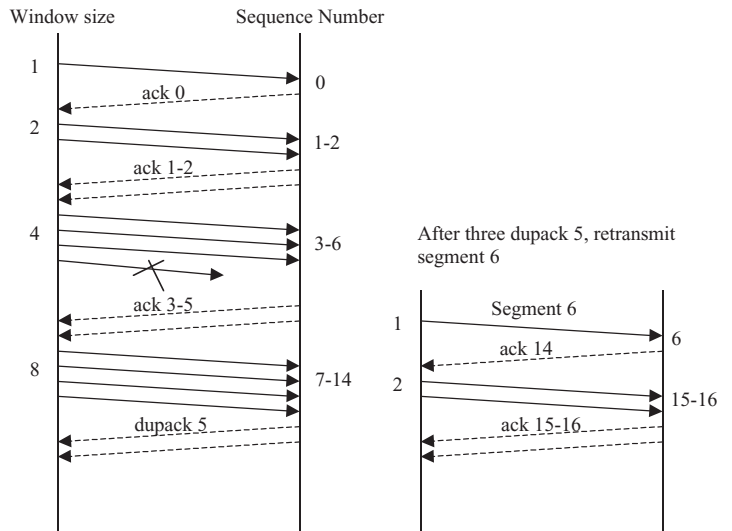

Figure 5: Fast retransmit example.

congestion, especially for large windows. Here, after fast retransmit sends the missing segment, congestion avoidance is performed. The reason for not performing slow start in this case is that the receipt of the duplicate ACKs tells TCP that more than one packet has been lost. There are still data flowing between the two ends, and TCP does not want to reduce the flow abruptly by going into slow start. The fast retransmit and fast recovery algorithms are usually implemented together.

TCP SACK (selective acknowledgment) is an extension to the normal TCP that allows the sender to recover from multiple packet losses in a window without resorting to coarse time-out (Mathis, Mahdavi, Floyd, & Romanow, 1996). Multiple packet losses from a window of data can have a catastrophic effect on TCP throughput. TCP uses a cumulative acknowledgment scheme in which received segments that are not at the left edge of the receive window are not acknowledged. This forces the sender to either wait an RTT to find out about each lost packet or to unnecessarily retransmit segments that have been correctly received. With a cumulative acknowledgment scheme, multiple dropped segments generally cause TCP to lose its ACK-based clock, reducing overall throughput. SACK is a strategy that corrects this behavior in the face of multiple dropped segments. With selective acknowledgments, the data receiver can inform the sender about all the segments that have arrived successively, so that the sender retransmits only the segments that have actually been lost.

Allman, Balakrishnan, and Floyd (2001) propose a new TCP mechanism that can be used to more effectively recover lost segments when a connection's congestion window is small or when a large number of segments are lost in a single transmission window. The "limited transmit" algorithm calls for sending a new data segment in response to each of the first two duplicate acknowledgments that arrive at the sender. Transmitting these segments increases the probability that TCP can recover from a single lost segment using the fast retransmit algorithm, rather than using a costly retransmission time-out.

The *cwnd* must not be changed when the new segments are transmitted. Assuming that these new segments and the corresponding ACKs are not dropped, this procedure allows the sender to infer loss using the standard fast retransmit threshold of three duplicate ACKs. This is more

robust to reordered packets than if an old packet were retransmitted on the first or second duplicate ACK. Limited transmit can be used both in conjunction with, and in the absence of, the TCP SACK mechanism.

According to Mathis et al. (1996), Padhye and Floyd (2001), and Dobrota (2003), the popular TCP implementations are *Tahoe without fast retransmit* (includes slow start and congestion avoidance), *Tahoe* (includes also fast retransmit), *Reno* (Tahoe TCP with fast recovery), *New-Reno* (enhanced Reno TCP using a modified version of fast recovery), *Reno Plus* (on some Solaris systems), and *SACK*.

TCP OVER WIRELESS

TCP was originally designed for wired networks; however, with the advent of wireless technology, handheld devices, cell phones, and laptops have become popular as networked devices. Most of these devices interconnect using wireless links, and some of these devices require reliable data transfer. Because TCP is the most widely used transport-level protocol that provides reliable data transfer, it is important to improve its performance in wireless networks without any modification to the application interface provided by TCP on fixed hosts.

The current strong drive toward Internet access via wireless links includes wireless systems such as *cellular communications* (CC) and *wireless local area networks* (WLANs). Unlike conventional wired networks, wireless systems provide freedom of mobility to wireless hosts. Mobile networks can be classified as cellular networks and ad hoc networks.

A cellular network consists of mobile hosts served by a central coordinator (base station). The mobile hosts communicate directly only with the base station. If the hosts belong to the same cell, then the base station behaves as a one-hop relay. If the hosts belong to different cells, then a backbone network is used. In contrast, in an ad hoc network, mobile hosts establish a network without a backbone or base station. In such an environment, it may be necessary for one mobile host to enlist the aid of other hosts in forwarding a packet to its destination, because of the limited range of each mobile host's wireless transmissions. Figure 6 illustrates the communication pattern in cellular and ad hoc networks. CC, WLAN, and ad hoc

Figure 6: Cellular (left) and ad hoc (right) communication.

systems raise many performance issues, which in turn affect the performance of TCP.

Limitations in a Wireless Network

As discussed in the previous section, TCP adapts to changing end-to-end delay conditions and assumes that packet loss and delay are mainly due to network congestion. The source responds by reducing its window size and thereby reducing the transmission rate. In a network with wireless links and mobile hosts, the potentially high bit-error rate in the wireless channel can cause false alarms, which trigger congestion control. Consequently, end-to-end throughput and latency of detecting packet loss are severely degraded. Some of the limitations of a wireless network include these (Pentikousis, 2000):

- **High bit-error rate:** Wireless media are more prone to transmission losses, for example, because of fading channels, shadowing, and so forth. TCP was designed with a wired medium in mind, which has *bit-error rates* (BER) on the order of 10^{-6} to 10^{-8} . This translates into a segment loss rate of about 1.2% to 0.012% for 1500-byte segments. BER are much higher in the wireless domain, usually on the order of 10^{-3} and sometimes as high as 10^{-1} . With BER on the order of 10^{-3} , the packet loss rate is an order of magnitude more in a wireless environment (approximately 12%).
- **Limited bandwidth:** Wireless links offer less bandwidth as compared with the wired links. Wired Ethernet connections can offer 10 Mbps to 100 Mbps (theoretical maximum for Fast Ethernet). In contrast, wireless LANs using 802.11b support a maximum theoretical bandwidth of 11 Mbps. Therefore, optimum use of available bandwidth is essential.
- **Longer RTT:** The limited bandwidth in wireless media leads to longer latencies than wired media. This affects the overall throughput and increases interactive delays.
- **Mobility:** The frequent mobility of wireless devices contributes to data loss.
- **Power consumption:** Wireless devices have limited power and processing capacity, which require more efficient energy utilization techniques.

It is thus necessary to modify TCP such that it adapts to a wireless network without degrading the network performance.

TCP Performance in a Wireless Network

In this section, we discuss the TCP performance issues raised by the high transmission error rate and mobility in WLAN, CC, and ad hoc networks.

Impact of High Bit-Error Rate

The high bit-error rate in a wireless network is the primary source of performance degradation for TCP applications. Although some errors may be corrected by low-level *forward error correction* (FEC; Lin & Costello, 1983) codes, most errors may lead to packet corruption. Corrupted packets are discarded without being handed over to TCP, which assumes that these packets were lost. Because packet loss is considered a sign of network congestion, TCP reacts to these losses by reducing its congestion window. However, in most cases wireless transmission errors are not related to network congestion. Thus, these inappropriate reductions of the congestion window lead to unnecessary throughput reduction for TCP applications. The resulting throughput degradation can be very severe, depending on factors such as the distance between the sender and receiver and the bandwidth of the communication path.

Impact of High Bit-Error Rate in WLAN

In a typical WLAN infrastructure configuration (IEEE, 2005), there are two basic components (IEEE Standards Board, 1997): *access point* (AP) and *wireless client*. An access point/base station connects to a LAN by means of a wire, most often an Ethernet. Access points receive, buffer, and transmit data between the WLAN and the wired network infrastructure. A WLAN client may also be a desktop, laptop, or handheld device that is wireless enabled. Wireless-enabled devices use wireless *network interface cards* to connect to access points in the network.

A characteristic example of WLAN is the Lucent WaveLAN (Hassan & Jain, 2004). The WaveLAN suffers from a *frame-error rate* (FER) of 1.55% when transmitting 1400-byte frames over an 85-foot distance, with *clustered* losses. File transfer tests over a WaveLAN with a nominal bandwidth of 1.6 Mbps achieved a throughput of only 1.25 Mbps. This 22% throughput reduction resulting from a FER of only 1.55% is caused by the frequent invocations of congestion control mechanisms, which repeatedly reduce TCP's transmission rate. If errors were uniformly distributed rather than clustered, throughput would increase to 1.51 Mbps (Nguyen, Katz, Noble, & Satyanarayanan, 1996). This is consistent with other experiments showing that TCP performs worse with clustered losses (Fall & Floyd, 1996).

Table 1 shows the TCP throughput over a LAN path, consisting of a single WLAN, versus a WAN path, consisting of a single WLAN plus 15 wired links (Balakrishnan, Padmanabhan, Seshan, & Katz, 1996). It shows the throughput in the absence of any losses, the actual throughput achieved (with a FER of 2.3% for 1400-byte frames), and the percentage of the nominal bandwidth

Table 1 TCP Throughput

	Nominal bandwidth	Actual TCP throughput	% Achieved
LAN	1.5 Mbps	0.70 Mbps	46.66%
WAN	1.35 Mbps	0.31 Mbps	22.96%
IEEE 802.11	2 Mbps	0.98 Mbps	49%
IEEE 802.11b	11 Mbps	4.3 Mbps	39.1%

that was achieved. In WAN, this percentage is half of that in the LAN. Because TCP recovers from errors via end-to-end retransmissions, recovery is slower in high delay paths.

The success of the original WaveLAN and other similar, but incompatible, systems prompted the IEEE to create the 802.11 standard for WLANs (Ramani & Karandikar, 2000). The standard offers various enhancements over the original WaveLAN. Table 1 shows the nominal bandwidth and actual TCP throughput measured over a single link path, using either an IEEE 802.11 or an IEEE 802.11b WLAN. The percentages here show that the high-speed link (802.11b) is affected more by losses. Because TCP drastically reduces its throughput after each loss, it takes longer to reach the peak throughput supported by higher speed links.

Impact of High Bit-Error Rate in Cellular Networks

Unlike first-generation CC systems (analog), second-generation CC systems are digital. They are characterized by modest bit rates and circuit mode operation, using either TDMA (GSM and IS-54; Cellular Networking Perspectives, 2004; Ludwig & Rathonyi, 1999) or CDMA (IS-95; Hendry, n.d.; Karn, 1993) to share the medium. Digital CC links carry small frames, which may contain either encoded voice or data. Compared to WLANs, CC systems exhibit higher transmission and propagation delays because of the lower bit rates and longer distances involved. Because of the real-time requirements of voice telephony, FEC information is added to each frame, allowing damaged frames to be recovered without retransmissions. The traditional Internet approach is to delegate error control to higher layers of the network. This is adequate for wired links where losses resulting from errors are very rare. For error-prone wireless links, however, local (link-layer) error recovery can be faster and more adaptable to link characteristics. Voice-oriented CC systems offer a *nontransparent mode* that incorporates link layer-error recovery in addition to their native *transparent mode*.

Digital CC systems are interconnected to other networks using an *interworking function* (IWF; Alanko et al., 1994) located at the boundary of the CC system. A *radio link protocol* (RLP) is used between the wireless host and the IWF, offering IP datagram segmentation and reassembly (Karn, 1993). As a result, the wireless host may exchange IP datagrams with any host on the Internet, using the IWF for routing purposes. The RLP may also provide error recovery to hide wireless losses from the Internet (Nanda, Ejzak, & Doshi, 1994).

CC networks are divided up into cells where each cell is serviced by one or more radio transceivers (transmitter/receiver). The cellular topology of a network helps in frequency reuse. Cells, a certain distance apart, can reuse the same frequency, which ensures the efficient usage of limited radio resources.

CC links in transparent mode (for voice) suffer from a FER of 1% to 2%, after low-level error recovery, despite their short frames (Karn, 1993). Frame errors are less bursty than bit errors, because multiple frames are bit interleaved before transmission. Although this process reduces the loss rate and randomizes frame errors, thus avoiding audible speech degradation, it considerably

increases processing delay because of interleaving before transmission and deinterleaving after reception. If we reduce the size of IP datagrams to reduce the packet loss probability, user data throughput also decreases because of the higher TCP/IP header overhead. TCP/IP header compression may be used over slow CC links, shrinking TCP/IP headers to 3 to 5 bytes (Jacobson, 1990). Header compression may, however, adversely interact with RTT(s), TCP error recovery, and link layer resets, leading to a loss of synchronization between the *compressor* and *decompressor*, thus causing entire windows of TCP data to be dropped (Ludwig, Rathonyi, Konrad, Oden, & Joseph, 1999).

Although the RLP used in the nontransparent mode of GSM (global system mobile communication) usually manages to recover from wireless losses before TCP timers expire (Ludwig, Rathonyi, et al., 1999), it exhibits high and widely varying RTT values. Measurements using ping over a GSM network in San Francisco showed that 95% of the RTT values were around 600 ms with a standard deviation equivalent to 20 ms (Ludwig & Rathonyi, 1999). Large file transfer experiments, however, reveal that RTT can be occasionally much higher with real applications over operational networks, reaching values of up to 12 s. The conclusion is that the high latency is due to interleaving, rate adaptation, buffering, and interfacing between GSM network elements (Ludwig & Rathonyi, 1999).

Increasing the size of the TCP *maximum segment size* (MSS) reduces TCP/IP header overhead, thus improving bulk transfer throughput, but also increases the response time of interactive applications. Measurements over operational GSM networks show that TCP throughput is optimized for an MSS size of approximately 700 (Hassan & Jain, 2004). Although small fixed-size frames simplify RLP operation and make it more robust in worst-case conditions, choosing a frame size appropriate for prevailing conditions can provide throughput improvements of 18% to 23%, depending on the radio environment (Ludwig, Konrad, & Joseph, 1999).

When the end-to-end path includes multiple wireless links, the losses accumulate, leading to more frequent invocations of TCP congestion control mechanisms. This reduces throughput and also causes wireless links to remain idle for prolonged periods of time. Furthermore, when a TCP packet is lost after crossing some wireless links in the path, its retransmission has to cross them again, risking new losses and wasting wireless bandwidth. Losses have more pronounced effects on paths with higher end-to-end delay, which require TCP to maintain large transmission windows to keep data flowing. On such paths, TCP also suffers from *spurious time-outs*, that is, time-outs that would be avoided if the sender waited longer for acknowledgments. In addition to the high and unpredictable delays caused by RLP error recovery, CC systems explicitly allow prolonged disconnections during handoffs, causing numerous spurious time-outs (Hassan & Jain, 2004).

Impact of Mobility in Cellular Networks

To understand the impact of mobility in a network, we provide a brief introduction to the mobile Internet protocol (mobile IP; IEEE Computer Society, n.d.) and

its operation. Mobile IP is an extension to the Internet protocol proposed by the Internet Engineering Task Force (IETF) to support user mobility. It enables mobile computers to stay connected to the Internet regardless of their location and without changing their IP address (Perkins, 1996). Because mobile IP is the most widely used standard to support mobility of Internet users, it has a direct impact on the performance of TCP connections.

IP routes packets from a source end point to a destination by allowing routers to forward packets from incoming network interfaces to outbound interfaces according to routing tables. The routing tables typically maintain the next-hop (outbound interface) information for each destination IP address, according to the number of networks to which that IP address is connected. The network number is derived from the IP address by masking off some of the low-order bits. Thus, the IP address typically carries with it information that specifies the IP node's point of attachment.

To maintain existing transport-layer connections as the mobile node moves from place to place, it must keep its IP address the same. In TCP, connections are indexed by a quadruplet that contains the IP addresses and port numbers of both connection end points. Changing any of these four numbers will cause the connection to be disrupted and lost. In contrast, correct delivery of packets to the mobile node's current point of attachment depends on the network number contained within the mobile node's IP address, which changes at new points of attachment. To change the routing requires a new IP address associated with the new point of attachment.

Mobile IP has been designed to solve this problem by allowing the *mobile node* to use two IP addresses. In mobile IP, the *home address* is static and is used, for instance, to identify TCP connections. The *care-of address* changes at each new point of attachment and can be thought of as the mobile node's topologically significant address; it indicates the network number and thus identifies the mobile node's point of attachment with respect to the network topology. The home address makes it appear that the mobile node is continually able to receive data on its *home network*, where mobile IP requires the existence of a network node known as the *home agent* (HA). Whenever the mobile node is not attached to its home network (and is therefore attached to what is termed a *foreign network*), the HA gets all the packets destined for the mobile node and arranges to deliver them to the mobile node's current point of attachment.

The basic entities of mobile IP operations are the *mobile host* (MH), the home network or the network to which the mobile host is connected, the foreign network or the network to which the mobile host has moved, and the *static corresponding host* (SH) with which the MH communicates. It also includes an HA in the home network and a *foreign agent* (FA) in the foreign network. The HA and FA are stationary.

When the mobile node is on its home subnet (the one specified by its IP address) the mobile node informs the HA of its presence. Once the mobile node has registered with the HA and is on the FA's network, IP traffic addressed to the mobile node is received by the HA, encapsulated in another IP datagram, and then *tunneled* to the FA. The FA

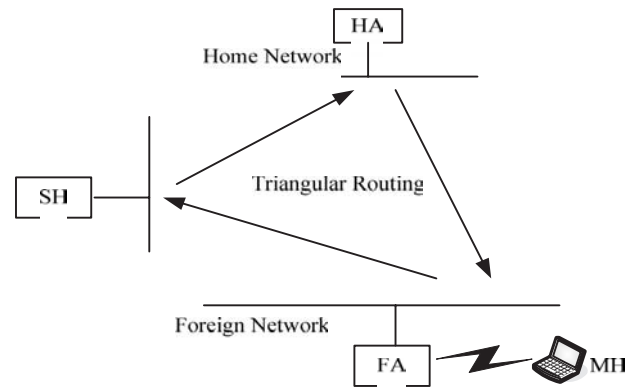

Figure 7: Mobile IP operation.

forwards the datagrams to the MH. In the reverse direction, the mobile node can bypass the HA and send datagrams directly to the SH. This results in a triangular routing of traffic (refer to Figure 7), which is not necessarily efficient but is effective. In addition, when a mobile node changes its location, it can register with a new FA, although traffic directed by the HA to the old FA will be lost until the new mobile node has registered its location.

Although mobile IP supports user mobility in the Internet, it suffers from several drawbacks. This is especially true for TCP connections because of the following reasons (Hassan & Jain, 2004):

1. *Blackouts*: Sinha, Monks, and Bhargavan (200), through field experiments, show that MH can experience periods of blackouts during mobility. Blackouts are periods during which the MH is not connected to the base station. It could be due to the specific location that the user is passing through, or fading, and can last for a few seconds. During a blackout, the TCP retransmission timer expires and is misinterpreted as network congestion. Hence, the congestion window is reset to one, and the TCP enters into the slow start mode. Thus, frequent blackouts will severely degrade TCP performance.
2. *Handoff latency*: When a MH moves from one cell to another, it takes some amount of time for mobile IP to react to the handoff (reroute packets to the new cell). In the meantime, the old base station drops the packets sent to the old cell. During these types of bursty losses, TCP retransmission timer expires, reset, its congestion windows and enters slow start mode. Thus, frequent handoffs degrade TCP throughput.
3. *Triangular routing and larger RTT*: When triangular routing of mobile IP is performed, the path from the SH to the MH is artificially long because of the two stage tunneling from the host to the HA and then from the HA to the MH. This results in increased RTT for the connection. Because TCP's throughput is inversely proportional to the RTT, increased RTT results in less throughput. In addition, some security mechanisms in the current Internet require even the reverse path from the MH to the static host to go through the HA, resulting in larger RTT.

Impact of Mobility in Ad Hoc Networks

Unlike conventional networks, in ad hoc networks, routing is a basic function of every node. The mobility of the nodes affects the performance of the routing protocol and TCP. This is due to these factors:

1. *Route failures:* An ad hoc network experiences frequent route failures because of mobility of the nodes. When there is a route failure, a TCP connection that is using the route potentially loses packets. Because TCP cannot distinguish between losses resulting from route failure and those resulting from congestion, it resets the congestion window and enters into the slow start mode. Because every route failure resets the congestion window and takes a few RTTs to resume to its available capacity, it experiences severe throughput degradation. In addition, ad hoc networks experience high RTT variations, resulting in a high mean deviation of the RTT because the retransmission time-out value is initially set to average RTT plus four times the mean deviation. This further exacerbates the problem, resulting in severe throughput degradation.
2. *Route recomputations:* When route failures occur, the routing protocol sends route error messages to the source. The TCP connection at the source will not be able to send any more packets until the route is recomputed. TCP perceives the route recomputation time as increased RTT, resulting in a more inflated retransmission time-out. The problem worsens when the network is heavily loaded because the recomputation time further increases.
3. *Network partitions:* Ad hoc networks communicate through multihop paths, where every node performs the routing functions. A partition in the network implies that the source and destination of a TCP connection belong to two different partitioned components of the network and cannot communicate (as long as the partition exists). During a partitioning, TCP resets the connection if the partition lasts for more than some predetermined amount of time (100 s). Even if the partitioned network gets connected again, TCP will enter the slow start phase. This behavior severely degrades the network performance.

Classification of Proposed Schemes

There are two fundamentally different approaches to improve TCP performance in wireless systems (Balakrishnan, Padmanabhan, Seshan, & Katz, 1996). The first approach hides any noncongestion-related losses from the TCP sender and therefore requires no changes to existing sender implementations. The rationale is that because the problem is local (to the wireless link), it should be solved locally, and that the transport layer need not be aware of the characteristics of the individual links. The second class of techniques attempts to make the sender aware of the existence of wireless hops and realize that some packet losses are not due to congestion. The sender can then avoid invoking congestion control algorithms when noncongestion-related losses occur.

We can classify the many schemes into three basic groups, based on their fundamental philosophy: end-to-

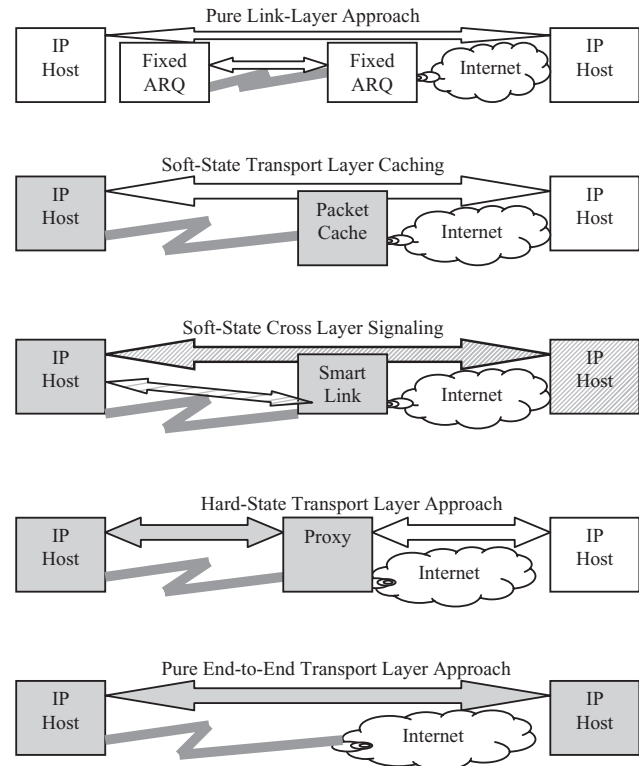

Figure 8: Classification of TCP over wireless approaches.

end proposals, split-connection proposals, and link-layer proposals (Balakrishnan et al., 1996). The end-to-end protocols attempt to make the TCP sender handle losses through the use of two techniques: SACK and explicit loss notification (ELN). Split-connection approaches completely hide the wireless link from the sender by terminating the TCP connection at the base station. Such schemes use a separate reliable connection between the base station and the destination host. The second connection can use techniques such as negative or selective acknowledgments, rather than just regular TCP, to perform well over the wireless link. The link-layer solutions are between the other two classes. These protocols attempt to hide link-related losses from the TCP sender by using local retransmissions and perhaps FEC over the wireless link. Figure 8 illustrates a more detailed classification as in Ludwig (1999). Note that the fully shaded areas indicate whether a transport protocol or its implementation must be changed, or whether transport protocol dependent state has to be maintained in the network. The partially shaded areas indicate changes required at the link layer.

Pure Link-Level Approach: This approach hides the unwanted characteristics of the wireless links from the higher layers. A critical factor here is the link-level timeout value. An example is the AIRMAIL protocol, which is a link-layer protocol for indoor and outdoor wireless networks (Ayanoglu, 1995). However, pure link-level approaches alone will not be sufficient, because they cannot completely prevent the sender from timing out and invoking the congestion control mechanisms. To preserve

the end-to-end semantics, other promising solutions propose to correct errors at the wireless link level by using a combination of FEC and ARQ (automatic repeat request; Balakrishnan et al., 1996).

Soft-State Transport-Layer Caching Approach: This approach maintains a soft state of the network. In other words, the state is not crucial and preserves the end-to-end semantics. The approach is aware of the transport layer and uses caching to prevent the sender from unnecessary invocation of the congestion control mechanism. The disadvantage is that it requires changes at the intermediate node (base station) and optionally at the mobile host. They also fail in the presence of encryption as intermediate nodes try to interpret the transport header.

Soft-State Cross-Layer Signaling Approach: In this approach, the transport-layer sender is aware of the wireless link. This can be achieved by having the link or the network layer send a signal to the transport-layer sender about specific events so that it can adapt accordingly. The advantage here is that it helps distinguish congestion losses from the error losses but this may not be possible if the network is extremely congested, in which case it is not possible for the network to inform the sender through any kind of signaling. They also involve changes at some or all of the intermediate nodes and at the transport layer of the sender's protocol stack in order to appropriate actions in response to the signals received from the network.

Hard-State Transport-Layer Approach: This approach encompasses all forms of splitting in that the end-to-end semantics may be sacrificed. The advantage here is that the wireless link is completely shielded from damage or loss. However, there is a high cost associated with the maintaining of the state information crucial to the end-to-end connection.

Pure End-to-End Transport-Level Approach: The advantage of an end-to-end approach is that a sender can quickly recover from multiple lost packets in a single RTT and that such an event is treated as one congestion signal instead of one signal for each lost packet.

PROPOSED SCHEMES FOR WIRELESS TCP

There are several proposed solutions to extend TCP in a wireless or heterogeneous network. In this section, some of proposed schemes are discussed.

Pure Link-Level Approaches

The techniques used here include adaptive FEC, interleaving, adaptive power control, and fully reliable and semireliable link-layer ARQ protocols. Pure link-layer solutions can yield excellent TCP bulk data throughput without interfering with end-to-end error recovery. Interactions between link-layer and end-to-end error recovery have been studied (Balakrishnan et al., 1996; Bhagwat, Bhat-tacharya, Krishna, & Tripathi, 1997). A key advantage is that local knowledge about the link's error characteristics, which can vary largely over short time scales, can be exploited to optimize error control efficiency. The second advantage is that it does not require any changes to the

IP-based protocol stacks. The drawback is that the error control schemes are applied irrespective of the *quality of service* (QoS) requirements of individual flows sharing the link. A flow that requires link-layer ARQ cannot share the link with a delay-sensitive flow introduced by link-layer retransmissions. In contrast, an adaptive application might be able to tolerate higher loss rates in return for higher available bit rates than the link's channel coding scheme provides.

Soft-State Transport-Layer Caching Approaches

Snoop Protocol

Snoop (Balakrishnan et al., 1996; Balakrishnan, Seshan, & Katz, 1995) is classified as a TCP-aware link-level protocol. It involves modification of the network layer (IP) software at the *base station* by adding a module called snoop. The snoop module looks at every packet on the connection in either direction. It maintains a cache of TCP packets sent from the *fixed host* (FH) that have not been acknowledged by the MH. When a new packet arrives from the FH, snoop adds it to its cache and passes the packet on to the routing code that performs normal routing function. The snoop module also keeps track of all the acknowledgments sent from the mobile host. When a packet loss is detected (either by the arrival of a duplicate acknowledgments or by a local time-out), it retransmits the lost packet to MH if it has the packet cached. In this way, the base station hides the packet loss from the FH by not propagating duplicate acknowledgments, thereby preventing unnecessary invocations of the congestion control mechanisms at the sender (FH). It does not completely shield the sender from wireless losses as the sender may time-out because of repeated losses or bit errors caused by the wireless link. Because the protocol is TCP aware, it would fail if the packets were encrypted.

Soft-State Cross-Layer Signaling Approaches

Explicit Congestion Notification (ECN)

(ECN Ludwig & Rathonyi, 1999) is an extension proposed to *random early detection* (RED; Floyd & Jacobson, 1993). RED is an active queue management mechanism in routers that detects congestion before a queue overflows and provides an indication of this congestion to the end nodes. Routers using RED operate by maintaining two levels of threshold, minimum (min) and maximum (max). RED drops packets probabilistically if and only if the average queue size lies between the min and max. ECN, in contrast, marks a packet instead of dropping it when the average queue size is between min and max. Upon receipt of a congestion-marked packet, the TCP receiver informs the sender (in the subsequent acknowledgment) about incipient congestion, which in turn will trigger the congestion avoidance algorithm at the sender. ECN requires support from both the router as well as the end hosts, that is, the end-host TCP stack needs to be modified. Although it provides a simple solution, it cannot handle high bit-error rates.

Explicit Loss Notification (ELN)

ELN (Balakrishnan et al., 1996) adds an ELN option to TCP ACKs. When a packet is dropped in the wireless network, future cumulative acknowledgments corresponding to the lost packet are marked to identify that a noncongestion-related loss has occurred. Upon receiving this information along with duplicate acknowledgments, the sender may perform retransmissions without invoking congestion control procedures. ELN also cannot handle high bit-error rate.

Explicit Bad State Notification (EBSN)

EBSN (Bakshi, Vaidya, & Pradhan, 1997) proposes to update the TCP timer at the source to prevent the source from decreasing its congestion window, provided there is no congestion. EBSN's are sent to the source after every unsuccessful attempt by the base station to transmit packets over the wireless link. EBSN would cause the previous time-outs to be cancelled and new time-outs put in place, based on existing estimate of RTT and variance. The EBSN approach does not interfere with actual RTT or variance estimates, and at the same time prevents unnecessary time-outs from occurring. This, in turn, prevents time-outs for packets that had already been put on the network before the wireless link encountered the bad state. EBSN also cannot handle high bit-error rates.

Mobility Awareness Incorporated as a TCP Enhancement (MAITE)

MAITE uses link-layer messages to inform TCP of high BER and host disconnection resulting from mobility (Karn & Partridge, 1987). A high BER can be detected when the cyclic redundancy check on received frames continuously fails. Similarly, the MH disconnection can be detected by sensing the lack of the beacon that is periodically sent by the access point in WLAN standard implementations.

When the link layer detects a high BER it sends a HighBER notification message to the transport layer. During a HighBER period, the MH will freeze its TCP timers and will not attempt any transmissions until it receives a HighBEROver message from the link layer. Similarly, a disconnection notification message is used when a MH disconnects and the TCP timers freeze during this period.

Now that high BER and disconnections conditions are distinguished, any time-out that occurs at the transport level is only due to intermediate congestion and the regular congestion control mechanisms are followed.

Multiple Acknowledgments

The multiple acknowledgments method distinguishes the losses (congestion or other errors) on the wired link and those on the wireless link (Biaz, Mehta, West, & Vaidya, 1997). It uses two types of ACKs to isolate the wireless host and fixed network, such as *partial acknowledgment* (ACKp) and *complete acknowledgment* (ACKc). The sender strictly follows regular TCP when sending packets with slow start, congestion avoidance, fast retransmit, and fast recovery. RTO is the maximum time that can elapse between the reception of a packet at the base station and its acknowledgment by the MH.

When a sender gets ACKp with sequence number Na from the base station, the sender understands that the base station has received packets up to $Na - 1$ but is having difficulty sending these packets to the wireless host; that is, it has not received the acknowledgment from the wireless host after waiting for RTO time. So, the sender updates RTO to give more time to the base station to accomplish the retransmission. This will avoid end-to-end retransmissions, thus avoiding triggering the slow start and congestion avoidance mechanisms. On receipt of ACKp, the sender marks the corresponding packets. On time-out, the sender checks if the packets are marked; if they are not marked, then it acts as normal TCP would. If they are marked, then it will not retransmit and will not initiate any congestion control methods except backing off the timer.

ACKc is a complete acknowledgment of the received packet. When the sender receives ACKc, it takes the same steps as in normal TCP. Corrupted TCP segments are often detected at the data-link layer and discarded by the link-level drivers.

Hard-State Transport Layer Approaches

Indirect TCP (I-TCP)

The indirect protocol model for mobile hosts suggests that any interaction from a MH to a machine on the fixed network should be split into two separate interactions—one between the MH and its *mobile support router* (MSR) over the wireless medium and another between the MSR and the fixed host (FH) over the fixed network (Bakre & Badrinath, 1995). At the transport layer, use of indirection separates the flow control and congestion control functionality on the wireless link from that on the fixed network. It allows a separate transport protocol for the wireless link, which can support notification of events such as disconnections, relocation, and other features of the wireless link. This includes the available bandwidth to the higher layers that can be used by link-aware and location-aware mobile applications. Indirection also allows the base station to manage much of the communication overhead for a MH. Thus, a MH that runs a very simple wireless protocol to communicate with the MSR can still access fixed network services that may otherwise require a full TCP/IP stack running on the MH.

When a MH wishes to communicate with some FH using I-TCP, a request is sent to the current base station (which is also attached to the fixed network) to open a TCP connection with the FH on behalf of the MH. The MH communicates with its MSR on a separate connection using a variation of TCP that is tuned for wireless links and is also aware of mobility. The FH only sees an image of its peer MH that in fact resides on the MSR. It is this image that is handed over to the new MSR when the MH moves to another cell.

One consequence of using I-TCP is that the TCP acknowledgments are not end to end; instead, we have separate acknowledgments for the wireless and the wired parts of the connection. However, I-TCP does not yield weaker end-to-end semantics in comparison with regular TCP, provided that there are no base station failures and that

the MH does not stay disconnected from the fixed network for too long.

Pure End-to-End Transport-Level Approaches

Freeze-TCP

Freeze-TCP is a true end-to-end mechanism and does not require any intermediaries (Goff, Moronski, Phatak, & Gupta, 2000). No change in TCP code is required on the sender side or the intermediate routers. Freeze-TCP can be classified as a proactive mechanism because it is a congestion-avoidance technique whereby the client takes care that the TCP on the sender side that does not invoke congestion control mechanism unnecessarily.

A MH can monitor the strength of its wireless signal and detect an impending handoff or a temporary disconnection (if the signal strength is fading, for instance). If a MH detects such a situation, it will advertise a zero window size, freeze all retransmit timers, and enter a persist mode. This includes sending *zero window probes* (ZWPs) until the receiver's window opens up. This prevents the sender from dropping its congestion window. Because these probes are not delivered reliably, the sender does not drop its congestion window if a ZWP itself gets lost.

If a receiver senses an impending disconnection, it will try to send out a few acknowledgments wherein its window size is advertised as zero. The issue here is how much in advance of the disconnection should the receiver start advertising a window size of zero. This period is called the warning period prior to disconnection and a reasonable warning period is the RTT (Goff et al., 2000). If the receiver shrinks its window to zero, all outstanding packets will be lost without affecting the sender's congestion window, and the sender will enter the persist mode described previously.

Wireless TCP (W-TCP)

W-TCP (Sinha, Venkitaraman, Sivakumar, & Bharghavan, 1999) was designed for wireless wide area networks and uses purely end-to-end semantics. It tries to distinguish random losses from congestion losses by measuring the packet interarrival time with the packet interdeparture time. It uses rate-based, rather than window-based, transmission control. It shapes its data traffic, never allows a burst of packet transmissions, and is fair when competing connections have different RTTs.

The basic idea here is that TCP should not reduce its transmission rate for just a packet loss as this happens very frequently in wireless networks. The sender does not decide if packets have to be transmitted because some of the ACKs have failed but probes the receiver to find out if a packet has to be resent. The transmission rates at the sender are controlled by the feedback of the receiver. W-TCP uses the ratio of the interpacket separation at the receiver and the interpacket separation at the sender as the primary metric for rate control rather than using packet losses and retransmit timeouts. W-TCP uses the standard TCP mechanism for flow control and connection management. The key aspect of congestion control is that it uses interpacket delay as a metric and performs the rate adaptation computation at the receiver's end. It

thus distinguishes the cause of packet loss and behaves accordingly.

TCP- Santa Cruz (TCP-SC)

TCP-Santa Cruz (Parsa & Garcia-Luna-Aceves, 1999) uses a similar idea as in W-TCP. RTT is not considered as a metric for retransmission time-outs (Parsa & Garcia-Luna-Aceves, 1999). Instead, the sender depends on intermessage delay and explicit notifications (selective acknowledgments) for retransmissions. TCP-SC monitors the queue developing over a bottleneck link, and this determines whether congestion is increasing in the network. It can then distinguish losses as congestion-related or random and respond appropriately. Congestion is determined by calculating the relative delay that one packet experiences with respect to another as it traverses the network.

The losses resulting from congestion are usually preceded by an increase in the network bottleneck queue. A wireless loss, in contrast, can be identified as a random loss that is not preceded by a build-up in the bottleneck queue. TCP-SC monitors the changes in the bottleneck queue. Once losses are discovered, it retransmits without reducing the transmission window. This can also be implemented as a TCP option by utilizing the extra 40 bytes available in the options field of the TCP header.

Mobile-TCP (M-TCP)

M-TCP is designed to work well in the presence of frequent disconnections and low bit-rate wireless links and maintains end-to-end semantics (Brown & Singh, 1997). The implementation of M-TCP is based on a three-level hierarchy (refer to Figure 9). At the lowest level are the MH that communicate with *mobile support station* (MS) nodes in each cell. Several MSs are controlled by a machine called the *supervisor host* (SHH). The SHH is connected to the wired network, and it handles most of the routing and other protocol details for the mobile users.

The SHH uses the split connection approach for implementing M-TCP because it allows modifications in TCP on the mobile network. Thus, every TCP connection is split into two at the SHH. The TCP sender on the FH uses unmodified TCP to send data to the SHH, whereas the SHH uses M-TCP for delivering data to the MH. The FH sends TCP segments to the SHH. SHH passes them to the MH, which acknowledges the packets that it received. SHH, on receipt of ACKs, sends ACKs back to the FH. Unlike other

Figure 9: Three-level hierarchy of the network.

split connection techniques, it saves the ACK of the last byte to prevent loss of outstanding packets.

If the MH is disconnected, then the SHH will stop receiving ACKs and assumes that MH has been temporarily disconnected and sends the ACK of the last byte that it saved previously. This ACK will contain the advertised window of the MH as having size zero. The sender, upon getting the advertised window as zero, enters the persist mode and freezes all the timers related to the session, and starts sending the exponentially backed-off persist packets to the SHH. The SHH responds with the zero window size at the receiver to each persist packet, until it receives some nonzero window size indication from the MH. Upon receiving it, the SHH immediately replies to the persist packet as the appropriate window size and resumes all its frozen timers. Thus, the sender can resume transmitting at full speed. The FH resumes transmitting from the next byte that was unacknowledged.

TCP Westwood (TCPW)

TCPW is a sender-side modification of the TCP congestion window algorithm that improves upon the performance of TCP Reno implementation in wired as well as wireless networks (Mascolo et al., 2000). The general idea is to use the bandwidth estimate, BWE, to set the congestion window ($cwin$) and slow start threshold ($ssthresh$) after a congestion episode. The important distinguishing feature of TCPW with respect to TCP Reno is TCP Reno halves the congestion window after three duplicate acknowledgments or after a time-out, whereas TCPW attempts to select a slow start threshold and a congestion window consistent with the effective bandwidth used at the time congestion is experienced.

The source performs an end-to-end estimate of the bandwidth available along a TCP connection by measuring and averaging the rate of returning ACKs. Whenever a sender perceives a packet loss (i.e., a time-out occurs or three duplicate ACKs are received), the sender uses the bandwidth estimate to properly set the congestion window ($cwin$) and the low start threshold ($ssthresh$). In this way, TCPW avoids overly conservative reduction of $cwin$ and $ssthresh$ and thus it ensures faster recovery.

TCPW does not require inspection and/or interception of TCP packets at intermediate (proxy) nodes and complies with the end-to-end TCP design principles. It is very effective in mixed wired and wireless networks. When coexisting with TCP Reno, better throughput, delay performance, fairness, and friendliness (coexistence with connections from TCP variants) were observed in experimental studies (Mascolo et al., 2000). However, it performs poorly when random-packet-loss rate exceeds a few percent.

TCP Delayed Congestion Response (TCP-DCR)

TCP-DCR is based on the simple idea of allowing the link-level mechanism to recover the packets lost as a result of channel errors, thereby limiting the response of the transport protocol to mostly congestion losses (Bhandarkar & Reddy, 2004). TCP-DCR works in conjunction with a simple link-level protocol to provide the benefits of standard TCP implementations without the associated degradation

in performance resulting from channel errors in wireless networks. In TCP-DCR, the response to the receipt of duplicate packets is delayed by a short bounded period τ . If the packet is recovered by link-level retransmission before the end of the delay period τ , TCP-DCR proceeds as if the packet loss never occurred. However, if the packet is not recovered by link-level retransmission by the end of the delay period, TCP-DCR protocol triggers the congestion recovery algorithms of fast retransmission and recovery. By doing this, we effectively change the paradigm of TCP that all losses are due to congestion to the paradigm that all losses are due to channel errors for a period of τ . It may be noted here that no changes need to be made for the TCP at the receiver, and base stations are not required to maintain any TCP-related state information.

Eifel

Retransmission ambiguity is defined as the TCP sender's inability to distinguish between an ACK for the original transmission from that of an ACK for its retransmission. The Eifel algorithm (Ludwig & Meyer, 2003) eliminates the retransmission ambiguity, thereby solving the problems caused by the *spurious time-outs* and *spurious fast retransmits*. Spurious time-outs are defined as time-outs that would not have occurred if the sender had waited "long enough." Spurious fast retransmits are defined as fast retransmissions that occur because of the reordering of packets beyond the dupack threshold (normally set to three). Experiments have shown that in fact a large number of time-outs and fast retransmissions that occur are really spurious. Spurious time-outs affect the TCP performance in two ways: TCP sender unnecessarily reduces its load and TCP sender is forced into the go-back-N retransmission mode.

The Eifel detection algorithm (Ludwig & Meyer, 2003) uses the TCP time stamps option to eliminate the retransmission ambiguity. It thereby allows a TCP sender to detect a posteriori whether it has entered loss recovery unnecessarily. This added capability of a TCP sender is useful in environments where TCP's loss recovery and congestion control algorithms may often get falsely triggered. This can be caused by packet reordering, packet duplication, or a sudden delay increase in the data or the ACK path that results in a spurious time-out.

Based on an appropriate detection algorithm, the Eifel response algorithm (Ludwig & Gurtov, 2004) provides a way for a TCP sender to respond to a detected spurious time-out. It adapts the retransmission timer to avoid further spurious time-outs and can avoid—depending on the detection algorithm—the often unnecessary go-back-N retransmits that would otherwise be sent. In addition, the Eifel response algorithm restores the congestion control state in such a way that packet bursts are avoided.

SECURITY

Security Issues

To provide security in a network, it is essential to understand the requirements of a secure communication. The basic requirements for a secure system are these:

Confidentiality: The data transmitted over a network should be able to accessible only to the intended receiver.

Cryptographic algorithms can be used to ensure confidentiality. It is a process of encrypting messages such that only the intended receiver can decrypt and use the message. Currently, there are two types of cryptosystems used, namely symmetric encryption and public key encryption. In symmetric encryption, a single key is used for both encryption and decryption. In public key encryption, in contrast, two different but mathematically related keys are used.

Integrity: The data received should be identical to the data sent. If not, any accidental or malicious changes should be detectable.

Availability: A service should be available for use to an authorized user at any time and without unreasonable delay.

Authentication: The identity of a user or service can be verified.

Accountability: It refers to the keeping and protecting of audit information so that the party responsible for any action affecting security can be tracked.

Nonrepudiation: It must not be possible for a user to deny sending or receiving a message. This requirement demands integrity and authentication.

Possible Attacks

This section discusses common attacks in a network and the possible countermeasures that can be used to minimize the risk of these attacks.

Sniffing/Eavesdropping

A packet sniffer is a software application that uses a network adapter card in promiscuous mode to capture all network packets that are sent across a LAN. Because specifications for network protocols, such as TCP/IP, are widely published, it is possible to sniff and interpret these packets. It can be used as an administrative tool as well as a hacking tool.

Given the radio-based nature of wireless networks, sniffing is always a possibility because communication is through open air, facilitating confidentiality and integrity attacks. Even if the data streams are successfully sniffed off the air, if the data are encrypted, then it will be of no use. In 802.11b, the *wired equivalent privacy* (WEP) can be used to encrypt data.

IP Spoofing

IP spoofing is a technique used to gain unauthorized access to computers whereby the intruder pretends to be a trusted computer either by using an IP address that is within the range of the network or by using an authorized external IP address. The intruder must first determine the IP address of a trusted host and then modify the packet headers so that it appears that his or her packets are coming from that trusted host. IP spoofing is mostly limited to providing anonymity for an attacker launching attacks against the IP layer, for example, SYN flooding, TCP session hijacking, and so forth.

Firewall arrangements can offer protection against IP spoofing. A firewall is a system designed to prevent unauthorized access to or from a private network. It examines all the messages that pass through the network and filters

the messages that do not meet the specified security criteria.

Denial of Service Attacks

A denial of service (DoS) attack focuses on making a service unavailable for normal use, which is typically accomplished by exhausting some resource limitation on the network or within an operating system or application. It can be implemented using common Internet protocols, such as TCP and Internet control message protocol (ICMP). The attack exploits the weakness of the system being attacked rather than a software bug or security hole. DoS attacks can lead to severe degradation of network performance.

Application-Layer Attacks

Application-layer attacks can be implemented using several different methods. One of the most common methods is exploiting well-known weaknesses in software that is commonly found on servers, such as sendmail, PostScript, file transfer protocol (FTP), and so forth. For instance, if an organization that runs a public FTP service does not separate its sensitive organizational data, then with today's network speeds it may be possible to download all the sensitive data in a matter of minutes. In this way, by exploiting the weakness in the software, the attackers can gain access to a computer with the privileged access.

Man-in-the-Middle Attacks

A man-in-the-middle (MITM) attack is an attack where the attacker is able to read and modify messages between two parties without letting either party know that their communication has been compromised. The attacker must be able to observe and intercept messages going between the two victims. Using public key encryption, an attack might look as follows:

Adam wishes to communicate with Beth. Ed is an intruder who wants to eavesdrop on the conversation, or deliver a false message to Beth. Initially, before Adam and Beth communicate, Adam will ask Beth for her public key. Beth will send her public key to Adam, but Ed will intercept it and send Adam his own public key instead. Adam then encrypts his message with Ed's key (which he believes is Beth's) and sends it back to Beth. Ed again intercepts, decrypts the message, and reads the contents. He then encrypts the message (possibly altered) with Beth's key and sends it to Beth, who believes she has received it directly from Adam. Figure 10 illustrates this attack.

Standards in Wireless Networks

In this section, we discuss briefly the security standards available in WLANs. WLANs are implemented as an extension to wired LANs within a building and can provide the final few meters of connectivity between a wired network and the mobile user. WLANs are based on the IEEE 802.11 standard. In IEEE 802.11, the security services are provided by the WEP protocol. WEP does not provide end-to-end security but only security for the wireless portion of the connection. The three basic security services defined by IEEE for the WLAN environment are authentication, confidentiality, and integrity. Unfortunately,

Figure 10: Man-in-the-middle attack.

several security flaws were identified in WEP. Although the application of WEP may stop casual sniffers, experienced hackers can crack the WEP keys in a busy network within 15 minutes. The standard also does not address other security services such as audit, authorization, and nonrepudiation.

To help address the security issues in WLANs, the IEEE 802.11 Working Group instituted Task Group “T” to develop 802.11i standard with enhanced security features. The 802.11i standard includes two main developments: *wi-fi protected access* (WPA) and *robust security network* (RSN; Cohen & O’Hara, 2003).

WPA uses *temporal key integrity protocol* (TKIP) to improve security of keys used with WEP. It changes the way keys are derived and rotates keys more often for security. It also adds a message-integrity-check function to prevent packet forgeries. Although WPA goes a long way toward addressing the shortcomings of WEP, not all users will be able to take advantage of it because WPA might not be backward-compatible with some legacy devices and operating systems. Moreover, not all users share the same security infrastructure. For instance, some users will have a PDA and lack the processing resources of a PC. TKIP/WPA may also degrade performance unless a WLAN system has hardware that will run and accelerate the WPA protocol. For most WLANs, there’s currently a trade-off between security and performance without the presence of hardware acceleration in the access point.

RSN uses dynamic negotiation of authentication and encryption algorithms between access points and mobile devices. The authentication schemes proposed in the draft standard are based on 802.1X and extensible authentication protocol (EAP). The encryption algorithm is *advanced encryption standard* (AES). Using dynamic negotiation, EAP, and AES, RSN is significantly stronger than WEP and WPA. However, RSN will run very poorly on legacy devices. Only the latest devices have the hardware required to accelerate the algorithms in clients and access points, providing the performance expected of today’s WLAN products.

THREATS TO TCP

This section describes a number of common attacks that exploit the limitations and inherent vulnerabilities in TCP (Morris, 1985).

SYN Flooding

SYN flooding is a DoS attack that occurs when a server receives several connection requests. The basis of this attack is the resource investment made by the target to support a TCP connection. The attack obliges the target to maintain, for some period of time, the invested resources. Eventually, because of the dwindling target’s resources, the target becomes unable to respond to further legitimate requests. The attack exploits the three-way handshake procedure used in connection establishment over a TCP connection.

In SYN flooding, an attacking source initiates a TCP connection request to the server. The server responds to the request using a SYN ACK and waits for the source to respond. However, because the attacker does not wish to establish a TCP connection, it does not reply and so fails to complete the handshake. This leaves a half-open TCP connection. Because TCP can simultaneously support several half-open connections, the source may initiate several such requests and block the server from responding to other valid requests. This results in DoS. The situation lasts until a time-out occurs. When TCP reaches its maximum limit for half-open connection, all other pending requests will be queued in its backlog queue. Once the backlog queue is also full, all further requests to the TCP port will be ignored until the original requests begin to time-out and reset. After each time-out, the server port sends a RST to the unreachable client. At this point the attacker must repeat the process to continue the DoS attack.

The attacking host must ensure that the source IP address is spoofed (a routable but unreachable host), as the target host will be sending its response to this address. If the source address is reachable, then it will receive the SYN/ACKs sent by the server, as this would elicit an RST from that host and defeat the attack.

An analogy to understand SYN flooding: say there is a single telephone connection with 10 parallel lines, that is, the same number has 10 lines. If you use 10 telephones and dial this particular number 10 times, once from each telephone, then all the 10 parallel lines of the target telephone would be busy answering the 10 calls. Any additional calls to this number would not be able to go through. Thus as a result, we can say that the services of the target telephone have been rendered unavailable. SYN flooding is even worse than this scenario, as in the former the connection requests are from spoofed source addresses, thus making it difficult for the target system to trace the source of the attack.

Countermeasures

There is no single countermeasure to protect your system against SYN flood attacks. However, there are certain sets of steps, which can be followed to minimize the risk of damage caused by such attacks:

1. Reduce the duration of time required for a time-out of a connection to take place. This will ensure that if a large number of connection requests is sent to the target system, the spoofed requests would be discarded sooner, thus minimizing the hogging of memory.

2. Increasing the queue of connection requests. This means to increase the number of connection requests that can be accepted by a particular host at one time. However, one disadvantage is that it will result in hogging of more memory and resources of the host.
3. Installing vendor-specific updates and patches or by employing a firewall, which will detect SYN attacks and effectively respond with fake responses and try to trace back the spoofed source address to the actual attacker.

Sequence Number Attack

TCP segments are encapsulated within IP datagrams, and as a result there is no guarantee that the datagrams will follow the same route and therefore arrive in the order they were sent. Also, network errors may require datagrams to be resent. The TCP protocol uses sequence numbers to ensure that the application layer receives data in the same order that it was sent. Although this is a simple and effective method of ensuring a sequenced data stream, it unfortunately introduces vulnerability. If attackers can guess the correct sequence number, they can then generate their own TCP segments that will be accepted by the target host's TCP layer.

Despite the specification of ISN calculation in Rey (1981), the majority of TCP implementations simplify ISN allocation by incrementing using a constant value, a scheme originally introduced in Berkeley UNIX kernels. The Berkeley implementation of TCP increments the ISN clock by 128,000 each second and by a further 64,000 for each new connection. This practice is so widespread that it can be viewed as a standard, but it unfortunately introduces vulnerability into applications using security mechanisms.

An attacking host can forge a connection request to a server such that it appears to come from a host the server trusts. The server will then follow the connection establishment procedure described previously and send a segment back to the apparent client (that is, not the attacker), setting the SYN and ACK header bits. On receipt of this segment, the apparent client finds no record of a connection request and will respond by sending a RST segment, closing the connection request.

However, if the attacker ensures that the apparent client does not respond, then the attacker could forge the connection request, wait a suitable period of time to allow the server to respond with the SYN and ACK segments and then the attacker could forge another segment, this time containing the final ACK required for the three-way handshake. From the server's perspective, it has successfully completed the connection initiation phase and has an active connection with a trusted client.

The only requirement for this attack to be successful is the ISN. If the attacker chooses a quiet time, from the point of view of the server, then it can open a legitimate connection to the server to some public service, discover the ISN used on this connection, and then immediately begin the attack predicting the next ISN issued by the server to be 64,000 higher. Although nontrivial, this attack is usually successful within a few attempts. It is also popularly called the blind spoofing attack.

Countermeasures

- Increase the change rate of the initial sequence number variable. The TCP specification requires that this variable be incremented 250,000 times per second.
- Randomizing the ISN increment. This can be achieved by using a cryptographic algorithm for ISN generation.

TCP Session Hijacking

TCP session hijacking is also called nonblind TCP/IP spoofing. This attack can be viewed as impersonating a connection from another machine but not using prediction to find the sequence numbers. By sniffing packets between the server and the apparent client, the NSN (next sequence number) can become available to the attacker.

An intruder initiates a three-way handshake between a spoofed client and server. A spoofed TCP packet with the SYN flag set is sent to server, which responds to the client with a SYN and an ACK. At this point, the attacker sniffs the traffic off the wire to find what sequence number the server is expecting and then crafts an ACK packet using that information. The server, however, will think that the responses are arriving from the client. It has the same effect as blind IP spoofing (sequence number prediction), but can be used for a number of different purposes. It is used when the attacker is on the same network segment as the victim (spoofed client) host.

Countermeasures

- Prevent IP datagrams with source addresses outside their network from reaching the Internet. Unfortunately, there are many organizations that provide unregulated Internet access.
- A firewall can be used to block all IP datagrams from the Internet that are source routed or that have source addresses originating from the internal network.
- Trust relationships between hosts communicating across the Internet should never be permitted, unless they are used in conjunction with strong authentication and encryption.

TCP FIN and RST Bit Attacks

TCP packets have control flags, which indicate the status of a segment. The RST and FIN flags can be used for DoS attacks. Under normal circumstances the RST flag is used to reset a connection, whereas the FIN flag indicates that no more data will be sent and initiates shutdown of the connection. As with TCP session hijacking, the only requirement for this attack is the TCP sequence number. The attacker must have access to the IP datagrams sent between the server and spoofed hosts to predict the next possible TCP sequence numbers.

For a RST or FIN to be accepted, the TCP segment needs the correct sequence number, as there is no ACK involved. Therefore, the attacker simply analyzes the IP datagrams in the connection between the target and spoofed hosts and calculates the sequence number that the target host would expect the next TCP segment from the spoofed host to contain. The attacker then generates a TCP segment with the RST flag set and sends it in a

spoofed IP datagram to the server. On receipt of the RST, the target host will prematurely terminate the connection with the spoofed host. A very similar attack can be launched with the FIN flag, thereby initiating an invalid TCP connection close request. The advantage of a FIN-based attack, from a hacker's point of view, is that TCP mandates that on receiving a segment with the FIN flag set, the host must reply with one of its own. It makes this attack more successful than the RST attack.

Countermeasure

Because TCP sequence number plays a vital role in this attack, the countermeasures described in the previous section are applicable here.

Land Attack

The land attack involves sending spoofed packet(s) with the SYN flag set to the victim's machine on any open port that is listening. If the packet(s) contain the same destination and source IP address as the host, the victim's machine can hang or reboot. In addition, most systems experience a total freeze up, where the mouse and keyboard become unoperational and the only solution is to reboot via a reset button on the system or by turning the machine off (Morris, 1985).

Countermeasure

Using a firewall to prevent spoofed packets can help reduce the effects of this attack.

SECURITY PROTOCOLS

In the previous section, we discussed the possible attacks on TCP and their countermeasures. In general, these attacks can be minimized by preventing unauthorized/malicious users from gaining access to the network. This is achieved using firewalls and proxies. In addition, cryptographic protocols such as SSH, SSL, and IPsec can also be used to control access to the network. Cryptographic protocols are security protocols that use encryption to encode data to ensure privacy.

Secure shell (SSH; Lonvick, 2004) is a protocol for secure remote login and other secure network services over an insecure network. The *SSH transport layer protocol* (SSH-TRANS) typically runs on top of TCP/IP. It provides a single, full-duplex, byte-oriented connection between client and server, with privacy, integrity, server authentication, and MITM protection. It may also provide compression.

Secure sockets layer (SSL; Dierks & Rescorla, 2004) is the leading security protocol on the Internet. One advantage of SSL is that it is application-protocol independent. A higher-level protocol can layer on top of the SSL protocol transparently. Developed by Netscape, SSL has been merged with other protocols and authentication methods by the IETF into a new protocol known as *transport layer security* (TLS). TLS has goals and features similar to those of the SSH transport and user authentication protocols. It provides a single, full-duplex byte stream to clients, with cryptographically assured privacy and

integrity and optional authentication. However, it differs from SSH in the following principal ways:

- TLS server authentication is optional: the protocol supports fully anonymous operation, in which neither side is authenticated. Such connections are inherently vulnerable to MITM attacks. In SSH-TRANS, server authentication is mandatory, which protects against such attacks.
- Both client and server authentication are done with X.509 public key certificates. This makes TLS a bit more cumbersome to use than SSH in practice, because it requires a functioning *public key infrastructure* (PKI) to be in place, and certificates are more complicated things to generate and manage than SSH keys. However, a PKI system provides scalable key management for your trouble, which SSH currently lacks.
- TLS does not provide the range of client authentication options that SSH does; public key is the only option.
- TLS does not have the extra features provided by the SSH component: the *SSH connection protocol* (SSH-CONN). SSH-CONN uses the underlying SSH-TRANS connection to provide multiple logical data channels to the application, as well as support for remote program execution, terminal management, tunneled TCP connections, flow control, and so forth.

SSH and SSL can protect TCP from session hijacking and injected data. However they cannot protect TCP from DoS attacks caused by spoofed packets.

IP security protocol (IPsec; Kent, 2004a; 2004b) is the security protocol developed by IETF as a part of Ipv6. It was designed to address security problems in Ipv4 such as session hijacking, spoofing, and snooping. As an encryption protocol, IPsec provides for secure encrypted data transmission at the network layer across the Internet. IPsec consists of two subprotocols:

- *Encapsulated security payload* (ESP) protects the IP packet data from third-party interference by encrypting the contents using symmetric cryptography algorithms (such as Blowfish, 3DES).
- *Authentication header* (AH) protects the IP packet header from third-party interference and spoofing by computing a cryptographic checksum and hashing the IP packet header fields with a secure hashing function. This is then followed by an additional header that contains the hash to allow the information in the packet to be authenticated.

ESP and AH can either be used together or separately, depending on the environment.

The IPsec headers (AH and ESP) can be used in transport mode or tunnel mode. In transport mode, IPsec can be used to directly encrypt the traffic between two hosts. In tunnel mode, IPsec can be used to build *virtual tunnels* between two subnets, which could be used for secure communication between two corporate networks. The latter is more commonly known as a *virtual private network* (VPN).

Because IPsec supports several modes of operation, both sides must first decide on the security policy and mode to use, with which encryption algorithms they wish to communicate, and what type of authentication method to use. Once an IPsec tunnel is created, all protocols—such as TCP, UDP, and HTTP—are encrypted between the two communicating parties regardless of whether they have built in security and encryption. IPsec can protect TCP from session hijacking, spoofing, and DoS attacks. Other chapters discuss IPsec, SSH, and SSL in detail.

CONCLUSION

TCP is a connection-oriented, reliable, byte-stream, transport-layer protocol. It is the most commonly used transport-layer protocol in the Internet. The recent demand for wireless communication indicates that wireless communication links will be an integral part of the future internetworks. Hence, it is essential to study how TCP can be extended for use over wireless links. In this chapter, we provide an overview of the challenges and the proposed schemes to extend TCP over wireless links. Communication in a network is prone to security threats; hence, the requirements of a secure network and common threats in a network are discussed. Some security threats exploit the vulnerabilities in a protocol to attack a network. A summary of security threats that exploit the vulnerabilities in TCP and the services provided by TCP is provided. Although security threats are much greater in a wireless network than in a wired network, some general precautions are suggested that can minimize the risk of those threats.

GLOSSARY

Access Point In a WLAN, the access point receives, buffers, and transmits data between the WLAN and the wired network infrastructure.

Active Open The host that initiates a TCP connection request performs an active open.

Blackout A period during which the mobile host is not connected to a base station.

Congestion Window The sender's perception of network congestion.

Connection Oriented Connection oriented implies that the path between two communicating parties is fixed for the duration of their communication, and this necessitates a set-up phase (connection) and a tear-down (disconnect) phase.

Fast Recovery Congestion control algorithm: a sender invokes the fast recovery after fast retransmit. This algorithm allows the sender to transmit at half its previous rate (regulating the growth of its window based on congestion avoidance), rather than having to begin a slow start.

Fast Retransmit Congestion control algorithm: when a TCP sender receives several duplicate ACKs, fast retransmit allows it to infer that a segment was lost. The sender retransmits what it considers to be this lost segment without waiting for the full time-out.

Forward Error Correction (FEC) By adding redundant FEC information to each frame, damaged frames can be recovered without retransmissions.

Handoff Latency The time for mobile IP to react to a mobile host moving from one cell to another.

Hard-State Transport-Layer Approach An approach for extending TCP to wireless links that encompasses all forms of splitting such that the end-to-end semantics may be sacrificed.

Land Attack An attack involving the sending of spoofed packet(s) with the SYN flag set to the victim's machine on any open port that is listening.

Man-in-the-Middle (MITM) Attack An attack where the attacker is able to read (and modify) messages between two parties without either party knowing that their communication has been compromised.

Mobile IP An extension to the Internet protocol proposed by the Internet Engineering Task Force (IETF) to support user mobility.

Passive Open The host that responds to a TCP connection request performs a passive open.

Pure Link-Level Approach An approach for extending TCP to wireless links that hides the unwanted characteristics of the wireless links from the higher layers.

Retransmission Ambiguity Denotes the TCP sender's inability to distinguish between an ACK for the original transmission from that of an ACK for its retransmission.

Sequence Number In TCP the sequence number denotes the number assigned to the first byte of data in the current TCP segment.

Sequence Number Attack An attack in which the attacker guesses the correct sequence number and can then generate his or her own TCP segments that will be accepted by the target host's TCP layer. It is also called blind IP spoofing.

Slow Start Congestion control algorithm used to gradually increase the size of the TCP congestion window. It operates by observing that the rate at which new packets should be injected into the network is the rate at which the acknowledgments are returned by the other end.

Soft-State Cross-Layer Signaling Approach An approach for extending TCP to wireless links in which the transport layer sender is aware of the wireless link.

Soft-State Transport-Layer Caching Approach An approach for extending TCP to wireless links that maintains a soft state of the network that is aware of the transport layer and uses caching to prevent the sender from unnecessary invocation of the congestion control mechanism in response to packet loss.

Spurious Fast Retransmits The fast retransmissions that occur as a result of the reordering of packets beyond the dupack threshold.

Spurious Time-Outs The time-outs that would not have occurred if the sender had waited "long enough."

SYN Flooding A denial of service attack that occurs when a server receives several incomplete connection requests.

TCP FIN and RST Bit Attacks The RST and FIN flag are used to perform a DoS attack.

TCP Session Hijacking This has the same effect as blind IP spoofing (sequence number prediction), but can be used for a number of different purposes. It is also called nonblind TCP/IP spoofing.

Window Size This specifies the size of the sender's receive window, that is, the buffer space available in bytes for incoming data.

INTRODUCTION

Current interest in wireless and cellular communications is aimed at high-speed data transmission. The fundamental system enhancements being developed will lead to many new mobile data services. Many different standards and systems have already appeared for cellular networks, wireless metropolitan area networks (MANs), wireless local area networks (WLANs), and personal area networks (PANs). Typical representatives, in the same order, are UMTS (universal mobile telecommunication system; <http://www.umtsforum.org>); WiMAX (<http://www.wimaxforum.org>, worldwide Interoperability for Microwave Access) standard, based on IEEE 802.16; and Wi-Fi (wireless fidelity) standard, based on IEEE 802.11 and Bluetooth. Although MANs, WLANs, PANs, and so forth are gaining significant momentum, cellular systems still offer the highest degree of mobility. Although cellular systems are the main carriers for mobile data services, mobile data services impose heavy demands on cellular systems, in particular with respect to security. For instance, if international roaming, such as in global standard for mobile communication (GSM), is to be implemented, the same security standard must be adopted by different operators in different countries. Because of the difficulty in such challenges, in the following we concentrate on cellular systems.

Some important facts and implications can be seen when looking at the history of cellular networks. To develop that thought, we analyze different generations of cellular systems using typical representatives from a European perspective. The list of systems mentioned in this review is incomplete, because our intention is to show the driving forces for cellular systems and the implications for future systems, with particular focus on mobile data services. The developments in cellular communications can be categorized into four major generations as illustrated in Figure 1.

The first significant shift was the transition from an analog system (first generation, 1G) to a digital system (second generation, 2G) both of which primarily supported a single service: voice. The second generation

cellular systems also supported data services to a limited extent—the maximum data rate being approximately 10 kbps. The enhanced data rates for global evolution (EDGE) standard is considered a 2.5-generation system because it allows data rates up to 384 kbps. However, the spectrum efficiency and flexibility of second-generation systems are only moderate, and the deployment costs for the operators are high [e.g., one radio frequency (RF) unit in GSM can only handle eight voice users, whereas an RF unit in UMTS is able to serve about 70 voice users]. Data rates, spectrum efficiency, flexibility, and deployment costs were the main drivers for entering into the specification of third generation cellular systems. It was obvious that the new paradigm, wireless multimedia traffic, would have a significant effect on the air interface technology. Three factors are essential in this context: (a) high data transmission, (b) data rate scalability, and (c) adaptability to channel asymmetry with respect to UL and DL traffic. High data-rate transmission is necessary for services such as video transmission. Data rate scalability is required for the numerous supported multimedia services, each of which can demand a different transmission rate (Welzl, Franzens, & Mülhäuser, 2003), and adaptability to traffic asymmetry is required because, unlike voice, many data services impose different loads on the UL and DL channel. (For example, file downloads from the Internet require high capacity in DL direction and hardly any capacity in UL direction; Mohr, 1999; *Book of Visions*, 2001.) The air interface must be tailored to maximize efficient use of the radio spectrum.

With the advent of third-generation cellular systems it was possible for the first time to substantially increase the transmission rate on the air interface. The original goal was that third-generation (3G) cellular systems should achieve a maximum data rate per user of 2 Mbps. Data-rate scalability in 3G cellular systems is accomplished by use of CDMA (code division multiple access) technology. CDMA avoids splitting the radio resource into frequency sub-bands and time slots. All users transmit continuously using the entire channel bandwidth. The user data-rate is adjusted by a user-specific spreading code. The length of

1st Generation	2nd Generation	2.5 Generation	3rd Generation	4th Generation
NMT	GSM	EDGE	UMTS	?
analog, voice	digital, voice	digital, voice + packet data	digital, voice + high speed packet data	digital, voice + high speed packet data + ultra high data rates?

Figure 1: Generations and paradigm shifts in cellular communications.

the spreading code is inversely proportional to the data-rate. As a consequence, the flexibility of assigning variable data-rates is significantly improved when using CDMA. In UMTS, transmission rate enhancements and adaptability to channel asymmetry is supported by technology upgrades such as HSDPA (high speed downlink packet access). Currently fourth generation (4G) wireless system concepts are being discussed that should enable data rates up to 1 Gbps while at the same time maintaining data-rate scalability and support of channel asymmetry. This will primarily be achieved by multicarrier transmission techniques, network hierarchies and hybrid *ad hoc* and cellular networks.

In the past a new generation of cellular systems was launched about every 10 years. It is interesting to note that the development of the target data rate of each generation over the past 20 years is approximately equivalent to doubling the data rate every 18 months. This complies with Moore's law from microelectronics, which is not surprising because with increased signal processing capabilities, techniques that help to increase spectrum efficiency can be supported, such as antenna-array signal processing. Furthermore, the higher the spectrum efficiency, the higher the possible data rate for a fixed bandwidth.

In the near future, numerous mobile data-based services will be supported that will revolutionize the ways in which businesses, individuals, and machines operate. Wireless Internet, teleworking, wireless and interactive television, car-to-car communication, telemedicine and teliagnostics, mobile offices, and wireless home networking are only a few examples. So far, wireless services have been limited primarily to humans. Now the objective is to allow communication with and between everything and anything (ubiquitous services). If everything that moves becomes an object for mobile communication, the number of mobile terminals will increase dramatically and lead to much greater traffic.

In Japan, the leading country for mobile data services, the mobile Web browsing service is already widely used. The number of subscribers for this type of data service was 48.5 million (72% of mobile subscribers) at the end of 2001 and is still growing. Market analyses (Mohr, 1999) have predicted that in Europe more than 90 million mobile subscribers will use mobile multimedia services in the year 2010 generating about 60% of the traffic in terms of transmitted bits. This can be attributed to the effect that the majority of electronic and communications devices and digital communication systems [e.g., cellular, broadcast, fixed wireless access, wireless LANs, Bluetooth, xDSL (digital subscriber line), satellite, etc.]

are either already digital or in the process of being transformed into digital systems.

In the private sector, personalization of information, such as leisure and entertainment preferences, stock portfolio management, and multimedia messaging services, are key drivers for mobile data services. In the business sector, WLAN infrastructures, in combination with wireless MAN infrastructures such as WiMAX, offer a cost-efficient alternative to wired networks. Because of such uses, current and future mobile data services might carry very sensitive information. An important quality criterion in mobile communication is global availability. This, in fact, was a key prerequisite that guaranteed GSM (<http://www.gsmworld.com>) its global success. Service availability "everywhere" and for "everyone," however, leads to great challenges for security, because general availability is clearly in contradiction with security. Personalized information and sensitive company data should not be accessible by "anyone" just because the information is available "everywhere." As a consequence, the more mobile data services become an integral part of our everyday life, the more important security issues will become. Therefore, in enhanced 2G systems, and in 3G systems, an entirely different approach was taken to overcome the security weaknesses of past generations.

A new set of cryptographic functions, globally designated as *Milenage*, were defined. The functions are transparent, as opposed to being secret such as the A3 and A5 algorithms in GSM (Gindraux, 2002; 3rd Generation Partnership, 2003b). The evolution from voice to data-based services results in another important issue involving global roaming. The huge variety of services and the possibility for operators to differentiate based on services makes it impossible to test all roaming partners' networks and to establish a common security standard (Roos, Hartmann, & Dutnall, 2003). Advanced and flexible security mechanisms will be necessary to reduce risk and enable private communication, commercial transactions, and m-business. Fortunately, many security mechanisms can be adopted from current wired Internet technology, because the underlying protocol, transmission control protocol/Internet protocol (TCP/IP), will be the same for both fixed and mobile data services. Therefore, in this chapter we concentrate on a different aspect. Mobile data services all rely on electromagnetic waves to carry information, and this is the key property that distinguishes them from existing Internet-based fixed line services. We therefore discuss particular air interface technologies and specific algorithms that lead to efficient spectral usage by mobile data services. Specifically, we stress the

physical layer, the data link layer, and radio resource management. (We do not consider the ISO OSI model, because it is generally realized that this model is not entirely suitable for wireless communications; Lin, Zhou, & Giannakis, 2004.) For the higher-layer protocols and algorithms, the interested reader is referred to other chapters in this *Handbook*. Security-enabling functions, in the sense of mechanisms against fraud and misuse, such as ciphering and authentication, primarily reside in those higher-layer functions. Therefore, our main purpose in this chapter is to provide necessary background information on the underlying air interface technologies that serve as key enablers for mobile data services and to highlight how those technologies can support security protocols.

Reliable high data-rate transmission requires techniques that enhance the bandwidth efficiency of a cellular system because bandwidth is scarce and expensive. As a consequence, particular attention has to be paid to the physical limitations of the wireless channel. Therefore, we discuss spectral efficiency and interference problems.

In the past, including the third generation, air interfaces were predominantly designed based on link-level, that is, physical channel, requirements. The requirements of the actual mobile services were clearly neglected—primarily because it was unclear which mobile data services would be used (“killer applications”). However, the initial problems that systems such as UMTS were facing showed that it is essential to include the mobile service requirements when designing an air interface. Therefore, in this chapter the air interface requirements are predominately derived from service properties. These requirements are discussed in the third section. Because of QoS and security requirements, the assignment of resources is an important issue, which is covered in the fourth section.

SPECTRAL EFFICIENCY AND INTERFERENCE

In some countries, such as the United Kingdom and Germany, the spectrum for the third-generation cellular system was auctioned. In Germany, for example, the operators paid approximately US \$ 50 billion for 2×60 MHz + 20 MHz of frequency spectrum. About the same amount of money is assumed to be required to build the network infrastructure.

Current wireless-access technology for cellular operation allows the transmission of about 0.5 bits per Hz bandwidth, per cell. With new technological enhancements such as multiple-input multiple-output (MIMO) transmission, it is possible to improve this factor by an order of magnitude, which directly translates into an order of magnitude increase in revenue per bit, given constant service costs for the subscriber. In addition, because usually more than one user requests a particular service at any given time, a mobile communication system has to support several simultaneous high-data-rate transmissions. As a consequence, the bandwidth required would soon exceed physical limits. With 100 Mbps per user, 10 simultaneously active users per cell, and 0.5 bits/Hz/cell, the bandwidth required is 2 GHz per operator. Assuming, on average, four operators, this amounts to 8 GHz of radio frequency spectrum [neglecting guard bands and

duplex distance in the case of the FDD (frequency division duplexing) technique], compared with 140 MHz in 3G systems.

In summary, the bit-per-Hertz cost factor and the requirement to transmit with very high data rates are the two main driving forces for increasing bandwidth efficiency. The efficiency of bandwidth usage in a cellular system is known as its spectral efficiency and is defined as

$$\kappa = \frac{\text{total traffic}}{\text{total bandwidth} \cdot \text{total area}}. \quad (1)$$

It can be seen that the spectral efficiency of a particular system is not determined by the traffic carried within a particular isolated cell, but rather by the traffic carried within some given area covered by several cells. In that way, cochannel interference (CCI) can be accounted for. The modified normalized Shannon channel capacity is introduced in the following to point toward potential techniques that might be used to increase spectral efficiency:

$$C \propto \min(R, T) \log_2 \left(1 + \frac{SINR}{T} \right) \quad [\text{bits}/(\text{s} \cdot \text{Hz})]. \quad (2)$$

Here R and T are respectively the number of antennas at the receiver and at the transmitter, and $SINR$ is the signal-to-interference-plus-noise ratio. This effectively takes account of both CCI and adjacent channel interference (ACI), and it assumes that interference is Gaussian. Equation (2) holds under the conditions of non-line-of-sight rich scattering channels. Moreover, it assumes ideal modulation and perfect channel coding. Therefore, Eq. (2) can be considered as an upper bound of spectral efficiency. Because in Eq. (2) multiple antennas at the receiver and at the transmitter are considered, we have a MIMO system. The $SINR$ is assumed to be the same at each receiving antenna. First, it can be observed that in a MIMO system the supportable traffic per cell increases linearly with the minimum number of antennas at either the transmitter or the receiver. This is intuitively clear because with multiple antennas, simultaneous transmissions can be realized. If cross-interference is then cancelled, R or T times, the number of bits can be transmitted per unit time. (This is analogous to having R or T pairs of wires in a cable.) Second, the supportable traffic per cell increases logarithmically with increasing $SINR$. The $SINR$ can be improved either by augmenting the transmitted power, provided that the interference doesn't rise proportionally, or by reducing the noise and interference power in the system. To sum up, Eq. (2) shows that there are three basic means that can be used to improve the spectral efficiency of a wireless system:

- using multiple antennas at the transmitter and/or at the receiver,
- increasing the received signal power level, and
- eliminating interference and noise.

Each of these is linked to specific technical concepts that are being intensively studied. For example, in combination with appropriate interference cancellation techniques, MIMO will increase the number of transmitted bits per unit time because of parallel data transmissions. Further, ad hoc communication will on average result in

increased received power because of short hops, multiuser detection will reduce multiuser interference, and dynamic channel assignment will help to avoid CCI and thereby allow frequency reuse factors of about one in a cellular system.

SYSTEM REQUIREMENTS

Data services impose entirely different requirements on the air interface than voice. These requirements affect the physical layer as well as the data link layer and the entire radio resource management. (The latter two are referred to as the system level.) For instance, the particular modulation scheme (physical layer) affects the effective bit rate, and the packet scheduling (radio resource management) will have an impact on the delay. In turn, delay and throughput will jointly determine the QoS. Modulation and data scheduling are usually independent of each other because they are located at different levels of the protocols stack. This has proven to be a drawback, and therefore the key to solving these issues lies in joint layer considerations. Joint layer optimization requires new approaches and system solutions. Those high-level system functions that are affected most by joint layer considerations are discussed in this section.

Multiuser Access

The first three generations of mobile radio were based on a model of multiple access in which the radio resource was divided into discrete channels. These have variously made use of FDMA (frequency division multiple access), TDMA (time division multiple access), and CDMA. These are all well matched to systems supporting real-time, delay-constrained services such as voice. This was logical for services in which all users had the same bandwidth requirements and in which this represented a small fraction of the total bandwidth. Moreover, such were the delay constraints that a rigid structuring of the multiple access scheme was necessary.

Arguably, the existing (or soon-to-be-existing) generations already support these services, so that any new air interface for high-speed mobile data services will usefully be optimized for non-real-time, or packet, services. However, the requirements for these air interfaces will be such as to still allow limited delay performance as might be required, for example, for video. This poses great challenges on the air interface design. Moreover, in conventional cellular systems the available spectrum is subdivided into several partitions. Different operators obtain some fraction of the spectrum (either by a beauty contest in which a government controls the licensing of spectrum or by spectrum auction). With this spectrum partitioning, it is unavoidable that some adjacent carriers belong to different operators. Because in principal two operators do not coordinate their cellular network planning, adjacent channel interference is a severe issue unless large guard bands are introduced between adjacent carriers. Needless to say, these guard bands cause a loss in spectrum efficiency. As a consequence, bandwidth per channel has to increase in current and future high-speed mobile data services. Because of the particular filters required, the guard bands between adjacent carriers increase proportionally to the

channel bandwidth. This clearly results in unwanted loss of spectrum efficiency—in particular, if one operator requires several channels because of the use of frequency reuse distances greater than one.

By the same reasoning, the duplex distance increases when using the FDD method. This means that the separation between UL and DL transmission is in the GHz range for a data rate up to 1 Gbps. It is obvious that finding paired frequency spectrums for such systems is very difficult, if not impossible. Therefore, it seems more advantageous, or even necessary, to avoid spectrum partitioning and to allow all operators to share common, very large, single-frequency resources. Intelligent DCA algorithms, scheduling algorithms, and medium access control (MAC) protocols, that is, intelligent radio resource management algorithms, are necessary to allow for fair management of the limited frequency resource.

In the case that only a short message has to be sent, for example an ARQ (automatic repeat request) in the UL, the message might either be spread across the entire bandwidth, thereby enabling a number of parallel transmissions (single-carrier transmission), or the transmitter might use a subset of subcarriers in the case of multicarrier transmission, such as OFDM (orthogonal frequency division multiplexing). With either approach it is possible to retain high bit granularity, which allows for high spectral efficiency.

In such a packet system the optimum approach for delay-constrained services would be to transmit the packets to the users in a single queue, with each user occupying the whole bandwidth for a short period. The more conventional approach of dividing the available bandwidth into parts and using these for packet data dilutes the statistical multiplexing advantage. Furthermore, the conventional approach causes multiuser access interference (MAI), which reduces spectral efficiency. Another reason why multiple access was needed in earlier systems was to make the bandwidth of the transmitted signal significantly exceed that of the source data. This was desirable to obtain multipath diversity in the radio channel. In future systems the source bandwidth will be large enough for many radio environments to provide the multipath diversity inherently. A suitable form of modulation could be OFDM, for example.

For these reasons, a wireless communication system for mobile data services should be based on pure queued packet transmission. In this case, random medium access is provided by using the CSMA (carrier sensing multiple access) protocol with random back-off strategies. New spectrum efficient medium access strategies exploiting the channel reciprocity provided by a TDD-based air interface are discussed in a later section. In the queued transmission scheme the BSs (base Stations), or MSs (mobile Stations) respectively, transmit the packetized data in succession on a single common channel. The packets will be output from a prioritized queue generated from the available traffic. A packet scheduler will be deployed to ensure that all QoS constraints are met.

Duplexing

With an ever-increasing demand for packet data services such as Web browsing and media streaming, data traffic

on the air interface will soon exceed the amount of voice traffic. Although voice traffic puts symmetric loads on the UL and DL, this clearly does not hold true for packet data traffic. In the latter case, the traffic load in the two directions might differ significantly. For example, short ARQ messages might be sent in the UL direction, with large packets sent in a file download session. In general, data services require significant channel asymmetry with respect to UL and DL traffic—at least on an instantaneous basis. For IMT (International Mobile Telecommunications) 2000 systems the ITU (International Telecommunication Union) has predicted that, in 2010, on average the spectrum demand for the DL will be 300 MHz and for the UL 140 MHz. Estimates of the UMTS Forum differ even more, with 380 MHz for the DL and 160 MHz for the UL (*Book of Visions*, 2001). A further important observation in that study is that, with the availability of increased data rates for multimedia services, the asymmetry is continuing to grow. These numbers are average figures and do not provide a picture of the instantaneous traffic asymmetry. It is clear that for services such as video upload, the traffic imbalance is in favor of the UL; that is, significantly more resources are required in the UL direction.

In view of this, methods such as HSDPA used in UMTS only partially solve the problem of increasing traffic asymmetry because this method, for example, does not support fast file uploads. From this example it can easily be seen that the duplexing technique for mobile data services plays an important role. Therefore, in this section the different duplexing techniques are discussed and their relevance for data services are pointed out. In this context and based on the previous discussion, it should be emphasized that the duplexing technique is of much greater importance in such a system than any particular multiple access method.

1) *Frequency Division Duplexing (FDD)*: The FDD technique is primarily used in first, second and third generation cellular systems. This can be attributed to the fact that voice was the predominate service in those systems. Voice has the following basic properties. First, it is a symmetric service. Second, it is a real-time service that does not tolerate large delays. Both properties make the FDD technique an ideal choice. The reasons are that the transmission on both links is continuous and that the bandwidths required for the UL and DL channels of a full-duplex link are identical. This property of FDD, however, results in a significant limitation for asymmetric services because in this case the duplex distance for each channel would have to be different.

Figure 2 highlights this effect. If the bandwidth of channel $f_1^{(dl)}$ is different from the bandwidth of $f_2^{(dl)}$, the duplex distance for the channel, $f_1 = f_1^{(dl)} + f_1^{(ul)}$, would be different from the duplex distance of channel, $f_2 = f_2^{(dl)} + f_2^{(ul)}$.

Moreover, the dynamic adaptation of UL and DL bandwidth would require adjustable filters for the UL and DL channels. Both these requirements would result in very complex transmitters and receivers.

In addition, the fact that two separate frequency carriers are used for UL and DL traffic results in different channel characteristics for both links. As a consequence, the BS and MS need to estimate the channel properties. This creates overhead, which reduces the spectral efficiency and causes battery drain in the MS.

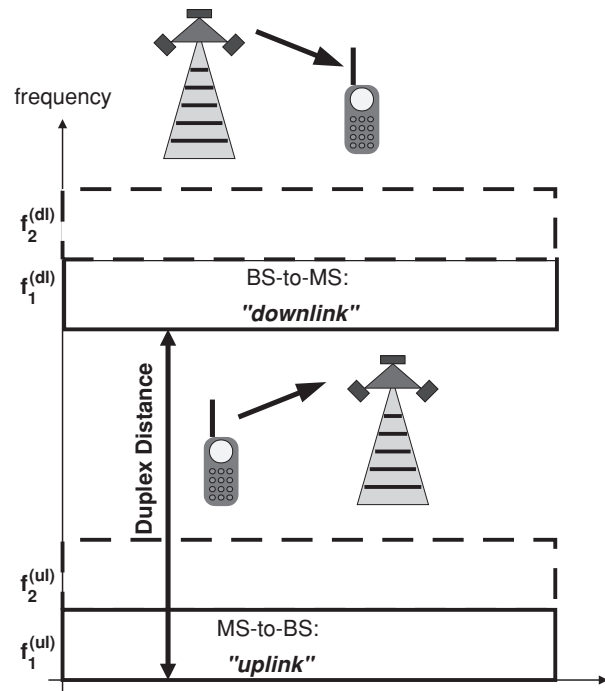

Figure 2: The FDD principle—different frequencies are used for uplink and downlink traffic. A fixed duplex distance between uplink channel and downlink channel is required. This renders the support of channel asymmetry difficult.

2) *Time Division Duplexing (TDD)*: The TDD mode has primarily been used in hot-spot wireless data systems such as Bluetooth and WLAN. Recent developments such as the Chinese 3G standard TD-SCDMA (time division-synchronous code division multiple access) demonstrate that the TDD technology can also be used in cellular systems. The main advantage of TDD is its inherent flexibility in supporting traffic asymmetry. This can be explained with the aid of Figure 3. The UL and DL are arranged at the same frequency carrier and the two links are separated in time. The data rate on each link is proportional to the time duration, given a fixed channel bandwidth. Therefore, the level of asymmetry can be adjusted dynamically by changing the “switching point.” This means that the time duration for each link can be changed without affecting the channel bandwidth. This is a very important property for mobile data services with different data-rate requirements.

In addition to its flexible support of traffic asymmetry, only the TDD mode offers an efficient and flexible support for ad hoc, multihop, or relaying communication. When a MS is in the ad hoc, multihop, or relaying mode it uses both BS functionality as well as MS functionality. This means it receives UL information from a neighboring MS and sends information in the DL direction to another neighboring MS. As a consequence, an MS needs to transmit and receive at the same carrier frequency, which can only be done using the TDD mode, as described earlier. Ad hoc, multihop, or relaying functionality will become a key property of future wireless systems that carry mobile data services. Therefore, a hybrid form of cellular and ad hoc mode operation may offer the most promising solution

Figure 3: The TDD principle—uplink and downlink is at the same carrier frequency, but separated in time. Therefore, channel asymmetry can be easily supported by varying the *switching point*. In addition, if uplink and downlink transmission is within the coherence time of the channel, the channel is said to be reciprocal. This property is utilized to develop simplified receivers, for example, as used in prerake or joint transmission (Baier, Meurer, Weber, & Tröger, 2000).

to meet the requirements for high data-rates, highly unbalanced UL and DL traffic, and heterogeneous user distribution in future wireless systems. This stems from the fact that in cellular systems with high data-rate transmission, the cell radius shrinks significantly, which, in turn, would require a large number of BSs to avoid coverage “dead zones.” This problem already exists in UMTS, and it will become more important with the envisaged high data rates of next generation wireless systems.

Because in TDD, the UL and DL use the same radio frequency channel, both directions experience the same propagation conditions. This results in channel reciprocity, provided that the TDD frame length is shorter than the coherence time of the channel (Ojanpera & Prasad, 1998).

Channel reciprocity has several implications for the system design. First, channel reciprocity can be exploited in the design of receiver structures. A notable example is the prerake architecture, first described by Esmailzadeh and Nakagawa (1993) and depicted in Figure 4. By using the prerake technique it is possible to retain the

advantages of the rake combining, and at the same time use a simple single-path receiver at the mobile unit. The channel will only be estimated once, at the BS. With the knowledge of the channel impulse response, the BS performs the rake combining function *before* transmission (hence prerake). Thus, the output signal of the prerake combiner is the result of the convolution of the spread spectrum signal and the time-reversed channel impulse response. Because it is assumed that the channel does not vary between the reception and transmission periods, a simple receiver structure can be used at the mobile unit, ideally consisting only of a matched filter. Therefore, the signal processing and signaling effort is reduced as compared with single link transmission in a system that uses FDD.

In the previous paragraphs a number of advantages were mentioned that demonstrate that the TDD technology is ideally suitable for mobile data services. The most important disadvantage is described in the following. If the TDD interface is used in a multiple cell environment, severe interference problems can occur (Povey, Holma, & Toskala, 1997). These problems arise primarily because TDD is exposed to additional interference mechanisms (in comparison to FDD). These mechanisms are illustrated in Figure 5. This figure shows a simple cellular structure consisting of two adjacent cells.

In each cell a different level of asymmetry is used. This causes asynchronous TS overlaps, which has a significant impact on the total interference. In this context, the BSs not only interfere with the neighboring MSs, and vice versa (FDD equivalent interference scenario), but also with other BSs. Similarly, MSs interfere with adjacent MSs. The latter interference scenarios are depicted in Figure 5 (BS → MS and MS → BS interference is left out for clarity).

In particular, the interference between MSs can be severe given that the distance between two MSs at the cell boundary can be very small. To avoid BS ↔ BS and MS ↔ MS interference, the frames must be synchronized and both cells need to use the same level of asymmetry, that is, in all neighboring cells a BS or MS must transmit and receive at the same time. This clearly results in a significant limitation, which penalizes the most

Figure 4: Block diagram of a prerake receiver. The signal to be transmitted in the downlink is convolved with the impulse response of the channel obtained from uplink transmission. As a consequence, the receiver at the mobile unit can be very simple (e.g., a matched filter). This particular prefiltering requires almost perfect correlation of the uplink and the downlink channel, which, for example, is provided by a TDD based air interface because uplink and downlink transmission is at the same radio frequency.

Figure 5: TDD specific interference scenarios in cellular TDD systems with cell-independent channel asymmetry. A mobile station can interfere with another mobile station. Similarly, a base station can interfere with neighboring base stations.

important advantage of TDD in adapting to cell-specific traffic asymmetries. It has been shown that dynamic channel assignment algorithms are an effective means to solving this interference issue in a cellular TDD system (Punt, Sparreboon, Brouwer, & Prasad, 1998; Chen, Yoshida, Murata, & Hirose, 1998).

3) *Hybrid Duplexing:* The basic duplexing techniques, FDD and TDD, can be combined to generate hybrid duplexing solutions. An example of hybrid duplexing is depicted in Figure 6. In this example, the FDD radio frequency bands have different bandwidths, motivated by the fact that the usage of an air interface that primarily supports mobile packet services is highly unbalanced with respect to UL and DL. To be able to flexibly assign this asymmetry to either the UL or the DL, the link direction is not assigned to a particular radio frequency band. Therefore, TSs are introduced and FDD link directions may vary from TS to TS. For example, at the second TS, the UL and DL assignments are interchanged in Figure 6, that is, the channel asymmetry is now in favor of the UL as opposed to the DL in the first TS. Consequently, each FDD frequency band resembles a TDD air interface with each having a different bandwidth. A hybrid duplexing solution was used in the TDD underlay (Haas & Povey, 1999) concept that was proposed for UMTS.

4) *Summary:* An air interface that efficiently supports mobile data services is expected to use the TDD mode. In fact, WLAN systems have successfully demonstrated the deployment of TDD in a hot-spot environment for packet data transmission. However, if the TDD mode is used in a cellular environment, some TDD-specific issues have to be addressed. Because UL and DL transmissions use the same frequency band, additional interference scenarios might exist, namely MS-to-MS and BS-to-BS interference. The extent of these depends on cell-specific channel asym-

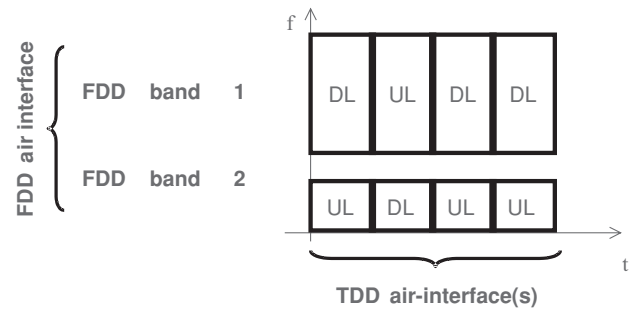

Figure 6: An example of hybrid duplexing in which one FDD radio frequency band has three times the bandwidth of the second FDD frequency band. It accounts for traffic asymmetry imposed by future mobile data services. Each frequency band can either be used for UL or DL. This finally results in two radio frequency bands of different bandwidth operated in the TDD mode.

metry and synchronization. These additional interference sources may cause severe capacity losses. But simple DCA algorithms might be found that avoid capacity losses. In fact, it has been demonstrated that in some cases capacity in a cellular TDD system can even be higher than in an equivalent FDD system (Haas, McLaughlin, & Povey, 2000).

Hybrid duplexing techniques can be considered as multiple TDD air interfaces.

Link Adaptation

Wireless and cellular system engineering is dominated by the challenging demands set by the communication medium. In particular, multipath propagation and Doppler effects cause frequency and time dispersion respectively. Hence, the amplitude of the received signal changes with location and with time. The variation can be several tens of decibels. Clearly, this affects the transmission performance significantly. Several trade-offs determine the performance of the communication link. The most important of these is spectral efficiency versus bit error performance. In the past, transmitters and receivers were sized for average channel characteristics. However, channel variation can be significant as indicated. Therefore, for most of the time the transmission technology is oversized (in favor of low bit-error performance), resulting in poor spectral efficiency.

The challenge is to find adaptive transmitters and receivers that adjust themselves to the varying nature of the channel. Modulation, coding, and power control are the key system functions that are affected by link adaptation. Adaptive modulation (Wong, Yeap, & Hanzo, 2000) changes the modulation order dependent on the channel state information (waterfilling). Incremental redundancy, or hybrid ARQ type II protocol (Sesia, Caire, & Vivier, 2004; 3rd Generation Partnership, 2004), changes the code rate, that is, the redundancy, depending on the channel state information, and power control adjusts the transmit power depending on the channel state information. All these techniques aim at flexible and robust spectrally efficient cellular systems. They all require feedback

information. Hence, the feedback must be obtained in a timely manner; otherwise, the efficiency will suffer.

Because the overall system performance does not depend just on a single link or a single cell scenario, additional effects such as CCI, ACI, and MAI need to be considered. In this context, link adaptation can be particularly problematic for a packet system, because the transmitter needs feedback of the path loss and the interference environment, and possibly also the bit error performance at the peer entity, to set the power, the modulation order, or the channel coding. In addition, power control and adaptive modulation are mutually dependent because a change in transmitter power would alter the overall interference scenario. However, adaptive modulation with constant transmitter power maintains a fixed interference environment. Each transmitter can regularly transmit a signature that will allow its received power to be measured in the presence of interference from the other transmitters at each respective receiver. The mobile terminal can thus measure its available $SINR$ and deduce an available bit rate for that particular link. In doing this the receiving terminal can use many criteria, including the history of $SINR$ fluctuations, the required QoS, and the resources available at the terminal (e.g., the number of antennas or the processing capability). This approach is advocated in (Chawla & Quia, 1998), where it is shown that adaptive modulation without power control provides close to the optimum achievable performance.

Thus, for example, the mobile terminals will signal the available DL bit rate to the BS on the UL on a regular and frequent basis. This signaling need not necessarily be related to any specific expectation of data being received on the DL. Rather, it allows the BS to send data to that mobile unit at the correct rate whenever it has some to send. If a mobile terminal has not received data from the BS for awhile, the signaling rate can be reduced. Reliability can be preserved by underestimating the available bit rate. Whenever a packet is received from the BS at that MS, it then increases its bit transmission rate until a timeout period after the last packet is received. Additionally, bit rate change requests could be event driven, so that a static terminal would not inform the BS of the current available bit rate if this had not changed significantly. This, again, reduces the signaling traffic.

Alternatively, the modulation order can be fixed, and then to ensure the required $SINR$, the transmitter power has to be adjusted. The disadvantage to this is that increasing the transmitter power at one location results in greater interference at all nearby locations. As a consequence, the transmitter power for those mobiles has to be increased, which might result in a ping pong effect. This problem would be avoided by using adaptive modulation as described.

RADIO RESOURCE MANAGEMENT

The growth of wireless Internet access, and wireless text, picture, and video messaging services, suggest that fourth generation cellular mobile communications must

adequately support a plurality of packet data services, with very high data rates, bursty traffic characteristics, heterogeneous QoS requirements, and traffic load asymmetry between cells and between the UL and DL in each cell. All the emerging mobile data services will have different QoS constraints. These need to be mapped onto a given radio frequency resource. Therefore, radio resource management is a key technique for efficient packet radio transmission in a wireless system. In addition, radio resource management has to deal with the particular constraints of radio transmissions, such as interference, which is discussed in the next section.

Moreover, ad hoc communication between mobile nodes requires decentralized radio resource management algorithms as opposed to centralized algorithms in conventional systems. Radio resource management can be subdivided into three main tasks: (a) DCA, (b) MAC protocols, and (c) packet scheduling. DCA algorithms for mobile data services, MAC algorithms, and packet scheduling techniques are discussed later.

Interference Considerations

From the definition of spectral efficiency it is clear that cochannel interference affects the spectral efficiency of a system, and is, therefore, an important parameter for MAC protocols and DCA algorithms. Furthermore, mobile data services require a transmission technology that caters for potentially very high data-rate transmission, variable UL/DL asymmetry, and so forth. Thus, the aim is to identify a technology that is resistant to interference, and which at the same time fulfills the requirements of mobile data services.

OFDM is viewed as a promising air interface technique in combination with TDMA to provide very high data rates for mobile data services, whereas TDD is considered the most efficient way to support UL/DL load asymmetry in a cellular mobile network. The potential disadvantage is that the TDD technology might result in additional interference in a cellular system that has 100% frequency reuse. In that case, the same radio frequency spectrum is used in all cells, and thus, no frequency planning is required. The reasons for a 100% frequency reuse are twofold: (a) It permits high spectral efficiency and (b) it permits high trunking efficiency for support of bursty packet data services.

Additional interference scenarios in TDD occur if neighboring cells have different UL/DL asymmetries. This can cause very high MS-to-MS and BS-to-BS intercellular interference in addition to the BS-to-MS and MS-to-BS intercellular interference scenarios known from conventional cellular systems (see Figure 7, for example). This situation is exacerbated in OFDM/TDMA-based systems, which have no processing gain from spreading but rely on powerful channel coding. Both BS-to-BS and MS-to-MS interference can be referred to as same-entity interference, whereas BS-to-MS and MS-to-BS interference is other-entity interference. In a TDD-based system with different UL/DL ratios in neighboring cells, both types of interference occur. In addition, both types of interference occur if slots in neighboring cells are not synchronized.

Figure 7: In a TDD-based cellular system with a frequency reuse of one, interference can potentially be significant because of the existence of mobile-to-mobile interference.

In general, slot synchronization in a TDD system affects the amount of same-entity and other-entity interference as is illustrated in Figure 8. This figure shows a possible TS arrangement between two cells. The model is composed of four entities: BSa, MSa, BSb, and MSb, where BSa and MSa, and BSb and MSb, respectively, form a communication link. That is, if BSa transmits, then MSa receives and vice versa. Lack of slot synchronization is modeled by an arbitrary time offset, t_{off} . This time offset is normalized by the TS duration t_{slot} , yielding the synchronization factor,

$$\alpha = \frac{t_{off}}{t_{slot}}. \quad (3)$$

Because of the frame misalignment, BSa and BSb interfere with each other, thereby creating I_{bb} . Similarly MSa and MSb interfere with each other and generate I_{mm} . Both types of interference have previously been categorized as same-entity interference. It can be found that same-entity interference is proportional to α . Similar properties can be found for other-entity interference, except that

Figure 8: Interference in a TDD system depends on slot synchronization. If the TSs in neighboring cells are time synchronized, that is, $t_{off} = 0$, the interference sets $\{I_{bb}, I_{mm}\}$ and $\{I_{bm}, I_{mb}\}$ will be disjointed.

it is proportional to $1 - \alpha$. Hence, as the synchronization factor α increases, other-entity interference diminishes, but same-entity interference increases, and vice versa. If $\alpha = 1$, only same-entity interference exists and similarly, if $\alpha = 0$, only other-entity interference exists. The consequence is that interference is present during the entire receive period. Because other-entity and same-entity interference can be considered as independent (because of different interference sources), the magnitude of each type of interference can vary greatly. Therefore, it is interesting to see whether it is possible to exploit the fact that same-entity interference and other-entity interference are different to minimize interference by altering frame synchronization. This particular property of TDD-based systems is exploited in DCA algorithms and MAC protocols, which are explained further in the following sections.

DCA Algorithms

In a cellular network a limited number of resources have to be managed in a way so as to enable a given user population to be served satisfactorily. This includes radio resource allocation methods that mitigate the detrimental impact of MAI, CCI, and ACI. Two main techniques can be distinguished (Ahlin & Zander, 1998; Cox & Reudink, 1974):

- static or fixed channel assignment (FCA) techniques and
- DCA techniques.

In the case of FCA, a fixed proportion of the available bandwidth is allocated to one cell. The same fractional bandwidth is only used in cells that are separated by a minimum distance. The frequency reuse distance ensures that CCI does not deteriorate the system performance greatly. However, it is well known that FCA techniques do not result in the most efficient use of the radio frequency spectrum. In contrast, DCA techniques enable a cellular system to adapt flexibly to different load situations, thereby increasing the throughput and decreasing the call blocking (Cox & Reudink, 1974). In addition, frequency planning can be avoided. An important issue, however, is to ensure that the DCA algorithm does not cause the system to become unstable. In this context, it is reported that under high-load conditions DCA algorithms can perform

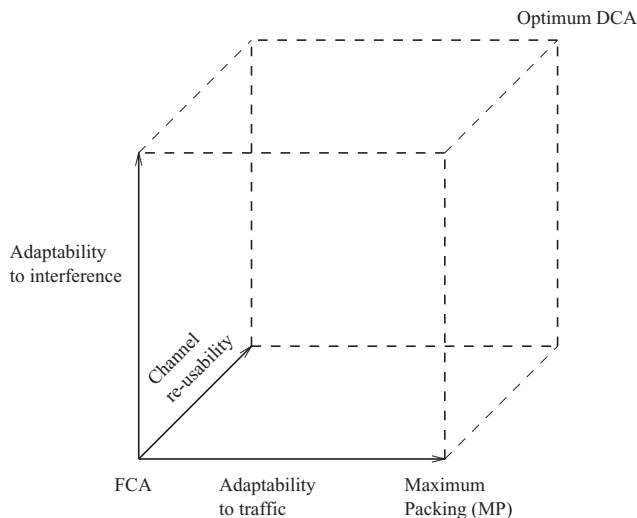

Figure 9: Three-dimensional classification of DCA algorithms.

worse than FCA techniques, because of continuous channel reassignments (Beck & Panzer, 1989). Consequently, systems have been designed in which FCA and DCA techniques are combined (Kunz, 1999; Tan, Soh, Gunawan, & Soong, 1989). As a result, for example, a subset of channels is assigned in a fixed way and the remaining channels are allocated to a common pool. A DCA algorithm uses the common pool from which it “borrows” channels to allocate them to cells where heavy traffic occurs. This way, the number of channels of a cell can be increased dynamically, but there is still a fixed number of channels, which ensure a certain QoS in situations where the entire network is heavily loaded.

A classification of different DCA approaches was made by Beck and Panzer (1989), which is repeated here for convenience (Figure 9). In the illustration, different DCA strategies are represented by points in the space, except the origin, which represents the FCA scheme. The three axes represent different optimization criteria.

A DCA algorithm can be designed to optimize the number of simultaneously active MSs in every cell (adaptability to traffic), resulting in maximum packing (MP). This requires knowledge about the load in every cell. A second criterion is the adaptability to interference variations, which is particularly important for interference-limited systems such as CDMA. This requires the DCA to have information on the instantaneous interference. A third criterion is to optimize the channel reuse distance, which would eventually mean that each channel can be used in every cell. An ideal DCA algorithm tries to optimize each of the three parameters, which would yield the optimum solution at the far upper corner of the cube. The ideal DCA algorithm would require information beyond the scope of a single cell. From this requirement it inherently follows that the respective DCA algorithm would ideally be operated at a central site. Consequently, two basic DCA schemes are distinguished:

- centralized DCA schemes and
- decentralized DCA schemes.

A centralized DCA algorithm collects the required information for channel assignment decisions from the associated BSs and MSs. This type of DCA algorithm is located at a higher hierarchical level of the mobile network architecture. A centralized DCA algorithm can, for example, be located at the radio network controller (RNC; Mihailescu, Lagrange, & Godlewski, 1999), which connects several BSs. The basic disadvantage is that a great amount of signaling is necessary to supply the vital information about the load, interference and channel status.

When using a decentralized DCA algorithm, the channel assignment decision is made by a local entity (Cimini, Foschini, Chin-Lin, & Milijanic, 1994; Das, Sen, & Jayaram, 1997a; Prakash, Shivaratri, & Singhal, 1999). Hence, the complexity is reduced considerably when using this type of DCA algorithm. The Digital European Cordless Telecommunications (DECT) standard uses such a decentralized DCA algorithm (Punt et al., 1998). Given that a decentralized DCA algorithm has only limited knowledge of the entire system, a global optimum is very difficult to achieve.

As a result of the DCA characterization in Figure 9, three types of strategies can be formulated:

- 1) *Traffic-adaptive channel allocation:* Instead of splitting the available frequency spectrum into subbands, which are then assigned to cells, traffic-adaptive channel allocation techniques try to assign the required bandwidth to cells dynamically (Haas, Winters, & Johnson, 1997). Compatibility matrices are set up to avoid use of the same frequency resource in a neighboring cell. Because the interference level from neighboring cells can vary significantly, the compatibility matrices have to be designed such that reliable connection under severe interference conditions is ensured. This results in capacity losses when using static compatibility matrices, because in low interference situations more channels per unit could be accommodated. The complexity of traffic-adaptive channel allocation algorithms increases exponentially with the number of cells. Because of this, graph theory is often used to solve these issues (Haas, Winters, & Johnson, 1997). The optimum traffic adaptive DCA algorithms result in the MP solution. This requires intracell handovers (channel reassignments). As a consequence, users may be reshuffled (although the QoS is still fulfilled) to optimize the total number of simultaneously active users. Hence, the complexity of MP strategies increases further, which makes this type of DCA algorithm difficult to analyze. Yeung and Yum (1995) proposed the cell group decoupling method to calculate upper bounds on blocking performance. However, the MP problem is easier to solve if the cells are placed along a line. In this scenario, the complexity only increases linearly with the number of cells. The optimum solution is found using the Greedy algorithm (Ahlin & Zander, 1998). In other studies, a different approach was taken to achieve the dynamic adaptation to traffic variations: channels were “borrowed” from a common pool and assigned to cells which experienced heavy traffic (Das, Sen, & Jayaram, 1997a; 1997b; Chang, Kim, Yin, &

Kim, 1998; Ortigoza-Guerrero & Lara-Rodriguez, 1996). This technique resembles the previously described combination of DCA and FCA methods.

- 2) *Reuse Partitioning*: The entire set of channels is divided into subsets, similar to the FCA strategy. But, in the case of reuse partitioning, every group of frequencies is associated with a different reuse distance (Zarder & Frodigh, 1992). A DCA algorithm always tries to use a channel with the lowest reuse distance, thereby increasing the capacity per unit area. It is reported that reuse partitioning algorithms can double the capacity of FCA schemes (Lucatti, Pattavina, & Trecordi, 1997).
- 3) *Interference-based DCA schemes*: Channels are assigned based purely on the interference power observed (no use of compatibility matrices). If the signal-to-noise ratio drops below a certain threshold, a new channel is acquired. This requires steady and reliable measurements of the interference power and power control to minimize interference. Because of its simplicity (easy to implement as distributed DCA algorithm) this type of DCA is widely used. Furthermore, interference-based DCA algorithms play an important role in CDMA systems, because they are interference limited (Shin, Cho, & Sung, 1999).

In TDD-based systems, which are ideally suitable for mobile data services, different sources of CCI exist. Moreover, an additional degree of freedom exists, namely, which TS to use for UL traffic and which to use for DL traffic. Both issues are addressed in interference-based DCA algorithms for TDD systems. In such systems, same-entity interference is, generally, viewed as most detrimental, and, therefore, it has been proposed to have the same TDMA frame structure in all cells with the same UL/DL slot allocation (Jeon & Jeong, 1999). This is referred to as common-slot-allocation (CSA), that is, an UL TS in one cell is also an UL TS in all other cells with the same being true for DL TSs. However, as demonstrated by Jeon and Jeong (2000), this is inefficient when the UL/DL load varies dynamically and independently in different cells. Therefore, more flexible slot allocation strategies, such as in Wieand Cho (2001), Lindstrom (2001), and Nasreddine and Lagrange (2003), have been proposed that permit same-entity interference provided the path gain estimates between same entities are sufficiently small. Also, it has been shown in Haas, McLaughlin, and Povey (2000) that occasionally same-entity interference is less than other-entity interference, and this diversity can be exploited to reduce overall intercellular interference. This has led to the development of various so-called time-slot-opposing (TSO) schemes (Haas & McLaughlin, 2001; Haas, Wegmann, & Flanz, 2002). Of all the proposed TSO strategies, random TSO (RTSO; Haas, Wegmann, & Flanz, 2002) is the most practical, as it requires no overhead in mitigating intercellular interference, as opposed to the centralized TSO technique proposed by Haas and McLaughlin (2001), which requires signaling to every node the path gains between every communicating node. The RTSO algorithm applies strategies similar to those known from frequency-hopping systems. It changes the TS configuration randomly, periodically, and independently within each cell (see Figure 10). Hence, instead

Figure 10: The RTSO algorithm randomly changes the allotted TS on a frame-by-frame basis. This means that during every frame period, each TS is exposed to a different level of interference. Therefore, analogies between this new TS-hopping approach and frequency-hopping systems can be drawn.

of changing the frequency, the TSs are changed according to a random sequence, which is reported to the MS during call establishment. Therefore, a user in a cell may experience other-entity interference within its allocated slot in one frame and same-entity interference in the next frame; that is, there is no bias shown against same- or other-entity interference. In this way RTSO exploits this inherent intercellular interference diversity to reduce the average intercellular interference. The RTSO algorithm has an important property: it does not require additional signaling during the duration of a call or session. These features make the RTSO algorithm suitable when cell-independent switching points are required. In addition, because the particular TS used for an arbitrary link randomly hops through the frame, a secure connection can be maintained if the hopping pattern is kept secret. If this is not sufficient, in addition to the TS hopping mechanism, frequency hopping can be applied. This results in a two-dimensional hopping process that increases transmission security significantly.

The RTSO is a “passive” slot allocation strategy and does not act to avoid high intercellular interference scenarios or act to mitigate high interference when it does occur. The strategies in Wie and Cho (2001), Lindstrom (2001), and Nasreddine and Lagrange (2003) are

innovative and “active” in avoiding high intercellular interference, but at the expense of some signaling overhead. In Nasreddine and Lagrange (2003) a novel slot allocation strategy was presented, referred to as path gain division (PGD). PGD is an enhancement of the strategies presented in Wie and Cho (2001) and Lindstrom (2001) and showed performance improvement over the latter schemes. In PGD, the path gain between an MS requesting a slot allocation and an MS in a neighboring cell is estimated as the path gain between the former MS and the BS serving the latter. If the MS requests an UL slot allocation, the slot allocation is not permitted if there is at least one MS in a neighboring cell receiving data on the DL in the same TS where the path gain estimate between these two MSs is greater than a specified threshold, thus limiting same-entity interference. However, if the MS requests a DL slot allocation, the PGD scheme does not apply this restriction on same-entity interference, under the assumption that same-entity interference and average other-entity interference will be comparable in this case. Clearly, PGD implicitly gives preference to other-entity interference over same-entity interference, regardless of which is higher at the time. The performance of PGD is also expected to be compromised by the potentially high margin of error in its inter-MS path gain estimates, especially for large cell sizes.

MAC Protocols

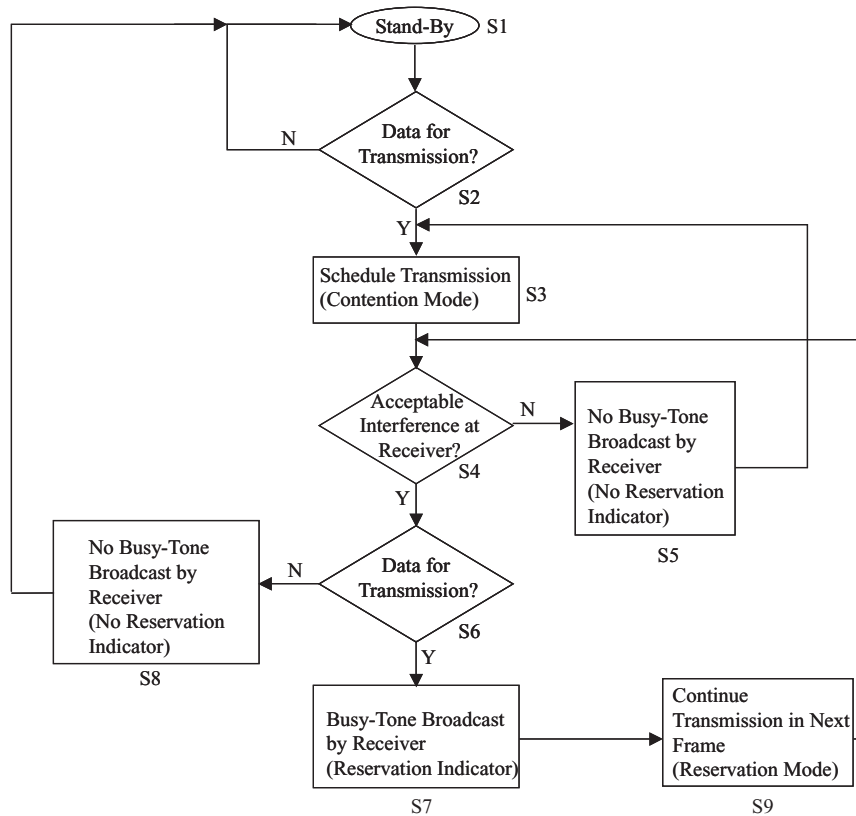

Omiyi and Haas (2004) describe active and reactive strategy for mitigating high intercellular interference in a cellular mobile communications network for mobile data services with 100% frequency reuse. This strategy is denoted as channel-sensing TDMA TDD (CSTDMA TDD), and it uses a modified busy-tone broadcast/channel-sensing mechanism to avoid or mitigate high intercellular interference scenarios. CSTDMA TDD is a distributed medium access control (MAC) protocol, which is being applied in a novel way; that is, to mitigate intercellular interference, as opposed to mitigating intracellular interference as is typically the case. Therefore, CSTDMA TDD is applied in addition to an intracellular centralized MAC protocol and does not replace the latter. In this section, we evaluate the performance of CSTDMA TDD in minimizing intercellular interference and maximizing capacity and spectral efficiency, and compare it to the state-of-the-art, namely CSA, RTSO, and PGD.

CSTDMA TDD is a “busy-tone” broadcast protocol, which uses TDD to support the additional signaling and which is compatible with the air interface. A BS or MS receiver that is currently receiving data broadcasts a busy tone, which prevents potential interferers from transmitting. The busy tone is broadcast in minislots that occupy a portion of the time frame structure, with one minislot for every slot. Therefore, every BS or MS transmitter must listen to the minislots to determine if it can transmit as scheduled without causing significant interference to other users. Clearly, the inherent channel reciprocity of TDD is the enabling factor in this process—it would not work with an FDD-based air interface. The busy tone broadcast approach has the advantage, over pure carrier sensing, of avoiding both the hidden and exposed node

problems, which are characteristic of the latter in the wireless environment. The fact that CSTDMA TDD resolves the exposed node problem is also an advantage over the RTS/CTS handshaking mechanism in 802.11 wireless LANs, which only combats the hidden node problem. In addition, the MAC signaling and information channels of the busy tone broadcast approach are physically orthogonal, and so they do not mutually interfere, unlike in RTS/CTS handshaking. Also, the busy tone broadcast approach requires less overhead than RTS/CTS handshaking and less stringent turnaround time constraints, which is especially critical in high-speed wireless networks. Finally, unlike traditional carrier-sensing/busy tone protocols, it seamlessly interoperates with the local centralized MAC protocol that coordinates cellular mobile communications. To support CSTDMA TDD, every BS (and cell) must be time synchronized. However, this is a typical requirement for TDMA TDD systems. In CSTDMA TDD, timeslots are organized into frames and a slot is either in contention or in reservation. A user is in contention mode if it attempts to transmit in a contention slot, and in reservation mode when it transmits in a reserved slot. There is no intracellular contention for cellular communication because the BS is in control locally at the cell level and schedules transmissions to avoid collisions among users in the same cell. However, there will be intercellular contention. Figure 11 shows the CSTDMA TDD flow chart. In CSTDMA TDD, when a user has data to transmit and is in contention mode, the transmission is scheduled for some random, future TDMA frame. The random time is determined as a function of congestion and real-time delivery requirements, and is based on the deadline-driven backoff strategy proposed by Omiyi (2000).

Within this frame, the transmitter selects an available contention slot, which is determined by not detecting a busy tone in the slot’s conflict-signaling minislot in the preceding frame. The intended receiver does not broadcast a busy tone in the slot’s minislot in the current frame if the transmission is received with unacceptable interference, that is, in outage, or if the transmission is received without outage but the transmitter indicates that it was not. However, if the transmission is received without outage and the transmitter indicates that it intends to continue its transmission in the subsequent TDMA frame, a busy tone is broadcast by the receiver in the slot’s minislot in the current frame. Thus, the user effectively reserves the timeslot at the intended receiver in the next frame, and all other users that can detect the busy signal will not transmit in this slot in the next frame. The transmitter enters reservation mode and continues transmission in the same slot in the subsequent frame.

Figure 12 illustrates the principle of CSTDMA TDD. This figure shows three adjacent BSs, namely BS1, BS2, and BS3, with the user equipment (UE) associated with each BS, namely UE1, UE2, and UE3. This figure also shows an example timeslot structure for CSTDMA TDD, consisting of three timeslots per frame with a minislot between consecutive timeslots. In this example, BS1 begins transmitting on the DL to UE1 in the third timeslot in the first frame. Because there is no collision, the receiver UE1 broadcasts a busy tone in the next minislot and thus reserves the third timeslot in the next frame. This process

(a)

S3 - Schedule Transmission

Figure 11: CSTDMA TDD flow chart: Every entity that wants to transmit a packet first checks whether the selected TS can be used by trying to detect an associated busy tone (S3). If a busy tone is detected a new potential TS will be selected for transmission, and the same procedure is carried out until either a free TS is found or the packet has to be buffered because of a lack of a free TS. If a TS is found, the packet will be transmitted. If interference at the receiver permits an error-free reception, a busy tone will be broadcast by the receiver indicating that the respective TS is now reserved (S4). If the interference at the receiver is too high, no busy tone is sent by the receiver which implicitly tells the transmitter to use a different TS (S5). The busy tone will be broadcast in the associated minislot until no further data is to be transmitted (S6). The important feature of this protocol is the implicit signaling using the reciprocity in TDD. If a transmitter does not hear a busy tone, this does not necessarily mean that there is no busy tone; it indicates that the received power at the minislot is too low, i.e., if that transmitter starts sending some data, it immediately follows that no significant interference at the other entity that has transmitted a busy tone can be expected.

Figure 12: Illustration of the CSTDMA TDD principle: UE2 postpones its transmission on TS1 as long it detects a busy tone. Consequently, significant interference to UE1 can be avoided. UE2 transmits on TS2. BS3 can simultaneously transmit in TS1 because it does not hear the busy signal from UE1. Thereby an optimum, self-organizing reuse of radio resources is achieved.

is repeated in subsequent frames, where UE1 broadcasts a busy tone after each successful reception of data in the third timeslot. However, UE1 experiences a collision in the first TS of the second frame from a UL transmission of UE2 in the neighboring cell. Therefore, UE1 does not broadcast a busy tone in the minislot following this timeslot, with the result that it is unreserved by UE1 and BS1 discontinues transmission in it in subsequent frames. On the other hand, UE2 is allowed to continue its transmission in this timeslot in subsequent frames, because its receiver BS2 experienced no collision. Now a busy tone is only detected when the condition in Eq. (4) is satisfied, where P_{TB} is the fixed, known busy tone transmit power; P_{RB} is the received busy tone power, P_{TD} is the intended data transmit power of the user listening to the busy tone; and I_{thresh} is the interference threshold, that is, the maximum acceptable value of interference from a transmitting user to another user.

$$P_{RB} \leq P_{TB} \frac{I_{thresh}}{P_{TD}} \quad (4)$$

This MAC protocol is designed particularly for mobile data services with mixed QoS, mixed data rate, and mixed UL/DL asymmetry requirements. Dynamic system level

simulations were carried out to evaluate the performance of the MAC protocol. The key system parameters can be found in Table 1.

Table 2 shows spectral efficiency results obtained from that simulation for 5% blocking, 5% outage, and QPSK modulation. It can be seen that the spectral efficiency of the TDD CSTDMA protocol is about an order of magnitude better than can be achieved using the CSA protocol. Similarly, the performance is improved by a factor of three as compared to the PGD technique.

Packet Scheduling

The packet-scheduling function in wireless systems is especially important for mobile data services in which many different services with specific QoS requirements exist. The four main physical-layer criteria with respect to QoS are (1) delay, (2) throughput, (3) outage, and (4) blocking. The first two are relevant for packet data services, whereas the latter two are relevant for circuit-switched services. Therefore, in the following we concentrate on delay and throughput. Formally the QoS requirement of some user, i , with respect to delay is defined as follows:

$$Pr\{W_i > T_i\} \leq \delta_i, \quad (5)$$

Table 1 Simulation Parameters

Parameter	Value
Number of cells	19
Number of slots per frame	7
Services	Mixed: voice and data
Data rate, voice	8 kbps
Data rate, data	128 kbps
Total DL/UL asymmetry	9.2:1
System bandwidth	20 MHz
Mobile speeds	36 km/h (50%), 3.6 km/h (50%)
BS separation	2000 m
C/I target	4.8 dB
Log-normal std. deviation	10 dB
Power control	C-based
Max. transmit power	30 dBm
Target received signal power	-100 dBm
CSTDMA TDD interference threshold	-103 dBm

where W_i is a packet delay for this user, and T_i and δ_i are the delay threshold and the maximum probability of exceeding it, respectively. A different notion of QoS is a requirement that the average throughput, R_i , provided to user i be not less than some predefined value r_i :

$$R_i \geq r_i. \quad (6)$$

All QoS criteria can be mapped onto different higher-layer service classes. In an initiative of the 3rd Generation Partnership Project (3GPP) four service classes are defined (2003a): (1) conversational class (e.g., voice), (2) streaming class (e.g., video streaming), (3) interactive class (e.g., Web browsing), and (4) background class (e.g., background download, e-mail). Voice, for example, is very sensitive to delay, blocking, and outage, but requires relatively low data rates, that is, throughput. These QoS properties are summarized in Table 3.

As opposed to a fixed line channel, the wireless channel changes with time and location. This corresponds to fast fading and slow fading respectively, caused by reflection, diffraction, and scattering. In a point-to-multipoint transmission scenario, for example, the signal amplitude at each receiver is significantly different and extremely difficult to predict. In addition, the interference level at any given location can vary significantly because the

Table 3 Traffic Classes and Their QoS Requirements

Class	Attributes of Traffic
Conversational	Low delay and loss rate, low bandwidth
Streaming	Insensitive to delay, high bandwidth
Interactive	Bursty, moderate delay and loss rate, high peak bandwidth
Background	Highly tolerant of delay and loss rate, moderate bandwidth

Source: 3rd Generation Partnership Project (2003a).

interference signal is subject to the same fading mechanism as the desired signal.

The problem is even more complex: as opposed to optical or wire channels, the wireless channel results in a high number of erroneous detection of some bits or bit clusters. In data transmission, as opposed to voice transmission, bit errors are not tolerable. Therefore, strong error correction mechanisms must be used, such as turbo or Reed-Solomon error coding/decoding. The drawback of these techniques is that they result in increased delay. Other techniques, such as the slow start procedure in the TCP/IP protocol, cause significant reduction in the throughput. As a result, the QoS criteria can be traded off against each other, and selection of the appropriate processing of the individual incoming bit streams depends on the actual service. For this purpose, the channel state information (CSI) is of vital importance. As demonstrated in the example, physical layer functions (e.g. coding), and network functions (e.g. transmission protocols) all have an effect on QoS. As a consequence, and as stated in previous sections, joint optimization across all layers is necessary in mobile communications to improve the performance of cellular systems. (Straightforward implementation of the ISO OSI model is therefore not appropriate in the wireless context.)

A key role in the cross-layer optimization is placed on the data scheduler. The central task of the scheduler is to maximize the number of packets transmitted to multiple users in such a way that the QoS constraints of the respective services are sufficiently maintained. This is referred to as the *multiuser variable channel scheduling* problem (Andrews et al., 2001). An overview of a packet scheduler is depicted in Figure 13. Incoming data packets are first stored in a queue. The scheduler assigns some priority to a particular packet based on a metric that is ideally composed of the QoS parameters of that particular service to that the actual packet belongs: the CSI, the required signal-to-noise-ratio, the queue length, and previous feedback information (a packet may have to be rescheduled). The scheduler may trigger a particular error-correction mechanism at the physical layer. The selected and encoded packets are framed and sent on over the air interface. Higher-level feedback information such as ARQ is received and forms an input to the scheduler. From this description it can be seen that the scheduler has a nontrivial task to solve. Furthermore, it is also clear that link adaptation, scheduling, MAC, and DCA cannot be treated independently. For instance, link adaptation

Table 2 Spectral Efficiency Comparison

Scheme	Spectral Efficiency, k (bits/s/Hz/cell)
TDD CSTDMA	1.334
TDD PGD	0.4
TDD CSA	0.13

Source: Omiyi and Haas (2004).

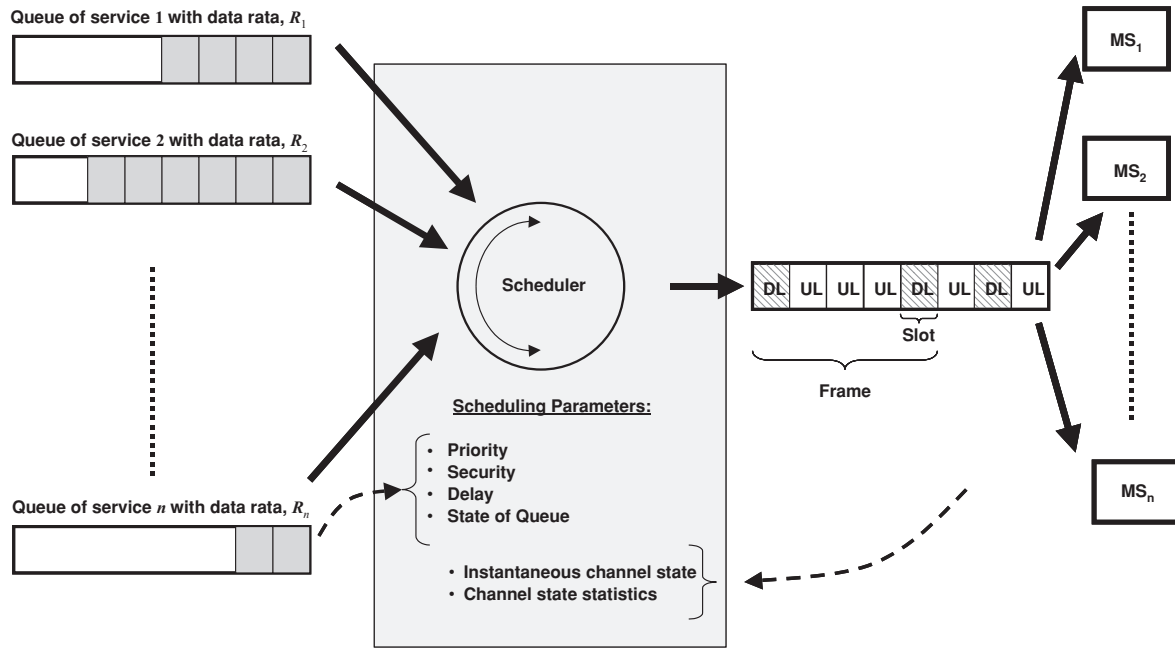

Figure 13: Different service classes and different users generate a number of data queues. The central task of the scheduler is to prioritize the packets in those queues based on service class parameters. As opposed to wired systems, the varying nature of the radio propagation channels of the spatially distributed users results in tremendously varying channel state characteristics. In addition, each of these users is exposed to interference resulting from radio resource reuse. Taking into account the prioritized service queues, the time-varying channel state characteristics and the interference at the respective receiver, the task of optimum scheduling (with regard to total throughput, delay, outage, and blocking) becomes nontrivial.

such as adaptive modulation may be used to favor data rate against bit-error performance. If, however, a packet of the conversational service class (especially delay sensitive, low bit-rate service) needs to be scheduled, the link adaptation strategy used is only suboptimum. The scheduler, which is informed of the particular service class—in this case the conversational class—might interact with the link adaptation algorithms to adjust the respective modulation technique.

In the following some state-of-the-art schedulers are introduced. The simplest and most straightforward scheduling scheme is round robin. Each queue, that is, each user, is served periodically regardless of priority, buffer length, channel state, and so forth. This is the most basic and most robust scheduling scheme. A round robin scheduler treats all users the same and is, therefore, not suitable for an environment that has to serve different QoS classes. More complex schemes introduce more or less sophisticated metrics. As different users (queues) fight for the same resource, the concept of “fairness” is vitally important. As a consequence, a whole family of so-called *weighted fair queuing* (WFQ) scheduling algorithms has been introduced; sometimes, they are also referred to as *generalized processor sharing* (GPS) algorithms (Nandita, Kuri, & Jamadagni, 2001). The key distinguishing feature of all these algorithms is the metric. For example, the buffer size can be used to control the scheduling of data packets. In this case, the metric is simply based on the buffer length. The buffer that stores the highest number of packets gets the highest priority for transmission. One possible metric of this type might be as follows: let n be the number

of total packets in all queues. The weight for the j th queue is then simply $w_j = \frac{n_j}{n}$, where n_j are the number of packets in the j th queue. The main disadvantage is that this method is insensitive to delays. For example, a packet in the shortest queue will be considered with the lowest priority, but if this packet belongs to a delay sensitive service, WFQ results in a nonoptimum solution for this particular case. Therefore, an improvement is made such that each packet stored in a certain buffer is assigned a deadline, t_k , calculated as, $t_k = t_{class} - t$, where $k = 1, \dots, n, t_{class}$ is a parameter that depends on the service class of that particular packet and t is the queuing time in its own buffer. The first packet to be sent is the packet with the lowest deadline to expiration. It is important to emphasize that this algorithm is able to distinguish between different service classes with different QoS requirements. At the same time, it avoids long delays. The disadvantage of this algorithm is its increased complexity, because each packet in a single queue needs to be assigned a deadline. All these delay-based scheduling schemes have in common that they do not consider the CSI in the decision process. The main reason for this is that they originate from fixed line networks where the channel is known and time invariant. The consideration of the CSI for fair packet data scheduling in a mobile environment is vitally important. The mobile channel is subject to severe fluctuation because of multipath propagation. With respect to throughput it is, therefore, clearly not optimum to assign all users the same proportion of the available resources. To account for these channel effects, so-called *proportionally fair* scheduling schemes have been introduced (Andrews et al., 2001).

A typical algorithm of this type assigns those users who experience better channels proportionally more resources (time, frequency, power, etc.). If for example, the channel capacity of user A is 100 kbps and that of a second user B is 200 kbps, user A will obtain 1/3 of the resources and user B 2/3 of the resources. Thereby, the throughput is maximized, while at the same time all users are served (fairness component). Again, the disadvantage is that the user who is experiencing the worst channel conditions will get least attention, which might lead to long delays. In summary, the basic proportionally fair scheduling algorithm maximizes throughput but might violate the delay constraints for some users.

All basic schedulers described here use a single metric that yields a maximization of only a single QoS criterion. Further enhanced types of schedulers introduce a combination of different metrics (Nandita, Kuri, & Jamadagni, 2001; Yang, Tseng, & Cheng, 2003; Hossain & Bhargava, 2004; Xu, Shen & Mark, 2004; Borst & Whiting, 2003) to trade off the four basic QoS parameters (throughput, delay, outage, and blocking) as described at the beginning of this subsection.

SUMMARY AND CONCLUSION

In this chapter we have discussed the main prerequisites for the support of mobile data services from a system perspective. A brief review of the history of mobile communication systems revealed that state-of-the-art cellular systems are primarily designed for a single service—voice. In this context, our intention was to demonstrate that the variety of mobile data services required today and in the future imposes entirely different requirements on wireless systems to maximize the efficiency of use of the scarce radio spectrum. These requirements were discussed for the basic building functions of radio resource management: DCA algorithms, MAC protocols, and data scheduling, all of which have been introduced in previous chapters. In addition, specific solutions for these radio resource management functions for mobile data services have been proposed. With respect to the radio frequency spectrum, a number of arguments were provided that support the fact that the conventional approach of splitting the available spectrum into smaller pieces, which are then distributed to individual operators, will not be appropriate for high data-rate cellular systems. For the same reason, new wireless network architectures, such as ad hoc networking, will have to be introduced to enable the efficient support of mobile data services. Ad hoc communication could effectively support information security as the coverage range is very limited, that is, the spreading of information is inherently restricted.

The main finding with respect to the duplexing technique was that the TDD technology is the key enabler for mobile data services. All other relevant and enabling system functions, such as DCA algorithms, MAC protocols, and data packet scheduling, are optimized for TDD operation. Because the existing cellular systems almost exclusively use FDD technology (apart from the 3G standard in China termed TD-SCDMA), one can expect that next generation (4G and beyond) datacentric cellular systems will use TDD, given the anticipated growth of mobile data

services. The additional interference scenarios in TDD will have to be arbitrated by intelligent DCA algorithms. One such DCA algorithm, referred to as RTSO, was introduced and it was shown that it also helps to increase security on the air interface if, for example, the hopping pattern is chosen appropriately. The TDD technology has a number of advantageous properties because it enables channel reciprocity. This property is exploited in MAC protocols for packet data-based wireless systems. Other issues such as time synchronization need to be dealt with when using TDD.

Packet data scheduling has an essential role in the efficient support of mobile data services because it has to maintain the different QoS constraints assigned to each individual mobile data service. However, an optimum scheduling process for wireless data services is not only determined by the QoS classes, but also by the actual state of the wireless channel. As opposed to fixed line transmission, the channel state in wireless systems is subject to severe fluctuations. This creates a number of trade-offs that have to be considered. These trade-offs also affect other system functions such as DCA algorithms and link adaptation methods (e.g., adaptive modulation). This makes clear the importance of optimizing a wireless system for packet transmission across different layers.

GLOSSARY

- A3** The A3 algorithm is implemented in the subscriber identity module (SIM) cards and in GSM network authentication centers. It is used to authenticate the user. The authentication process is a challenge/response mechanism; when receiving a request to access its resources, the network sends a random number to the device (the challenge) and waits for a response. A function that takes the secret key stored in the SIM and the challenge as arguments is computed on the SIM and the result sent back to the network as a response. The network derives the same number using its own copy of the secret key and compares the result with the device's response. A match indicates that the device has been successfully authenticated.
- A5** The A5 encryption algorithm scrambles the user's voice and data traffic between the handset and the base station to provide privacy. The A5 algorithm is implemented in both the handset and the base station subsystem (BSS). The effective key length is at most five bytes, which is its greatest weakness with respect to security.
- Ad Hoc** Information is directly sent from mobile to mobile or from device to device. Ad hoc communication does not require an infrastructure such as base stations in cellular communications.
- CDMA** CDMA multiple access technology using spread spectrum techniques. All users transmit and receive at the same time. Each user bit stream is multiplied by a unique, orthogonal (or pseudorandom) code that allows user separation at the receiver. The main advantage of CDMA is its inherent flexibility in assigning different data rates to different users.
- Cellular** The type of wireless communication that allows wide area coverage—in the ideal case, global

- coverage. The system uses many base stations to divide a service area into multiple cells. Cellular calls are transferred from base station to base station as a user travels from cell to cell.
- FDD** Uplink (reverse) link and DL (forward) link is separated in frequency domain.
- FDMA** Multiple access technique in which users share a common resource on a frequency basis. A given radio frequency band is divided into subbands. Each subband is used by a single user for a certain time period.
- HSDPA** HSDPA in UMTS enables peak data-rates on the *downlink* of up to 14.4 Mbps over a 5 MHz bandwidth, i.e., with HSDPA support of channel asymmetry with higher load requirements on the downlink is feasible. This is achieved by deploying adaptive modulation and coding (AMC), a technique used to compensate for variations in radio conditions. With this technique, a network node schedules the transmission of data packets to a user by matching the user's priority and estimated channel operating environment with the appropriate coding and modulation scheme, thus increasing throughput under favourable conditions.
- IMT-2000** Global standard for third-generation (3G) wireless communications, defined by a set of interdependent ITU recommendations. IMT-2000 provides a framework for worldwide wireless access by linking the diverse systems of terrestrial and/or satellite-based networks.
- MAN** A collection of several LANs that are linked by faster backbone connections. A MAN is smaller than a WAN (wide area network), and an example is a college campus with several LANs linked on the same network.
- Moore's Law** More than 25 years ago, when Intel was developing the first microprocessor, company co-founder Gordon Moore predicted that the number of transistors on a microprocessor would double approximately every 18 months. To date, Moore's law has proven remarkably accurate.
- OFDM** A modulation technique with which information symbols are transmitted on spectrally overlapping adjacent subcarriers. Interference on adjacent subcarriers is avoided by an orthogonal transformation of the data symbols to be transmitted. Using this modulation method, low complex receivers for high data-rate transmissions can be realized—especially in a wireless context that is exposed to multipath propagation.
- PAN** Allows devices to work together and share information. Personal area networks can be created in public places, in the home, in the office, in a car. This network enables everyday devices to communicate wirelessly.
- Rake** A receiver architecture used in CDMA systems with which different time-delayed replicas of the transmitted symbol are collected and combined. Thereby, the received useful energy is maximized.
- Roaming** The ability to use the same service in different networks, usually in different countries, with the same terminal.
- TDD** Uplink (reverse) link and downlink (forward) link is separated in time domain.
- TDMA** Multiple access technique in which users share a common resource on a time basis. A transmission frame is divided into time slots (TSs). Each TS is used by a single user for a certain time period.
- UMTS** 3G system standardized by ETSI (European Telecommunications Standards Institute) under 3GPP along with other regional standards organizations.
- Wi-Fi** Wi-Fi is a nonprofit organization created to provide an interoperability certification for wireless LAN products based on the 802.11 standard.
- WiMAX** WiMAX is an industry trade organization formed by leading communications component and equipment companies to promote and certify compatibility and interoperability of broadband wireless access equipment that conforms to the IEEE 802.16 and ETSI HIPERMAN standards.
- WLAN** Wireless local area networks provide cable-free connection between notebooks, desktop PCs, printers, and office networks via wireless access points.

INTRODUCTION

The wireless mobile Internet, which was a dream only a few years ago, is now progressing so fast that it could revolutionize the whole framework of the telecommunication industry. The wireless mobile Internet is not only an extension of the Internet into the mobile environment that gives users access to the Internet services while they are on the move, it is also about integrating the Internet and telecommunications technologies into a single system that covers all communications needs of human. With the extensive progress achieved during the past decade in wireless access technology, switching and routing in the Internet, and sophisticated hardware and software design, such a comprehensive Internet technology would no longer be a dream but a practical reality. Although the first cellular-based mobile Internet services provided users with a taste of an actual wireless mobile Internet system, there is still a need for more research to achieve the systematic goals of this network (Jamalipour, 2003).

Mobile and wireless Internet, as its name specifies, should provide a seamless transition from a geographically fixed domain into a mobile environment. By seamless transition, we mean that there should be no sensible change for a user who is connected to the Internet when moving from a fixed domain to a mobile domain. In a broad sense, this could be even the case when a user moves from one wireless network domain to another one. In technical terms, the Internet access for the user should be independent of the access technology used for the Internet services.

Changes in Network Protocol Stack

During the transition from the traditional wired Internet to the wireless Internet, network protocols and network

architecture will be changed dramatically. In a mobile Internet system, the user should not feel a dramatic change in quality of service (QoS) for the user's current application. The quality measure most easily sensed is the connection speed or data bit rate, which affects the requirements for the maximum allowable delay. Changes to protocols affect all layers of the network protocol stack. The link layer (Layer 2) has to be modified to concurrently establish two or more connections via different access networks supported by the physical layer (Layer 1). This change in the link-layer protocol has to be incorporated into the computer operating system (OS) so that, for example, two Internet connections can be set up and maintained at the same time.

At the physical layer, mobile devices have to be equipped with multiple interfaces to different access networks (wired networks, such as Ethernet cables and dial-up modems, as well as wireless networks, such as wireless LANs and infrared and cellular modems). The physical layer has to include several interfaces to Layer 2 in order to manage the best connection to higher layers, and if one connection cannot meet the quality requirements of the application, a combination of two access networks can be granted. This would be the start of a heterogeneous systems era.

At the network layer (Layer 3), the Internet protocol (IP) needs major changes so that it can handle the routing and other tasks that would be required of the network layer in wired and wireless environments. Mobility of IP addresses should be accommodated in the future mobile Internet. Signaling requirements of the IP layer protocol have to be simplified to provide more spectrum efficiency in future wireless access networks. IP addressing and global address translation between heterogeneous networks must be performed in Layer 3.

The transport layer on top of the IP layer may be considered the main part that needs modifications for future mobile Internet networks. The legacy design of this layer for wired networks avoids efficient use of the radio-channel capacity, and thus major modifications and extensions are required at the transport layer to the transmission control protocol (TCP), which is predominantly used today, and the user datagram protocol (UDP).

In a mobile Internet, the mobile user does not see any difference between the currently available service providers at a given time and location, and it is assumed that a user may access the Internet regardless of his or her point of attachment to the network and the supporting access and core networks. Therefore, a system for authentication and authorization of users when they move across different networks must be established. Authentication provides the proof of the user's identity to the network that the user is going to access. This process is usually performed through an authentication procedure. Authorization determines what type of services may be provided to an authenticated user. Therefore, it is not sufficient that a user is in a capacity to connect to a network; the user must also be subscribed to a list of services that he or she is going to receive from the connecting network. Accounting, the third A in the network AAA (authentication, authorization, and accounting), provides a history of which services a user has utilized and at which times while connected to a network.

Mobile Internet will be only one of many different telecommunication technologies and hence needs to share limited resources. A sophisticated resource management strategy thus would be vitally necessary to share those resources among all coexisting technologies. Resource management schemes such as bandwidth management, admission control, congestion control, and so on will guarantee reliable performance of the network as well as a fair allocation of resources to all eligible users.

Next-Generation Networks and the Mobile Internet

The current network architectures used in either the wired Internet or the cellular networks would not be appropriate and efficient for a future wireless mobile Internet, even if we assume that the cellular networks will provide the major infrastructure of the mobile Internet. In recent years many people have discussed this issue and how it may be possible to change the existing network architectures to be utilized by a mobile Internet (Macker, Park, & Corson, 2001; McCann, & Hiller, 2000; MWIF, n.d.; Noerenberg, 2001; Oliphant, 1998; Ramjee, La Porta, Thuel, & Varadhan, 2000; Umehira, et al., 1999). One major issue is making the core network independent of the underlying access technology.

Currently several access networks exist, such as second- and third-generation (2G/3G) wireless cellular, wireless LAN (WLAN), and satellite networks, that offer a broad range of services. Access-specific end terminals are required for the subscribers to enjoy seamless services across these networks. At present there is no single system available that can effectively replace all these technologies and offer all these services with the same terminal. As a

result research is underway to develop the next-generation network (4G or Beyond 3G—B3G) that will facilitate seamless mobility across heterogeneous technologies by means of a single handheld terminal. This envisaged network will be a fabric of internetworked existing and future access technologies (both wired and wireless) integrated together through an IPv6 transport protocol.

Several 4G/B3G network architectures have been proposed by researchers. Our review of these architectures has identified scope for improvement in the key areas of mobility and resource management. This has led us to develop a better common control and signaling mechanism to reduce battery power drain; to improve handover management across different networks for various degrees of mobility, resource reservation between peer end terminals to support real-time and non real-time applications; and end-to-end QoS management under varying network conditions; to design an adaptive handheld terminal to access heterogeneous services; and to create a reliable multicast protocol for signaling messages.

Chapter Outline

In this chapter, we propose a modular, open, hierarchical network architecture with cross-layer coordination for the future wireless Internet through well-defined message interfaces and distributed network functionalities. Our motivation for this research stems from the need to address the inherent limitations exhibited by contemporary 4G/B3G network architectures in the areas of mobility and resource management for the next-generation wireless Internet. We have aimed to improve on these network architectures by proposing suitable augmentations in the corresponding areas mentioned previously. Our novel augmentations in these areas enable seamless connectivity across different access networks. A software-defined, radio-based reconfigurable mobile terminal is used to access the proposed 4G/B3G network. In addition, a reliable multicast protocol is proposed over an incorporated common signaling system to support the signaling required for multicast services.

This chapter is organized as follows: after the general description of the mobile and wireless Internet provided in the first section, in the second section the heterogeneous network architecture of the future wireless mobile Internet is outlined. The third section summarizes some fundamentals of the wireless LAN, with emphasis on IEEE 802.11 standard. In this chapter, realization of wireless Internet by use of wireless LAN is also discussed. In the fourth section, we discuss the limitations of the key contemporary 4G architectures in terms of their essential components such as mobility and resource management techniques. Next we present the proposed internetworking architecture of the future wireless Internet. After that, we describe our proposal for the novel augmentations to the architecture, mobility management, resource management, and QoS techniques. The mobile terminal architecture of the future wireless networks is discussed in the seventh section. Reliable multicast signaling protocol is discussed in the eighth section and is followed by key conclusions for the chapter. These initiatives should pave

Figure 1: General view of the next-generation system showing overlapping heterogeneous access networks.

the way for the future mobile Internet infrastructure. The discussions provided in this chapter try to advance the knowledge of the network architecture necessary for the future mobile Internet and address fundamental issues related to the mobile Internet; thus, this chapter is considered as a comprehensive overview to the mobile and wireless Internet.

HETEROGENEOUS NEXT-GENERATION WIRELESS NETWORKS

The emergence of several access technologies has resulted in a multitude of heterogeneous systems targeting different service types, data rates, and users. Although the migration from first to 2G-generation cellular systems involved a transition from analog to digital technology, the evolution from 2G to 3G cellular system is driven by the popularity of the Internet and the need for data transmission availability on the move. The different available access technologies such as 2G GSM (Global System for Mobile communications) and IS-95 (cdmaOne); the enhanced data rate of the 3G packet-switched UMTS (Universal Mobile Telecommunication System) and CDMA2000; the high-capacity and high-bandwidth WLANs (IEEE 802.11, HIPERLAN, HIPERLAN2); and high-speed digital broadcast systems such as digital audio broadcast and digital video broadcast, with their own distinct characteristics, complement each other. However, the absence of a single architecture to integrate all existing and future systems prevents the subscribers from enjoying reliable and global end-to-end connectivity through a single subscription.

The main motivation for the research in next-generation network architecture is based on factors such as the following:

- Demand for better availability of services and applications.

- Global connectivity for any-type services at anytime, anywhere, and anyhow.
- Rapid increase in the number of wireless subscribers who want to make use of the same handheld terminal while roaming.
- Support for bandwidth-intensive applications such as real-time multimedia, online games, and videoconferencing as well as traditional voice service (VoIP).

The scalable and distributed next-generation (or 4G) network architecture is expected to offer any-type services over a diverse set of places such as indoor, outdoor, pedestrian, and vehicular locations. The services, as stated earlier, will be offered over a large range of overlapping access networks (e.g., WLAN, 2G, 3G, xDSL, DVB, DAB) that offer different data rates, coverage, bandwidth, delay and loss, QoS requirements, and so forth (Berezdivin et al., 2002; Frodigh et al., 2001; Gustafsson et al., 2003; Kellerer et al., 2002). Figure 1 shows a general view of such a next-generation system with overlapping heterogeneous access networks.

The key features visible to the user in such a network are the following:

- Mobile terminals will be able to autoconfigure to the specific access technology at the location of the terminal.
- Subscribers will have access to various services and enjoy a quality of service, cost, and security equivalent to wired LANs, even while running real-time applications.
- Ubiquitous and seamless connectivity will be provided through effective mobility, resource, and QoS management schemes.
- The investments made by the subscriber will be respected by limiting the changes required in the multi-access mobile terminal in terms of hardware or software.

Figure 2: A basic illustration of a WLAN system.

The key research objectives for such a harmonized, heterogeneous 4G network architecture are these:

- Integration of all existing and future communication access systems through a common IPv6 (Internet protocol version 6) gluing mechanism.
- Development of a modular and scalable architecture with well-defined distributed network functionalities.
- Development of effective mobility, resource, and QoS management schemes to offer seamless connectivity and end-to-end QoS between peer end terminals.
- Development of the physical architecture of a QoS-enabled mobile terminal capable of accessing the Internet and real-time services via a multitude of access technologies.
- Offering similar services (subject to network capacity and service policy) in both home and visited networks based on preferences and the service agreement in the user's subscription.

WIRELESS LOCAL AREA NETWORKS

One of the extensions to the wired Ethernet is the WLAN, defined in the IEEE 802.11 standards (Crow et al., 1997; Forouzan, 2003; IEEE 802.11, n.d.). WLAN is becoming very popular by providing mobile Internet access in offices and campus buildings because of the ease in movement of users while connected to the Internet. IEEE 802.11 standards define a set of medium access protocols to extend the wired Ethernet into the wireless domain. The FCC (Federal Communications Commission) in 1985 modified the radio spectrum regulations for unlicensed devices, so that WLAN could operate within the ISM (industrial, scientific, and medical) bands, if the equipment operates with less than 1 Watt of power. The 902-MHz and 5.725-GHz bands can be used only in the United States, whereas the 2.4-GHz band is available globally (Forouzan, 2003). The usage of unlicensed ISM frequency spectrums simplifies deployment of a new WLAN with very few and low-cost equipments. Nomadic Internet access, portable

computing, and multihopping, including ad hoc networking, are some of the applications of WLAN technology. Depending on the standard, WLANs can achieve speeds of 2 (IEEE 802.11), 11 (IEEE 802.11b), or 56 (IEEE 802.11a) Mbps in an ideal situation and good wireless channel conditions.

In principle, a WLAN domain can be provided easily through an access point (AP) cabled to the usual wired Ethernet in a LAN system. Therefore, the access point could be considered a router or a hub connecting several end hosts to the LAN system. The only difference here would be that the end host will access the AP through wireless channels rather than cables. Because each AP will give access to several end machines, some type of multiple access control has to be established by the AP to share the wireless channel among all end users. Spread spectrum technology, both direct sequence and frequency hopping, are used for this purpose in the standard.

Each AP in a WLAN system can provide coverage to mobile Internet users in an area of a maximum of 500 meters in radius. Therefore, by having several APs it is possible to establish a cellular-like WLAN. In such a case, cellular-type issues, such as handoff and maximum capacity, will become apparent. Figure 2 shows an illustration of a WLAN with two APs and several end machines. The users of a WLAN system can obtain an IP address through DHCP (dynamic host configuration protocol) similar to a dialup connection or by a fixed IP address provided by their network administrator similar to a desktop user.

Ad Hoc Networking Using Wireless LANs

The technology provided by IEEE 802.11 allows users also to dynamically form a private network without the need for an access point (Toh, 2002). Therefore, it is possible to make a temporary network of computers, for example, during a meeting, where no computer is a server. All users will have the same level of the network hierarchy. The computers in this network can exchange their data files through the WLAN network, which could be isolated from the local wired (wireless network). This is a very basic implementation of a mobile ad hoc network, which

Figure 3: A basic illustration of an ad hoc network.

clearly does not have any infrastructure behind it. The Internet Engineering Task Force (IETF) has a working group called MANET (mobile ad hoc network) that develops the RFCs and standards for this emerging technology. Figure 3 shows an ad hoc network with four mobile computers, which can be compared to the configuration previously given in Figure 2.

IEEE 802.11 Specifications

The IEEE 802.11 standard defines two types of services for the WLAN: basic service set (BSS) and extended service set (ESS). In the BSS, a network of computers is established either with a central base station (or an AP) that can connect the users of the WLAN network to the other parts of the wired network with or without a central base station, which provides an ad hoc network among several users without any access to other parts of the network.

Two or more WLANs that are using the BSS can be connected through any of the IEEE LAN standards, such as Ethernet or token ring, to make an infrastructure of wireless LANs so that the system covers a larger geographical area, similar to the concept of cellular networks. This configuration is the ESS for the IEEE 802.11 standard. The WLAN illustration shown in Figure 2 is this ESS.

Two types of medium access control (MAC) are defined by IEEE 802.11: distributed configuration function (DCF) and point coordination function (PCF). DCF is the basic MAC protocol for WLAN and it is the only access for the ad hoc networking configuration. DCF is a contention access technique, which means that the WLAN users need to compete to get a channel for data transmission. DCF is based on the fundamental Internet MAC protocol CSMA (carrier sense multiple access) with additional collision avoidance (CA), which makes it CSMA/CA (Comer, 1999; Stallings, 2000). One reason for using CSMA/CA in WLAN and not the usual CSMA/CD (CSMA with collision detection) used in wired LANs is that detecting a collision is not as easy for wireless media as it is for wired systems. Also, for wireless channels there is always a chance of getting involved in the *hidden-terminal* problem.

On the wired network, another signal from a user can be detected by measuring the current signal power on the wire. However, in a wireless environment, it is possible that a user is in range of the base station and thus visible by it, but outside the range of another user, who is also seen by the base station. This phenomenon is called the hidden-terminal problem. Therefore, when a user wants to transmit his or her packet over the radio channel, detecting the radio signal power would show only other users presence in his range and not the hidden terminals. If the user transmits a packet and at the same time another hidden-terminal transmits his or her packet, both packets will be lost. The hidden-terminal problem is illustrated in Figure 4.

To avoid the hidden-terminal effect, the wireless MAC needs to add an extra packet exchange before a transmission to make sure that no one else is transmitting at the same time. Therefore, the base station in the WLAN acts as a server that allows a user to transmit or not after a request proposal.

The point coordination function is implemented on top of DCF for time-sensitive transmissions in an infrastructure WLAN architecture. PCF uses centralized, contentionless polling access by utilizing a software package called point coordinator (PC; Oliphant, 1998). PC software

Figure 4: The hidden-terminal effect.

is located at the base station and polls users one after another to avoid any contention for their transmissions. As the PCF runs over the DCF, the sensing process of DCF is performed at the beginning of the PCF polling cycle only once.

IEEE 802.11 defines three types of specifications for the physical layer, based on frequency-hopping spread spectrum (FH-SS), direct sequence spread spectrum (DS-SS), and infrared communications. BPSK (binary phase shift keying) and QPSK (quadrature phase shift keying) were used as the modulation schemes in the DS-SS specifications of WLAN for its early standard, with a bit rate of 1 and 2 Mbps, respectively. Other modulation schemes have been added later in the IEEE 802.11b and IEEE 802.11a standards to allow higher bit rates of 5.5 and 11 Mbps, respectively. In the new standard IEEE 802.11b, the MAC and logical link control (LLC) layer protocols are kept the same as in original IEEE 802.11 and only the physical layer has been modified. For IEEE 802.11b, again DS-SS is utilized. Dynamic rate shifting is also allowed in IEEE 802.11b so that in a noisy environment bit rate could be decreased from 11 Mbps dynamically to 5.5, 2, or 1 Mbps.

WLAN for the Mobile Internet

WLAN is becoming increasingly popular, which makes it an appropriate solution to the future wireless Internet infrastructure. The mobile users' typical demand for information access is characterized by heavy data files and applications, and the WLAN can provide mobility and speed at the same time. Although the mobility feature of the WLAN is usually limited to a few hundred meters for a single AP, as it was discussed in the previous section, it is possible to increase this mobility coverage by deploying a cellular-type ESS wireless LAN.

The use of the wireless LAN as part of a future mobile Internet infrastructure comes for several reasons. In major structured hot spots such as airports and rail stations, the mobile radio infrastructure support of data communications seems to be inadequate and expensive. On one hand, for office users, mobility, simple and low-cost network scalability, and high-speed access are advantages. On the other hand, for home users, advantages of mobility without new wiring and, at the same time, high-speed access are the key issues. WLANs can also provide network flexibility: no infrastructure (ad hoc), a single-cell network (BSS), and a cellular topology (ESS). It also uses the unlicensed spectrum that reduces the end user's cost.

Simple structure and cost-efficient equipment involved in the WLAN can easily extend the fixed Internet into a mobile environment. On the negative side, in WLANs, mobility is supported on only a limited scale and is neither logically feasible nor economically efficient. Also, data integrity, user and network security, and billing methods are not sufficiently supported by the current standards. It is notable that however this can be done (as is ongoing) but this will add the complexity and cost of the network, which will result in negating some of the original advantages of the WLAN.

In a WLAN, traffic is loosely controlled through multiple access schemes, and more traffic requires better traffic

management and licensed spectrum, adding the cost and network complexity. Also, it is important to mention that co-located WLANs could interfere with each other easily because they all use the same unlicensed frequency spectrum.

In recent years, it has become clear that although 2.5G/3G cellular systems can provide some infrastructure for mobile Internet service, they are not necessarily sufficient. Some reasons for this statement are that the cellular deployment timetable was not fast enough and their data-rate growth has not followed the rapid increase in new applications' bandwidth demands. In addition, the cellular tariffs are not easily reducible. Cellular radio access will remain the limiting factor in competing speed with wired networks. Moreover, the compatibility and roaming issues between IP networks and cellular systems are not necessarily resolved within cellular-only implementations. This will create a need for hybrid integrated networks.

Hybrid integrated networks imply horizontal communication among existing access technology including cellular, cordless, WLANs, short-range connectivity devices (such as Bluetooth technology), and wired networks. These need to be on a common platform to complement the services of each other and to be connected through a common, flexible, seamless IP-based core network. An advanced media access technology that connects the core network to different access technologies will be also required. The hybrid integrated network will provide global roaming and interworking among different access technologies, both horizontal (intrasystem) and vertical (intersystem) handover. This will also provide a seamless, transparent service negotiation including mobility, security, and quality (data rate, delay, dropping probability, etc.) among heterogeneous networks.

There are both long-term and short-term solutions to the mobile Internet realizations. In the long term, merging IP and cellular networks at core and access sides, reducing dissimilarities in the management of the two systems, and improving radio access technology and global interconnection of cellular and IP networks would be necessary. In the short term, however, other solutions, such as the use of available infrastructures, trying to accommodate simple systems within individual cellular networks, pushing IP-oriented applications into cellular services, gradual decreasing in traffic load from non-IP services, and blending all traffic data into one mixed type, are available. The short-term solutions would be used in order to be prepared for longer-term solutions.

WLAN is currently considered the most accessible network to start with for the short-term solutions. It provides a much higher speed than 3G systems: 11–54 Mbps and greater as compared with 300 Kbps–2 Mbps for the cellular 3G networks. It already has close relations with the legacy wired IP networks (basically it is an extension) and use of unlicensed spectrum and low-cost equipment that may enable low end-user tariffs; it is already deployed in major hot spots and is rapidly expanding and easily deployable anywhere. It has potential to integrate elements in its architecture with cellular 3G systems and the advantage of huge ongoing research toward its standardization, regulation, access control, and security. All these factors

make WLAN a real potential starting point for the mobile Internet.

3GPP has already started the initiative for cellular WLAN internetworking architecture, which will be included in the 3GPP release 6 specifications. It is, however, important to mention that some issues still need to be considered:

- How to integrate a highly standardized system such as UMTS with a loosely standardized network, that is, the WLAN.
- How to standardize the WLAN network architecture or its radio interface.
- How to integrate a multiservice network such as UMTS with a mainly IP service network of WLANs.
- Whether the WLAN should be administrated by the UMTS operator or treated just as a foreign network.
- How to ensure user data routing and access to available services.
- Whether to use the UMTS core network or the IP backbone.

3GPP has investigated several integration options in cellular and WLAN networks (3GPP, 2002; 2003). The three main options are to use the WLAN as a peer network, with tight coupling or loose coupling. The peer network is really a kind of inclusion and not integration. In this method, WLAN and cellular systems are independently connected to the IP core network. In tight coupling, the WLAN is accommodated “tightly” inside the cellular core network, which will achieve virtual high speed at the end-user level. In the loose coupling scenario, we take advantage of both IP core network and cellular core network without getting virtual high speed. This would be a better option to get the two network, truly integrated. The loose coupling, however, will obviously have more overall complexity compared with the tight coupling, because signaling and data links are separated from each other and are handled by different networks. Ahmavaara, Haverinen, and Pichna (2003) and Salkintzis, Fors, and Pazhyannur (2002) provide detailed explanations of the three integration techniques and therefore these techniques are not discussed here because of limited space.

TECHNICAL REQUIREMENTS OF MOBILE INTERNET ARCHITECTURE

It is possible to identify several limitations in the contemporary 4G/B3G network proposals available in the literature. These are mainly in the areas of mobility and resource management. A brief discussion of these limitations is categorically given as follows.

Mobility Management

From the several 4G architectures proposed in the literature, we believe that the IST project, mobility and differentiated services in a future IP network (Mobydick; Mobydick, n.d.), and multimedia integrated network by radio access innovation (MIRAI; Inoue et al., 2002) are the few

that have dealt with the mobility management issue. We categorize the mobility management limitations of both MIRAI and Mobydick in the following.

Binding Update. Mobydick adopts fast handovers for mobile IPv6 (FMIPv6), which increases the frequency of a BU to a distant HA and a CN after every migration to a new AP. This results in a considerable increase of signaling overhead, especially with a large subscriber base in urban areas. Although MIRAI uses a hierarchical structure, it does not offer faster connectivity or a data transfer path across adjacent domains.

Common Control Signaling. There is no common signaling mechanism that the end terminal can use to perform wireless system discovery and paging in Mobydick. As a result, the end terminal scans all access networks, which imposes significant drain on battery power. On the other hand, MIRAI’s overlaid basic access network (BAN) architecture experiences different network conditions such as deep fades and co-channel interference, similar to the radio links within the corresponding access systems. Although BAN is a step toward offering a common control/signaling mechanism, such dynamic link characteristics limit its ability to provide a reliable, bidirectional, low data rate signaling channel.

Address Assignment. The stateless IPv6 autoconfiguration adopted in MIRAI is unreliable without duplicate address detection (DAD). However, DAD itself is not easily feasible in a wireless environment because of the absence of centralized infrastructure to detect terminals with duplicate addresses. Furthermore, it contributes toward increasing signaling load and handover latency.

Location Management. Mobydick is equipped with interfaces for wideband CDMA (UMTS-TDD), WLAN (802.11b), and Ethernet. As such, new technologies cannot be introduced without hardware changes. MIRAI on the other hand has a reconfigurable software-defined radio (SDR)-based end terminal that uses a global positioning system (GPS) receiver for location management. However, GPS cannot operate effectively in indoor environments of steel or concrete and also under thick foliage, such as in parks.

Resource Management

Resource management requires allocation/deallocation of resources to sustain a communication session. The allocation/deallocation is carried out within the serving domain and along the communication path between peer end terminals, before and during a session. Many resource management schemes have been proposed in literature that do not offer a truly global end-to-end scheme. For example, Nanda and Simmonds (2001) propose a centralized bandwidth broker (BB) for each domain that considers the profile of each piece of traffic encountered in the network and that supports dynamic allocations. However, this centralized approach suffers from a single point of failure, the BB. In addition, it is not stated how the ingress routers, egress routers, and BBs of the intradomain and interdomain are identified. Other schemes such as the

Mobydick project (Marques et al., 2003) propose a QoS broker, based on a hierarchical architecture. Their architecture, however, considers centralized QoS brokers shared across different domains, which increases the processing load on the QoS broker and also makes it a single point of failure.

The SMART/MIRAI (Havinga, Smit, Wu, & Vognild, 2001) project suggests that differentiated flows should use heterogeneous networks based on the QoS requirements, but does not propose any resource management scheme in this regard.

QoS Management During Handover

The QoS management schemes proposed in the literature either waste valuable resources by overprovisioning bandwidth or unfairly differentiating between real-time and non-real-time services. For example, the preemptive priority handover scheme of reserving bandwidth a priori to handover gives precedence to real-time traffic over non-real-time traffic (Lo & Lin, 1998). If enough resources are not available, then the non-real-time traffic may be slowed in comparison with the real-time traffic. Also, the handover requests get queued if all the reserved handoff channels are in use. MRSVP (a reservation protocol for an integrated services packet network with mobile hosts), proposed by Talukdar, Badrinath, and Acharaya (2001) is not scalable and wastes scarce resources by reserving bandwidth on different base stations even though the mobile host uses only one of the base stations.

The literature review has shown that algorithms can be devised to reduce the call-dropping probability but these do not ensure maintenance of QoS during handover; that is, if the mobile terminal (MT) moves from one cell area to another (Dingankar et al., n.d.). Ramnathan et al. (1999) have devised schemes that ensure some sort of reservation of bandwidth a priori to handover. These schemes are based on providing priority to handover calls rather than to local connections. The different strategies possible are the following:

1. **Fixed strategy:** Reserving a certain percentage of the bandwidth for handover requests.
2. **Steady strategy:** The base station is assumed to be aware of the steady fraction of connection requests for each traffic class. This fraction may be determined from historic traffic information available to the base station.
3. **Dynamic strategy:** In this strategy, each base station periodically queries neighboring base stations and computes an estimate of the rate at which handover connection requests are expected to arrive in the next update period. This estimate is derived from known stochastic of the connection duration times, cell residence times, and mobility patterns.

These strategies could be augmented with a preemptive priority handover scheme (Lo & Lin, 1998). In this scheme the real-time traffic is given precedence over non-real-time traffic. First, according to this scheme the handover requests get queued if all the reserved handoff channels are in use. Second, if enough resources are not available,

then the non-real-time traffic may be slowed in comparison with the real-time traffic.

An approach taken by the MIND project (Mobile IP-based Network Developments; <http://www.ist-mind.org>) is to focus on the mobile nodes' architecture to ensure some QoS during the handover process (Ruiz et al., n.d.).

The overall aim of the MIND project is to facilitate the rapid creation of broadband multimedia services and applications that are fully supported when accessed by future mobile users from a wide range of wireless access technologies. MIND is a follow-up to the BRAIN (Broadband Radio Access for IP-based Networks) project. This project is partially funded by the European Commission in the framework of the IST Program.

Talukdar et al. (2001) developed a resource reservation protocol for an integrated services network with mobile hosts termed mobile RSVP (MRSVP). The idea behind MRSVP is to carry out advanced reservation of resources in the network to the most likely base stations with which the mobile host is likely to have handover sessions. Stochastic predictive algorithms predict these base stations. The advanced reservations are carried out via a proxy node that receives the reservation requests from all the mobile nodes in a subnet. The reservation requests are then channeled via the proxy nodes to the base stations in the subnet.

The main drawback of the MRSVP scheme is that bandwidth will be reserved for the same mobile host on different base stations, although the mobile host will be using only one of the base stations. This scheme thus locks up the resource required by a mobile host on multiple base stations.

Just like RSVP, MRSVP is also not scalable, and the scalability would be limited based on the number of mobile hosts that require signaling for resource reservation and also on the number of available channels and network topology.

INTERNETWORKING OF THE HETEROGENEOUS WIRELESS INTERNET Internetworking Through IPv6

It is widely accepted that the next-generation heterogeneous network, as shown in Figure 5, will be all IP-based (see, for example, Berezdivin et al., 2002). IP version 6 (IPv6) is the promising candidate for the next-generation networks (Deering et al., 1998). The IPv6-based underlying transport mechanism will glue the heterogeneous networks together. The reasons for using IPv6 are enumerated:

- The address space of IPv4 is getting scarce and will not be able to cope with the expected number of mobile devices (such as cars, home appliances, and embedded electronics) in the future. IPv6 with its 128-bit address size will thus be required.
- IPv6 offers enhanced mobility support because of hierarchical addressing.
- IPv6 provides authentication and encryption that is enabled by IPsec and introduced through the extension headers.

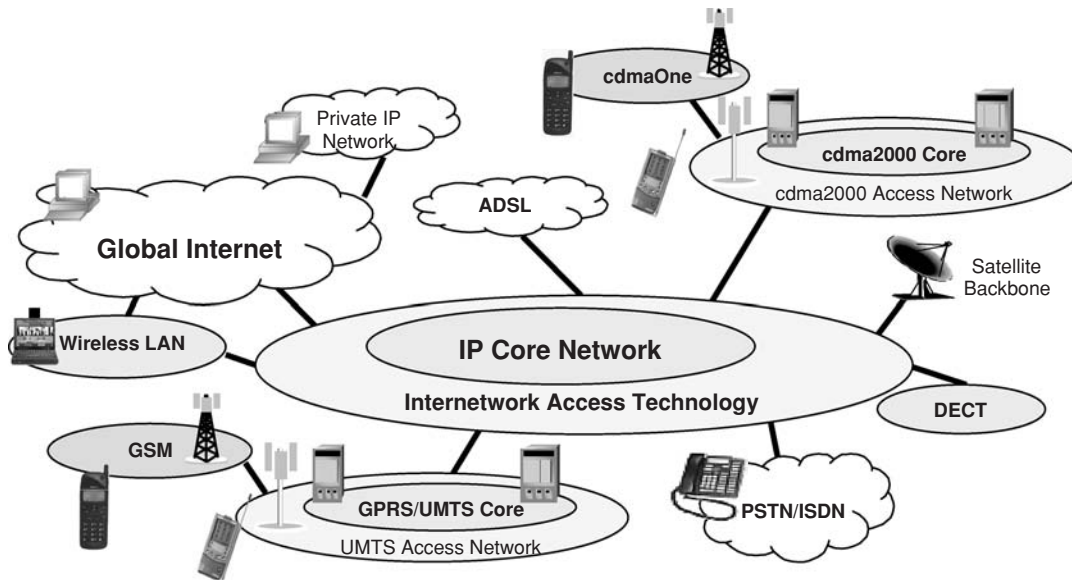

Figure 5: Overview of the next-generation heterogeneous network.

- IPv6 offers efficient packet processing in the routers because of fixed header size.
- IPv6 alleviates the ease in introducing existing Internet applications.

Therefore, the modular architecture of a 4G network is expected to have IPv6 as the dominant interworking layer. Unlike the TCP/IP protocol stack, where the adjacent layers solve particular problems, abide by stringent independent rules, and provide services to the upper layer, there will be cross-layer coordination (Carneiro et al., 2004) among different layers within the next-generation architecture. Such coordination will facilitate the network configuration by taking into consideration the access-specific information, available resources, and subscriber profile. For example, a video application, with a priori knowledge of the radio access network and user preferences, may adaptively vary the video rate as link quality deteriorates. Similarly, in the case of a highly mobile subscriber, the network may ascertain, by considering the service policy in the subscriber profile, whether the current resources available can support the ongoing session or whether a QoS renegotiation is required.

Technical Issues with Internetworking

Specification of an internetworking open architecture that enables seamless integration of mobile telephony and Internet services, independent of access technologies, requires implementation of novel mobility, resource, and QoS management schemes. Smooth interaction among these three schemes is essential for maintaining seamless connectivity and end-to-end QoS between peer end terminals. The key attributes of these schemes are given here:

1. Mobility management involves managing two forms of mobility.
 - A) Terminal mobility, where the MT moves within and across network domains while continuing to receive

access to telecommunication services without any data packet loss and with minimum handover delay (the time required to undergo successful handover).

- B) Personal mobility, where the subscriber obtains services in a transparent manner within any network and on any terminal, on the basis of subscriber identification and the network's ability to provide the requested services.
2. Resource management is the provision of adequate resources (allocation and deallocation) within both access and core network to support communication sessions. It involves
 - A) The capability to offer services to roaming subscribers similar to their home network environments (subject to visited network capability and services) upon subscriber authentication.
 - B) The management of local resources independent of roaming subscribers' home networks.
 - C) The allocation of adequate resources required by end terminal applications before the commencement of a communication session and possible renegotiation during the session.
 3. QoS management, which ensures QoS support to a wide range of services over dynamic link conditions. It involves these elements:
 - A) The capability to set up a data path and negotiate QoS between peer end terminals at the commencement of a session and dynamic renegotiation to sustain data transfer during the session. Some of the QoS parameters that influence the negotiation include available bandwidth, data rate, user preferences, end terminal capacity, and application requirements.
 - B) Distributed architecture that supports differentiated services, as per the user's service policy and type of subscription.

Because such schemes are imperative to the successful development and implementation of a modular 4G network

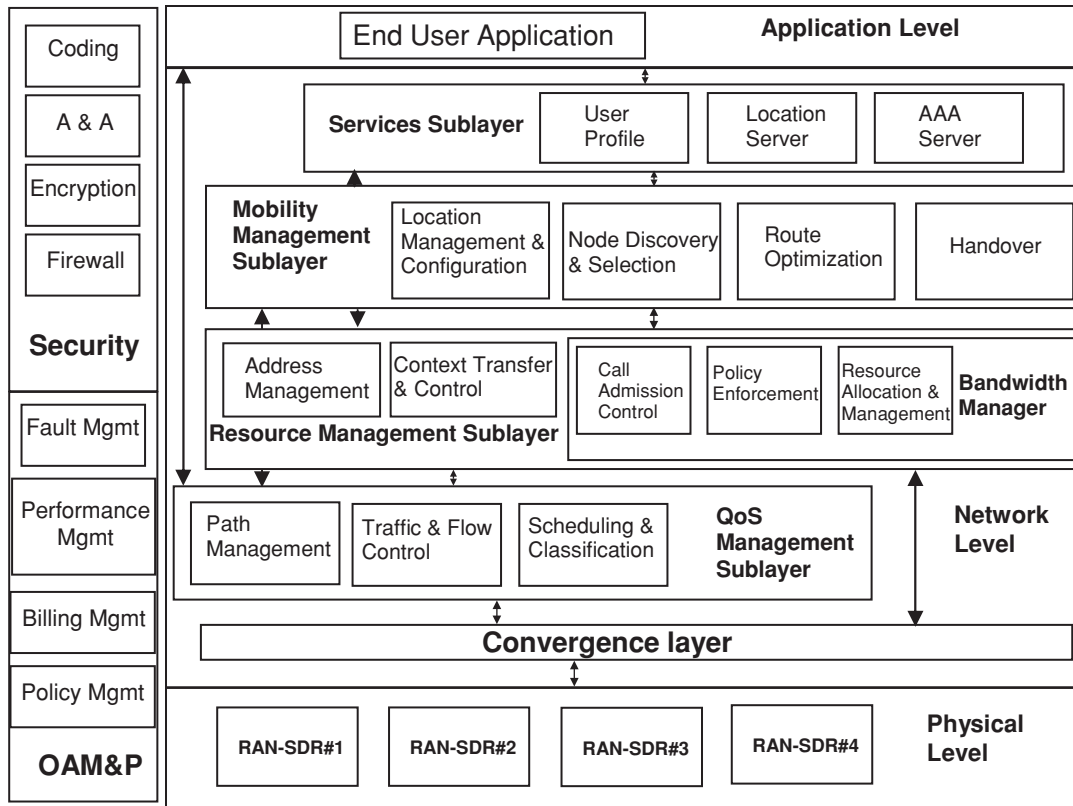

Figure 6: Proposed layered and modular 4G/B3G network architecture.

architecture, key issues considered in designing these schemes are the following:

1. Mobility management:
 - How to address both fast- and slow-moving subscribers?
 - How to handle intra-access router, interaccess router, and interdomain handovers that encompass both horizontal and vertical handovers?
 - How to solve the need for the mobile terminal to scan all possible access technologies for wireless system discovery with limited battery power?
 - How to reduce the signaling load when the mobile terminal experiences frequent handover across smaller cells?
2. Resource management:
 - How to ensure that resources, as required by the end terminal application, can be offered between peer end terminals?
 - How to make sure that resource allocation takes into consideration current network conditions?
 - How to provide a secure communication path between neighboring resource management entities, independent of the actual data communication path?
3. QoS management:
 - How to ensure end-to-end QoS between peer end terminals?
 - How to maintain QoS for an ongoing application session with degradation of link quality?
 - How to offer differentiated services across access and core networks based on subscriber profiles and service policies?

Layer Functionalities

Figure 6 depicts the proposed layered/level approach for the 4G/B3G network architecture shown in Figure 5. The functionalities provided by each layer and its modules are briefly described here.

Application. This layer comprises the third-party applications provided to the subscribers. Third party refers to applications provided by someone independent of the network operator. To enhance the service quality, value-added services can also be introduced with or without the subscriber's knowledge (a single subscription), as shown in the business model (MWIF, 2001) of Figure 7.

Network. This layer/level provides service control and mechanisms essential for the smooth operation of the

Figure 7: The business model.

network architecture. Acting as the linchpin, this layer provides management of services and dynamic cross-layer coordination between different layers to facilitate enhanced operation. Different sublayers comprising the network-layer functionality are listed:

- *Services sublayer.* The user profile, location server, and AAA server within this sublayer provide the repository for user preferences, dynamic information associated with the subscribers, terminal and service mobility, subscriber identity authentication, and charging information associated with the resource usage during user activity and so forth. The repositories are located both in the home network and the visited network.
- *Mobility management sublayer.* This sublayer consists of functions to enable subscribers with the ability to move among IP subnetworks, that is, to support roaming and handover control. This entity supports location update of a dormant or roaming subscriber, wireless system discovery and selection to initiate and sustain a communication session, optimization of the routing path between peer end terminals, seamless mobility with no packet loss, and minimum handover latency. This sublayer is primarily located within the serving domain to reduce signaling overhead during the handover period.
- *Resource management sublayer.* This sublayer manages IP addresses of roaming and home subscribers, initiates fast context transfer (e.g., user profile and QoS parameters) between access networks as the subscriber changes its point of attachment, and controls the resources within the domain through the bandwidth manager. Distributed throughout the serving domain, the bandwidth manager offers functionality regarding new call admission and support of existing sessions, session and service enforcement policy (e.g., expected QoS, valid times, routes), and allocation and deallocation of resources before and after a session between peer end terminals. This sublayer is located in home, visited, and all intermediate networks.
- *QoS management sublayer.* This sublayer offers end-to-end QoS service between peer end terminals through optimal path establishment before the commencement of a session and possible rerouting owing to link quality degradation. This can also be realized through effective traffic and flow control to eliminate bottlenecks, especially in access networks, and to offer differentiated services for different types of subscription and network policies. This sublayer is located in home, visited, and all intermediate networks.

Physical. This layer consists of core network and heterogeneous access networks. Reconfigurable SDR-based end terminals are required to support multimode services across a wide range of radio access networks (RANs).

The convergence layer allows access-independent network functionalities in the underlying network to communicate via different access technologies in a transparent manner, hiding access-specific signaling requirements within the layered architecture.

Finally, the security and OAM&P layer, spanning the entire layered architecture, involves the following functionalities:

- Assurance of authorized use of network resources and services by subscribers, and confidentiality and nonrepudiation of services and resources.
- Maintenance of all three layers (e.g., application, network, physical) during the life span of a communication session.
- Fault management when experiencing sudden breakdown of a link or a functional entity.
- Performance management to ensure user-requested QoS can be supported.
- Billing management in accordance with the real-time and non-real-time resource utilization during subscriber activity.
- Policy management to enforce functionality conforming to service policy and subscriber preferences.

Message Interfaces Between Layers

In next-generation mobile networks there must be cross-layer coordination among different entities within the architecture. Given here is a list of message interfaces among the functional entities to facilitate such cross-layer coordination:

- Wireless system discovery within the mobility management scheme requires BAN to provide a list of access networks and their associated QoS parameters capable of supporting end-terminal applications. Such a list is available through the interaction of application layer, QoS management sublayer, resource management sublayer, and mobility management sublayer.
- To support QoS-enabled application, direct communication between application layer and QoS sublayer are essential, such as adaptively varying the application rate to compensate for the link quality degradation.
- Mobility management involves location update, wireless system discovery, and so forth. Because services offered by the visited network depend on service policy and subscriber profiles, and because subscriber profiles are usually located at the serving domain repositories, signaling between the mobility management sublayer and the services sublayer is essential. For similar reasons, signaling between the services sublayer with resource management and the QoS management sublayer is necessary.
- Mobility management further requires a list of access technologies capable of supporting the end-terminal application. Such a list, along with the available resources, is available only from the resource management sublayer. Therefore, interaction between the mobility management sublayer and the resource management sublayer is essential.
- Furthermore, with vertical handover, it is possible that the requested application QoS cannot be supported by the underlying network. Therefore, interaction between mobility management and QoS management sublayers must take place to support QoS renegotiation between peer end terminals.

- Accounting information gathered from resources used, QoS provided, and time and duration of provision of network resources will be provided to the service management functions (OAM&P).
- Because the technology-specific RANs reside within the physical layer, the distributed functional elements within the network layer require a convergence layer to hide the underlying network from access-specific signaling and to communicate via diverse RANs.

Novel augmentations in mobility and resource management schemes incorporated in our layered 4G/B3G architecture aim to provide superior services as compared to other network architectures. A brief description of these augmentations is given in the following section.

AUGMENTED MOBILITY, RESOURCE, AND QoS MANAGEMENT

Mobility Management

Two forms of mobility are encountered during seamless connectivity across heterogeneous networks, namely macromobility and micromobility. Macromobility is defined as mobility across different subnetworks (between the home network and the visited network), whereas micromobility refers to mobility across different APs within the same subnetwork (within the home network or the visited network). Although there is no exact solution to the mobility problem in a heterogeneous environment, well-established solutions for the wired Internet may be taken as guidelines.

Mobile IP (Johnson et al., 2003; Perkins, 1996) is a solution proposed in the wired Internet to resolve the macromobility problem. With Mobile IP, roaming subscribers enjoy Internet connectivity in a transparent manner without any manual configuration. In a visited network, a roaming host is required to register with its HA to access the Internet. While attaching to the foreign network to support a call, the host acquires a local care-of address (CoA) through either stateless or stateful autoconfiguration and performs a triangular route optimization (Johnson et al., 1998) to the CN. Packets addressed to the mobile host are delivered using regular IP routing to the CoA, thereby offering a transparent, simple, and scalable global mobility scheme.

Even though network support for seamless mobility was not considered when Mobile IP was originally developed, it finds applicability in the wireless environment through the endeavors of the Mobile IP Working Group (WG). In a wireless environment an MT frequently changes its point of attachment, that is, performs handovers to initiate or continue communication sessions with other nodes in the network (known as micromobility). Because a local CoA must be obtained and communicated to the HA and the CN after every migration, the significant latency introduced by Mobile IP causes considerable packet loss during the handover period (especially if the home and foreign network are far apart), rendering real-time data transfer useless until the CN is notified of the new CoA. The micromobility handover scenario is

further aggravated with varying link conditions, higher subscriber mobility, and scarcity of resources.

With future networks composed of overlapping heterogeneous access networks glued together by a common IP core and nonproprietary protocols, the issues of both macromobility and micromobility need to be addressed. With hundreds of millions of wireless subscribers accessing the network in the future, service providers will have to resolve these issues in order to deliver quality service, minimize signaling, and scale to support the huge subscriber base. Hence, an effective mobility management scheme and reconfigurable MTs will be required to allow the 4G network architecture to provide real-time multimedia services with as little disruption as possible to the ongoing sessions.

We first discuss the mobility management in the two significant 4G architectures—Mobydick and MIRAI—and then we discuss our proposed mobility management scheme. We then summarize the key differentiators between our mobility management scheme and that of Mobydick and MIRAI.

Mobydick Mobility Management

The IST Mobydick proposed architecture offers an end-to-end QoS and seamless mobility across heterogeneous networks. Mobile end terminals, equipped with interfaces of W-CDMA (UMTS-TDD), WLAN (802.11b), and Ethernet, access the Internet through access routers (ARs) that provide interfaces between wireless access network and the wired core network. The network management entities such as QoS brokers, AAAC servers, and paging agents are located in the fixed core network.

Access to services across various administrative domains and different access technologies is provided according to the subscriber preferences stored in the subscriber profile at the home network. Seamless mobility and fast handover are provided through FMIPv6. However, FMIPv6 fails to eliminate handover latency completely. In addition, after every successful handover and after attaching to the new AR, the MT is required to send BU to both the HA and the CN. With highly mobile subscribers roaming across smaller cells that offer greater bandwidth and faster links, such BU results in considerable signaling load, especially with large subscriber bases in urban areas.

Because future networks will consist of overlapping heterogeneous networks, the MT is required to scan all terminal interfaces to find out available resources, determine whether a handover is imminent, select the target AR, and initiate a handover request to the current serving AR. The processing power required to listen to all broadcasts over different access technologies and select target AR after gathering required Layer 2 information imposes a considerable drain on the battery power. With small handheld terminals available in the market and drive toward increasingly miniaturized handsets, already limited battery power will be further compromised. It will be beneficial to have an energy-saving flexible system that offers minimal changes to the existing technologies through a common mechanism. However, such a common mechanism to provide Layer 2 information regarding all available access technologies within the radio coverage area is presently

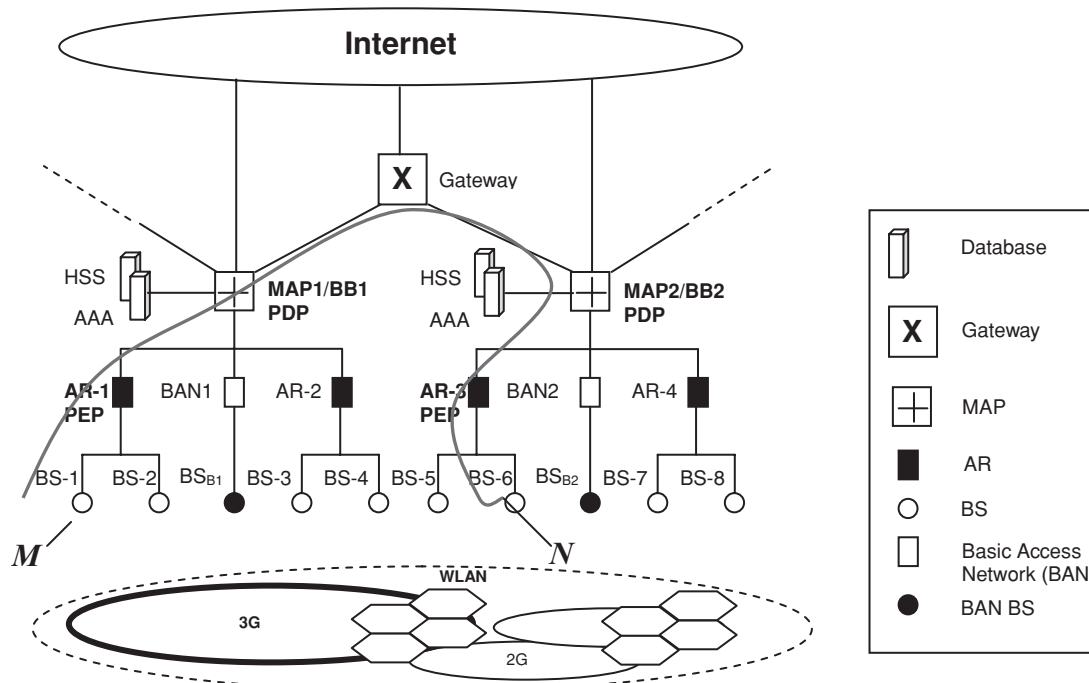

Figure 8: Hierarchical mobility management architecture.

absent in the Mobydick architecture. This common signaling mechanism will be essentially a low-bandwidth, low-cost dedicated network that provides paging, wireless system discovery, and assistance with mobility management. Currently these services are carried out inside the core and the access network in Mobydick architecture, thereby imposing additions to the already scarce radio resources of the access networks.

MIRAI Mobility Management

The MIRAI uses a hierarchical structure composed of base stations (BSs), ARs within the common core network (CCN), and a gateway router (GR) connected directly to the Internet. The signaling agent (SA), the key element in the architecture, is located on the same level as the ARs and maintains two databases, namely the location database (LDB) and resource database (RDB), for controlling the data transmission process within the domain. The BAN provides paging, wireless system discovery, and mobility management for the multiservice user terminal (MUT) through a common control and signaling channel.

The necessity of a common mechanism enveloping all access technologies to support such services is missing in the Mobydick project, whereas it has been addressed in the MIRAI architecture. This dedicated signaling network overlays the existing 2G cellular system, 3G cellular system, and WLANs to minimize the change to these systems. BSs belonging to this dedicated network and managed by the signaling gateway (SG) cover the whole geographical region of a domain. The entire MIRAI architecture is built around the BAN structure and the availability of a bidirectional, low-data-rate, reliable common control and signaling channel. However, with overlay BAN architecture, this low-data-rate channel will experience similar dynamic characteristics (e.g., deep fades,

co-channel interference, and small SNR) as the radio links within these systems, rendering control data transmission unreliable.

During initial registration, a roaming MUT determines its exact location using a GPS receiver embedded in the terminal and sends the information (e.g., latitude, longitude, altitude) to the network via the BAN to facilitate location management and service optimization. However, GPS signaling is severely undermined within indoor environments or by the presence of thick foliage. Moreover, the MUT generates local CoA through stateless IPv6 autoconfiguration (from the domain subnet prefix broadcast over the BAN system). Usually the generation of a local CoA by stateless IPv6 autoconfiguration from subnet prefix ID is accompanied by DAD to determine the uniqueness of the CoA. It is extremely difficult to run DAD in a wireless environment, and without DAD the generated CoA runs the risk of being a duplicate within the domain, causing service disruption. Lastly MIRAI suffers from the absence of a definitive QoS-enabled MUT terminal with cross-layer coordination and an effective QoS and resource management scheme.

Proposed Mobility Management Scheme

An underlying hierarchical structure, as shown in Figure 8, is proposed to facilitate seamless mobility across heterogeneous networks. Fast handover for hierarchical mobile IPv6 (F-HMIPv6; Jung et al., 2004) is incorporated as the micromobility scheme within the hierarchical system, unlike Mobydick, which uses FMIPv6. Jung et al. (2004) state that F-HMIPv6 considerably reduces the handover latency even more than FMIPv6.

Within the hierarchical architecture, the lowermost tier is formed by BSs that are controlled by ARs. Unlike the overlaid BAN architecture in MIRAI, our mobility

management scheme utilizes a *dedicated control and signaling* BAN system, independent from the existing heterogeneous access networks. This system provides (a) wireless system discovery and paging services, (b) location management, (c) support for vertical handover, and (d) simplicity and energy-reserving capability. All overlapping heterogeneous networks within the domain access the Internet through the mobility anchor point (MAP). The gateway (GW) connects multiple MAPs to offer faster connectivity and data transfer during interdomain handovers. Every domain is maintained by an administrative body and a service agreement exists among different access technology providers.

A roaming MT is identified by three IP addresses: (a) MT's home address, (b) MAP's IP address or regional care-of-address (RCoA), and (c) local CoA (LCoA) assigned by DHCPv6-enabled AR (every AR is allocated a pool of IPv6 addresses). The MAP, ARs, and BAN communicate among themselves through several Layer 2 signaling protocols, for example, PPP and L2TP, to formulate a list of resources offered by these heterogeneous access networks. The BAN periodically broadcasts this list of available access technologies within the coverage area on its reliable low-data-rate channel. This list includes Layer 2 ID of BSs, their associated AR IP addresses, and a limited number of QoS parameters, for example, supported data rate and video coding rate. If the list is too long to be accommodated in a single packet, it may be fragmented across smaller packets.

Similar to MIRAI, our proposed architecture utilizes micromobility protocols such as cellular IP (Campbell et al., 1999, 2000) and HAWAII (Ramjee et al., 2002) to support passive connectivity and paging. The home subscriber server (HSS) stores user profiles and service policy as repositories, whereas the AAA server stores authentication and accounting information. Both of these servers are located at MAP.

During the registration process, every node en route to the MAP caches (a) soft-state information of the LCoA of the MT and (b) interface ID over which the registration request packet is received. After initial registration, every subsequent data packet to and from the MT refreshes the routing path to the MAP and reduces the need for paging an MT with a recent data session history within a certain time-out period. The MT configured with LCoA listens to periodic broadcast of AR identification after the registration process, even in the sleep mode. This allows the MT to roam greater distances without initiating data sessions. Because the LCoA is valid only within the coverage area of a serving AR, if the MT roams into the coverage area of another AR then it must be configured with a new LCoA.

During inter-AR handover, in addition to context transfer (e.g., current session QoS parameters and video coding rate) between old and new ARs, the MAP bcasts data packets to both of these ARs. This consequently makes the change of LCoA and local handover process transparent from the distant HA and CN. During interdomain handover, the GW bcasts data packets to both the old MAP and the new MAP. As such, the GW allows faster connectivity across domains and hides the frequent interdomain handovers experienced by subscribers in fast-moving

vehicles. A new BU to the HA and the CN is required only when there is an interdomain handover or a dormant MT roams into a new domain.

In our mobility architecture three types of handovers are possible: inter-BS, inter-AR, and inter-MAP. Inter-AR and inter-MAP handovers are the most challenging of the three. Figure 9 summarizes the signaling process required during the inter-MAP handover as part of the mobility management scheme in Figure 8. Let us assume that a roaming terminal "M" linked to AR2 has an ongoing session with a terminal "N" linked to AR3 in a different domain. As the MT leaves its serving domain, it initiates an inter-MAP handover. The complete inter-MAP handover process includes (a) RAN list broadcast and reply to ascertain availability, (b) handover trigger and request by MT, (c) resource negotiation by GW with MAP2, AR3 pair in the target domain, (d) bcasting of data packets to both MAP1 and MAP2 by GW, and (e) MT registration with AR3 to reestablish the data session. GW then sends a request to MAP1 to release the connection. In the absence of such a request, a time-out period applies. The trace of this inter-MAP handover is shown by the solid line in Figure 8.

Resource Management

A distributed BB architecture is proposed inside the domain where each router is capable of becoming a BB (although MAP seems to be the prime candidate to take on the role of a BB). Elected through an election process, for example, based on time online or edge routers, the primary BB is shadowed by a backup BB in case the primary BB were to fail. The functional elements of the BB include service level agreement (SLA) and service level specifications (SLS), neighboring BB database, admission control service (ACS), authentication and authorization, policy decision point (PDP), and so forth. The routers at the edge of the domain identify/deduce themselves to be the edge routers based on the hierarchical source address obtained from their neighboring routers during an OSPF link-state database build-up. Interdomain BB identification for end-to-end QoS admission control is carried out through interactions among edge routers. RSVP is used at the network edges with DiffServ used in the core network for fixed network connections. Furthermore, a sub-network bandwidth manager (SBM) will be used at the AR so as to provide admission control for wireless connections.

Figure 8 also shows our resource management procedure during the setup of an interdomain communication session. The domains are DiffServ enabled and traffic is classified at the edge routers, in this case AR1 to AR4, and assigned to different behavior aggregates. Each behavior aggregate is identified by DSCP bits. Let us assume that a mobile unit "M" linked to BS4 needs to communicate with a peer mobile unit "N" linked to BS6. The BB1 will first verify with an AAA server if the mobile user "M" has permission to access the resources in its domain and if the request is for an intradomain or interdomain destination. In case of an interdomain request, the BB1 will develop a map of neighboring BBs that control different networks by constructing forwarding tables as in OSPF. The BB will

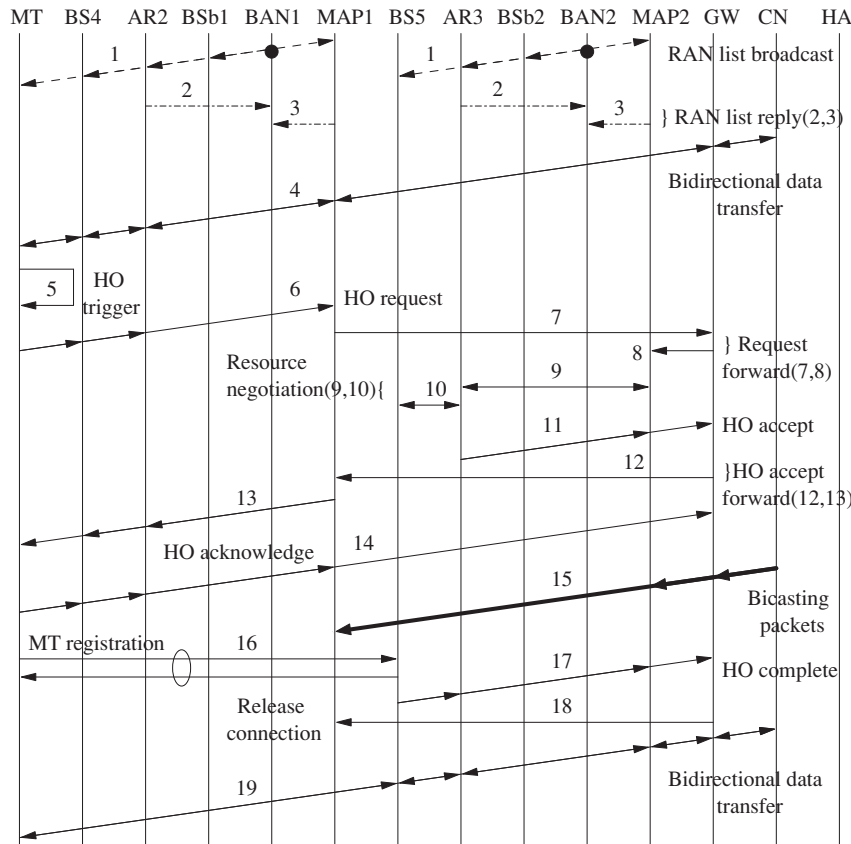

Figure 9: Bounce diagram for handover of MT “M” from BS4 to BS5 between different MAP domains (MAP1 to MAP2).

also incorporate a PDP to carry out admission control in its domain, based on prior administrative/dynamic policies. In a simple case, this will involve checking for the resource availability at the edge routers, that is, AR1–AR2 for the domain of MAP1. The BB1 will coordinate with the BB2 to determine (a) if the destination exists within BB2’s domain and (b) if resources are available in its domain to support the traffic from “M” to “N.” If not, BB2 will be able to negotiate with BB1 regarding “N’s requirements.” In case there are several BBs in between the source and destination, then coordination for resources will have to be carried out with each of the intermittent BBs. If the request for resources from BB2 is successful, then policy enforcement point (PEP) implemented in the AR will police the user “M” and verify “M” does not exceed the amount of resources it is paying for. The AR2 may also inform the AAA server of usage by the user “M,” which is especially important in the case of prepaid subscribers. For this discussion, the trace of BB operation is shown by the broken line in Figure 8.

Quality of Service

QoS means the ability of the network to support an application irrespective of network conditions. This means that the application works satisfactorily irrespective of the changes that may occur on the network. A good tutorial on QoS can be found in Chalmers and

Sloman (1999). The QoS is generally characterized by performance parameters:

- Delay (latency) of packet transfer
- Delay variation or jitter (time differences among the arrivals of packets on the same path)
- Throughput (rate at which the packets transit through a network)
- Packet loss (percentage of packets dropped or lost while transiting through a network)

The legacy IP infrastructure of the Internet was designed to offer best-effort service; that is, all network traffic is created equal and the service is based on availability rather than guarantees.

A common way by which network providers try to offer QoS is by bandwidth overprovisioning. However, such a method cannot cope with the rapidly increasing growth of the Internet as it requires too much of bandwidth reservation of the scarce communications resources. As such, initiatives have been taken by the IETF to offer degrees of IP-based QoS. Two popular methods proposed by WGs within the IETF to offer QoS are integrated services (IntServ) and differentiated services (DiffServ). RSVP protocol (Braden et al., 1997) is proposed by the IntServ WG, which essentially is a receiver-oriented reservation protocol. The receiver-oriented nature of the protocol allows support of diverse machine types on the Internet.

RSVP relies on the fact each router carrying the flow between the source and destination will maintain the state information of the reservation request. However, because there are several flows in a large network, the RSVP protocol results in a state explosion in the routers. As such, RSVP is not sufficiently scalable.

In contrast, the DiffServ protocol proposed by IETF is scalable because differentiation of service is offered for different traffic types by setting appropriate bits in the type of service (TOS) field of each packet. The TOS field is formed of a six-bit DiffServ code point (DSCP) field and two currently unused bits of each packet. The six bits of the DSCP subfield offer 64 unique service levels, which offer a very high level of traffic granularity. The IPv6 header has native support for DiffServ classification in the DSCP.

The DSCP corresponds to a per-hop behavior (PHB) that defines the relative priority and QoS parameters that a packet should be given by each node in a DiffServ domain. The PHBs have been standardized by the DiffServ WG based on the service type required. These are listed here:

- Best-effort PHB: For best-effort service.
- Expedited forwarding (EF-PHB): This is also referred to as premium service and is used to deliver guaranteed amount of bandwidth, while minimizing delay and packet loss. In effect it offers a virtual leased-line ToS.
- Assured forwarding (AF-PHB): This defines a class of service that is better than best effort but lower than that of EF. Within AF there are four different subclasses based on the drop precedence of the packet. IETF RFC 2597 describes the method for implementing the Olympic service model of AF—bronze, silver, and gold classes. Packets in gold class are forwarded ahead of the silver and bronze class. Silver class packets are forwarded ahead of the bronze class.

An important aspect of managing different traffic classes is traffic conditioning. The traffic conditioning in the DiffServ architecture offers

- Enforcement of SLAs among different domains.
- Classification of the traffic based on DSCP.
- Policing and modification of the traffic distribution characteristics in the network elements if required.
- A scheduling mechanism to manage the different class-type traffic in the routers. This is mainly done through

queue management techniques such as weighted fair queuing and random early detection.

As such, no state information needs to be maintained at each router between the source and destination. Furthermore, faster processing can be achieved by aggregating the similar traffic-type flows and representing the aggregated flow by unique DSCP bits.

QoS-Enabled Handover

QoS-enabled handover can be enhanced by the use of an umbrella cell. Instead of making prior reservations by means of MRSVP, the MT could establish a link with the more-resourced umbrella cell. The MT may use the umbrella cell until either resource can be reserved with a new base station or until a set timer value expires. If the hand-off timer value expires, the MT may be denied service from the new BS, or the new BS may use the tariff paid by the MT as a criteria to degrade some other MTs service in the local cell and provide the resulting resources to this new MT that wants to handoff.

Alternatively, during handover an Internet2-based mechanism known as alternative best-effort (ABE) service (Teitelbaum, n.d.) can be adopted to differentiate the best-effort service class into multiple “different but equal” BES classes that trade for delay or loss. In cases where a moderately loaded network is required to support applications with stringent real-time constraints such as interactive audio, ABE service will allow applications to choose between receiving lower end-to-end delay or receiving more overall throughput. A MT may use the ABE service during the handover period until resources are found and reserved in the new cell. This means that when a MT performs the handover algorithm it will consider all services to be best effort. It then will use the ABE-based algorithm to provide low latency or low throughput to services based on service requirements.

MOBILE TERMINAL ARCHITECTURE

The mobile terminal market is inundated with access-specific handheld terminals over a wide range of brands from various manufacturers. With a multitude of heterogeneous access networks glued together through a common mechanism, terminals built for specific systems (e.g., cellular, wired, and WLAN) will prove inadequate to support seamless mobility. Furthermore, constant evolution of link-layer standards and incompatibility of access technologies in different countries prohibit

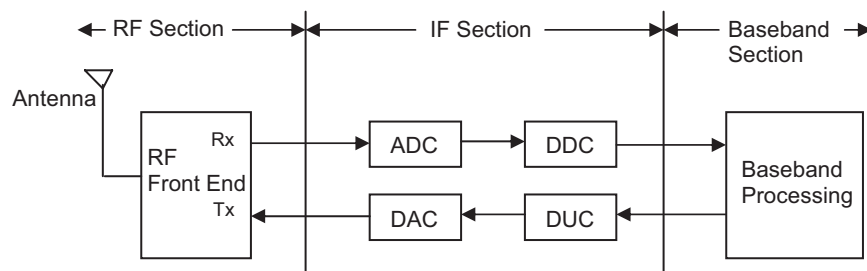

Figure 10: Block diagram of a traditional digital transceiver.

Figure 11: An ideal software radio receiver.

deployment of global roaming facilities. The limited services resulting from the presence of large-scale legacy (e.g., 2G) subscriber handsets complicate the impending problem.

Because the current digital transceivers shown in Figure 10 can support only one access technology, a unique standard is required to dynamically adapt to the radio environment in which the terminal is located. This will enable end-to-end connectivity over a wide range of frequency spectra in a highly diverse system with signaling requirements. SDR (Buracchini et al., 2000; WIPRO Technologies, 2002) promises to offer such a standard in a multiservice environment without being constrained by any specific standards. In SDR-based terminals, radio functionality for different access technology is implemented through software modules running on a generic hardware platform. Figure 11 shows the block diagram of an ideal software radio receiver.

The received analog signal is digitized by the analog-to-digital converter (ADC) and then processed by the reprogrammable baseband digital signal processor in accordance with the wireless environment in which the terminal is located. Because current conventional software radio technology utilizes only one antenna and one LNA (low noise amplifier), configuring the terminal over a wide range of frequencies pertaining to different access technologies will require parallel processing across multiple software modules, which will lead to further terminal design complexity and high power consumption and

dissipation. Moreover, current ADCs are not fast enough to offer adequate service benefits. Even though development of such terminals is still in their infancy, with advancement in processing power and digital technology, it will be possible to offer SDR-based MT to provide global connectivity in the near future.

MIRAI (Mahmud et al., 2002) has proposed the physical architecture of an SDR-based MUT. However, because of the use of a single antenna, the MUT fails to provide multiaccess service (multiple streams over different access networks from the same application; Laine et al., 2000) for the purpose of load sharing and better utilization of the available resources. The only downside to the multiaccess service is that it may not be feasible in rural areas with sparse radio coverage and an absence of overlapping access networks. Also the use of a GPS receiver to determine the exact location of the MUT prohibits usage within indoor environments and in areas with thick foliage.

Figure 12 shows the physical architecture of the proposed reconfigurable SDR-based MT. Although somewhat similar to the MUT design in MIRAI, the MT does not have a GPS receiver and is equipped with multiple interfaces to meet the multiaccess service criteria.

The reconfigurable terminal communicates through the basic access component with the BAN to initiate a data session, respond to paging, or discover available resources to optimize service parameters. Different software modules can communicate over multiple interfaces to alleviate load sharing and spectrum usage.

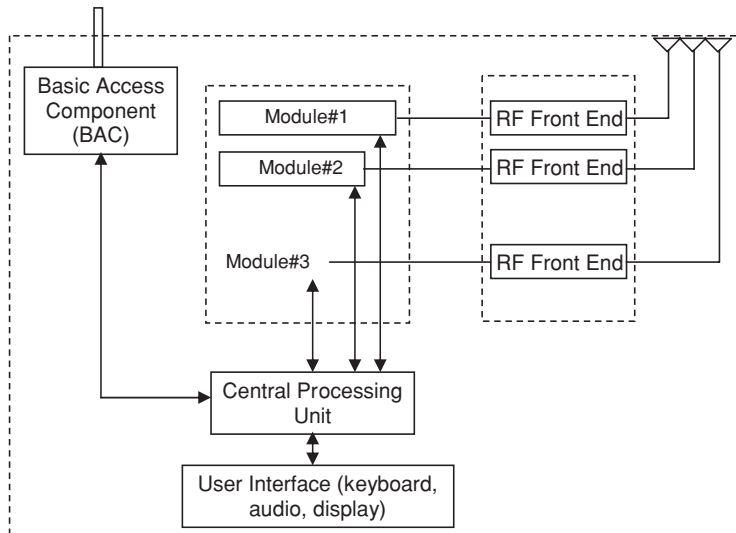

Figure 12: Physical architecture of SDR-based reconfigurable MT.

It is desired that the end-terminal architecture is modular (existing and future applications can be supported without any service disruptions), flexible (new signaling mechanism can be easily introduced), and open (relevant protocols developed later by bodies such as IETF can be supported). The proposed multiaccess, multi-antenna, reconfigurable terminal meets all these criteria. In the envisioned 4G network environment, every proprietary handset (i.e., hardware platforms not compatible with each other) from different manufacturers is equipped with a SIM (subscriber identity module) or smart card. The software required to configure the terminal to the technology-specific access network at its geographical location is embedded in the card. The compiler residing within the central processing unit generates a hardware-specific executable code from the software/source code in the card. The source code will be written in a universal standard format, irrespective of the underlying hardware.

It is believed that instead of acquiring software through over-the-air downloading, which presents issues such as slow downloading rate, considerable downloading time, unreliable channel characteristics, and so forth, it will be beneficial to download the software from the SIM/smart card within the terminal. Such a mechanism not only ensures faster processing and error-free download, but also allows for larger memory to be supported. With numerous recharging outlets located at supermarkets, gas stations, hotels, airports, train stations, and so forth across the country, it becomes just a matter of recharging the SIM/smart card at a reasonable price to ensure that the terminal supports the most advanced and recent technologies. Across countries where operators support a different signaling and download scheme, such a process will save subscribers the cost of purchasing a new SIM/smart card.

Another feature absent in the MIRAI MUT is the capacity to support multicasting to various interest groups. In our opinion, multicasting will turn out to be highly desirable service criteria in future networks as online games and video on demand rise in popularity. With increasing subscriptions of divergent preferences, the network will experience a sharp increase in signaling load. Aggregation of signals and data streams, according to the predefined differentiated service agreement and QoS parameters, will be necessary to keep the signaling load within an acceptable level. Buffering, along with a timing mechanism, will have to be introduced for the aggregation of multiple streams. For example, in the event of sudden degradation of link quality, the access network will be able to buffer the data stream until the terminal is able to receive the data packets under favorable network conditions. Also, an aggregated reply on behalf of the multicast group will be sent to the peer source terminal following a time-out period.

Although the SDR-based reconfigurable terminal must be able to adapt itself to a wide range of access technologies already standardized or to be developed in the future, it is equally desirable that the terminal adapts to unpredictable events such as sudden degradation of link quality/handover by possibly having a prenegotiated set of countermeasures. This requires the capability to renegotiate QoS parameters based on a predefined set of QoS

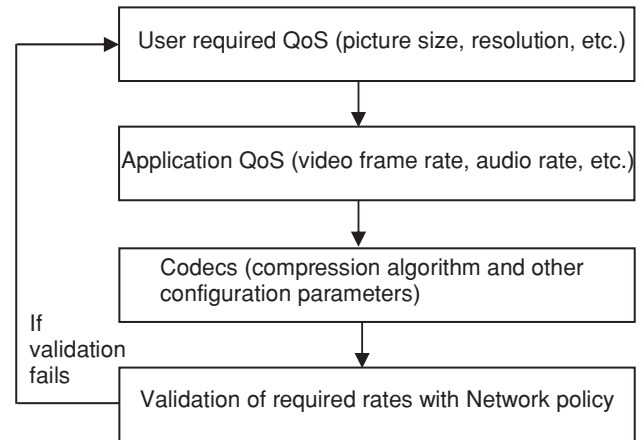

Figure 13: Mapping of QoS requirements between different entities in the end terminal.

contracts without running a full end-to-end QoS negotiation between peer terminals.

As the link condition deteriorates, the MT may continue the ongoing session at a predefined QoS agreement, for example, a lower video rate, smaller frame size, or better coding scheme, to compensate for the degradation of the link quality. A signaling protocol such as piggybacking with low bandwidth requirements may be adopted to inform the peer end terminals of the required change. Apart from such capability, the terminal will have an operating system to support QoS functionality and will be QoS enabled through middleware. Currently it is assumed that all applications running on the terminal are somehow QoS enabled. However, in reality, not all applications running on the terminal are QoS enabled; therefore, middleware is required to QoS enable an application. Figure 13 shows the mapping of QoS-enabled application requirements in the proposed MT.

RELIABLE MULTICASTING

A multicast session involves sending control/signaling messages to multiple MTs in different domains by MAP in our architecture. To ensure reliable transfer of signaling information over bandwidth-limited BAN, we have proposed a reliable multicast protocol. Because establishing a TCP session or each signaling message would prove inefficient, this protocol is based on an underlying UDP transport protocol. Each receiver agent (RA) in the MT affiliates itself with a set of other receivers and a local AR (in our architecture) to form a multicast session. Messages to be delivered to all the receivers in the session are transmitted using one of the IP multicast addresses associated with that session. Our reliable multicast protocol promotes efficient bandwidth use by the aggregation of acknowledgment messages from individual receivers into a larger, hierarchical acknowledgment messages (HACKs). The net effect is that for each message sent via the BAN links to a potentially large number of receivers, only one acknowledgment (HACK) goes in the opposite direction to the sender. This allows explicit acknowledgment of messages to take place without requiring a flood of acknowledgment messages over the low-speed BAN links.

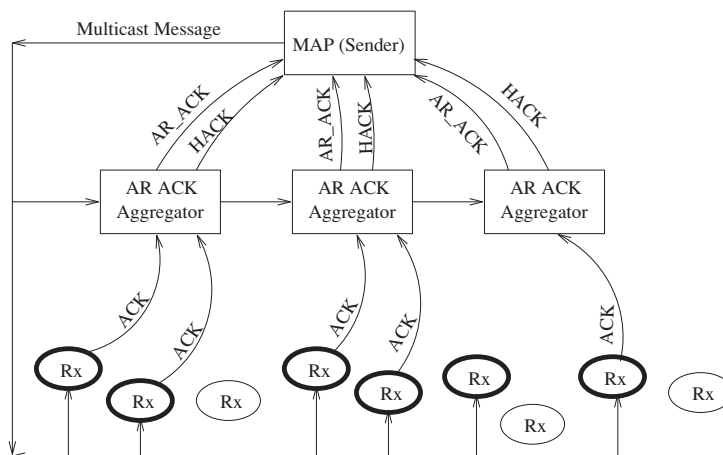

Figure 14: Reliable multicast operation.

As shown in Figure 14, all RAs and ACK aggregator agents (ARs in our architecture) associated with the multicast address receive the message sent by the MAP. Each message has an ID that is used in any acknowledgments limited to a particular multicast session and to detect and ignore duplicate transmissions. The ACK aggregators (ARs) associated with the multicast session on each AR zone will quickly and explicitly acknowledge reception of the message by sending an AR site acknowledgment message (AR_ACK) back to the sender. The AR_ACK is intended to allow timely retransmission by the sender in the event of packet loss on the BAN link. The ARs then collect the explicit ACKs from the receiver and produce a HACK, which will indicate the set of receivers that did not explicitly acknowledge the message. If all receivers successfully acknowledge the message, the HACK will contain "ALL_OK" and not an explicit list of successful receivers. It is possible for AR_ACK messages to be piggybacked onto a HACK as an optimization, reducing the number of packets required. When a receiver fails to acknowledge the message, the AR_ACK will be sent separately as indicated in Figure 14. This decouples the AR_ACK from the HACK and gives the MAP or other sender(s) the maximum amount of time to retransmit. The aggregators will wait for some specific time for an ACK from a RA before giving up and assuming it dead. During this time, the aggregator (AR) must retransmit a copy of the message on the local MT network in case it was dropped.

CONCLUSION

There is a gradual evolution occurring in the access network technology to offer more and more improved mobile services. Common mobile subscribers, with their mindset largely influenced by the Internet technology, expect the same level of service and application from mobile technology. Unfortunately the widespread proliferation of heterogeneous access technologies does not enable the consumer to use the same mobile terminal and enjoy a uniform level of service and applications globally. In this regard, a layered and modular architecture for 4G/B3G network was presented in this chapter to integrate the current access networks as well as those that would be developed in the future to support wireless

Internet applications. We further described our novel augmentations in mobility, resource, and QoS management schemes adopted in the architecture. We then compared these augmented areas with the corresponding areas in contemporary architectures. We believe that these augmentations will consolidate the 4G/B3G network architectures proposed in the literature. Furthermore, a multi-antenna and multiaccess mobile terminal architecture was proposed to facilitate seamless service. A reliable multicast signaling protocol over the BAN system was also described to support multicast services. The use of standards, specified by bodies such as IETF and MWIF (Mobile Wireless Internet Forum), in our proposed architecture makes our work viable for implementation and useful for the wider research community. Overall we believe that this proposal should make the next-generation network architecture flexible, make the handover process faster, allow the mobile terminal to support real-time applications anytime and anywhere, and make users transparent to different access networks that may exist. This will be the way toward real wireless Internet in the future.

GLOSSARY

- 2G** Second-generation wireless mobile cellular systems, mainly consisting of the global system for mobile communications (GSM) and cdmaOne.
- 3G** Third-generation wireless mobile cellular systems, mainly consisting of the universal mobile telecommunications system (UMTS) and cdma2000.
- Access Point (AP)** The base station of a wireless LAN or other types of networks.
- B3G** The temporarily system name for those under development for Beyond 3G wireless mobile cellular systems, sometimes referred to as 4G.

Basic Service Set (BSS) The usual form of a WLAN network with just one access point and several mobile devices.

Carrier Sense Multiple Access with Collision Avoidance (CSMA/CA) The medium access control protocol used in WLANs to avoid too many packet collisions.

Digital Audio Broadcasting (DAB) A technique to digitally transmit high-quality audio signals such as radio, usually by the satellite.

Digital Video Broadcasting (DVB) A technique to digitally transmit high-quality video signals such as television, usually by the satellite.

Extended Service Set (ESS) The cellular topology network of a WLAN with more than one access point.

Handover Change of receiving of service from one base station to another one for a mobile user who is moving; sometimes referred to as a handoff.

Heterogeneous Networks A network that consists of different types of systems such as cellular and WLANs.

IEEE 802.11 The main WLAN standard, developed by IEEE. It has several versions including the popular 802.11b and is usually referred to as Wi-Fi.

IP Internet protocol, the main protocol used in the Internet at the network layer (Layer 3). Currently it is in version 4 (IPv4), but IPv6 will soon be implemented.

Medium Access Control (MAC) The protocol at Layer 2 of the network that controls and governs network access by multiple users.

Mobile Ad Hoc Networks (MANET) Networks that are prepared and maintained temporarily for a particular purpose such as the establishment of a network among the computers of people attending a meeting or among mobile terminals in a battlefield.

Mobility Management Set of techniques that control the movement of a mobile device within a network and is usually composed of two elements: location management and handoff management techniques.

Quality of Service (QoS) Maintaining the required service conditions for a user in a network, such as providing a minimum data-transfer speed.

Resource Management A set of management techniques in a network that ensures that available resources, as required by the end-terminal application, can be offered between peer end terminals. These techniques ensure that resource allocation takes into consideration the current network conditions.

Resource Reservation Protocol (RSVP) A reservation control mechanism that provides quality of service (QoS) to users by reserving resources beforehand; usually used in the Internet QoS establishment.

Transmission Control Protocol (TCP) The vastly used transport protocol in the Internet that provides reliable data transfer among Internet terminals.

User Datagram Protocol (UDP) The unreliable transport protocol for the Internet that provides a smaller delay as compared with TCP, at the expense of lower reliability, and is used for short message transfers or delay-sensitive applications.

Voice over IP (VoIP) A technique to deliver delay-sensitive voice packets via the Internet, which can provide lower costs to users.

Wireless Local Area Network (WLAN) An extension of the traditional LAN systems in which the physical layer is changed from cable or twisted pair into GHz radio frequency for easier scalability and mobility within a building or a campus.

INTRODUCTION

The use of man-made satellites for telecommunication purposes started in the second half of the past century, with the requirement to greatly enlarge the visibility range between two earth stations utilizing the radio spectrum as propagation means and to overcome the limitations imposed by the Earth's spherical nature. For many years, satellite systems have been conceived as an alternative to terrestrial (both cabled and radio) systems and even as competitor of those systems, from commercial and market points of view. In addition to the negative effect on market penetration, the view of satellites as competitor sometimes caused invalid comparisons in the efforts to perform tradeoff analyses. In fact, satellites actually represent an excellent, sometimes unique, means to complement terrestrial facilities in order to complete the global information infrastructure (GII), in which every component (terrestrial cabled, terrestrial wireless, and satellite) must play the most suitable role to provide telecommunication services to every individual or machine everywhere at any time as efficiently as possible.

In this scenario, as long as the telecommunication systems assume an ever more important role in daily life (both personal and professional), the security of information represents a very critical issue. Security must be ensured at different levels, each requiring different implications. A first level of security concerns the possibility of establishing a physical link between two or several remote users. A second level of security concerns protection of

information from undesired reception or manipulation. As a component of the GII (global information infrastructure), for both aspects, satellites can provide an adequate level of security, as is stressed in the present chapter. As one of the most significant pieces of evidence, satellites are largely used by military. In addition, it is shown that satellites can even be utilized to provide security to other telecommunication systems.

In particular, a short history of satellite communications is presented; the main scenarios to utilize satellites are highlighted; the main characteristics of satellite systems are described; a reference scenario for security with satellite systems is introduced; communication, transmission, and information security issues are addressed; some examples of satellite systems actually implemented and operational that provide security communications are described; some elements on military satellite systems are provided; and finally, conclusions are drawn.

SHORT HISTORY OF SATELLITE COMMUNICATIONS

The satellite age can be assumed to have begun in 1687 when Newton theorized his law of gravitational force. In fact, the well-known equation

$$F = \frac{GMm}{r^2} \quad (1)$$

(where F is the force, G the gravitational constant, and M and m the two masses at distance r), which rules how two masses in space can be kept in equilibrium, represents the physical law that needs to be met to put a mass into an orbit around the Earth.

The satellite telecommunication age started when a body, in an orbit at relevant altitude (outside the atmosphere), was utilized as a mirror in space to connect two users located on the ground and so overcome the curvature of the earth's surface, if no other terrestrial infrastructures could efficiently provide telecommunication service. As a matter of fact, satellites in space can be used to achieve the same result Guglielmo Marconi achieved by working in the HF (high frequency) band, but can be extended to other frequency bands and therefore can obtain much better performance, but at the cost of increased complexity.

In this sense, after several science fiction papers and books, the paper "Extraterrestrial Relay" by Arthur Clarke, published by *Wireless World* in October 1945, represents the first real milestone of satellite telecommunications. In that paper, Clarke designed the orbital configuration of a satellite constellation utilizing an orbit located at 35,800 km over the Earth surface at the equator, coplanar with the equatorial plane, where the equilibrium between the gravitational force and the centrifugal force let a satellite appear fixed with respect to a point on the Earth surface. Clarke's constellation, called geostationary for this reason, was composed of three manned satellites angularly equally spaced 120° apart to get global coverage. Despite some limitations of this concept that are discussed in a later section, it represents the reference configuration for most of the satellite systems actually implemented. After Clarke's paper, another paper by John Pierce in 1954 titled "Telecommunication Satellites" suggests the use of unmanned satellites either in geostationary (GEO) or low Earth orbit (LEO).

Finally, in 1957, the Sputnik satellite launched by the former U.S.S.R. represented the first space mission. Even though not designed for telecommunication, the Sputnik mission validated the mechanical possibility of putting and keeping a body in orbit around the Earth.

After that, formal acts that actually set in motion the telecommunication satellite age include the Policy Statement on Communications Satellites signed by U.S. President John F. Kennedy in 1961; the U.S. Communications Satellite Act issued in 1962 with the birth of Comsat; the intergovernmental agreement Interim Arrangements for a Global Commercial Communications Satellite System, issued in 1964 with the birth of ICSC (Interim Communications Satellite Committee); and the formation of Intelsat (International Telecommunication Satellite, with headquarters in Washington D.C.), an intergovernmental organization.

For sake of conciseness, it will not be possible to mention and describe all the satellite systems (probably hundreds) implemented both for experimental and commercial missions. Nonetheless, a brief overview of the most important milestones is provided.

After some experimental missions using LEO, MEO, HEO (highly elliptical orbit), or GEO constellations (Score in December 1958, Courier in October 1960, ECHO

I in August 1960, TELSTAR I in July 1962, RELAY I in December 1962, TELSTAR II in May 1963, SYNCOM II in July 1963, ECHO II in January 1964, RELAY II in January 1964, SYNCOM III in August 1964, and MOLNIYA I in April 1965), the first commercial satellite (Early Bird) was launched in April 1965 by Intelsat, which aimed to provide intercontinental fixed services utilizing a constellation in geostationary orbit. In 1976, Marisat was the first system composed of three satellites in GEO orbit to provide mobile services. It preceded the foundation of INMARSAT (International Maritime Satellite, with headquarters in London), another intergovernmental organization that aimed to provide mobile satellite services and which, in 1982, launched the first fully operational system targeted to maritime users. In the following years, INMARSAT provided service even on land masses and for aeronautical users.

In 1988, Omnitrac, the first system for land mobile services, was launched. In 1991, the Italian Italsat satellite represented the first satellite to work in the Ka band using a regenerative payload and multibeam antennas. In 1993, ACTS (Advanced Communication Technology Satellite), funded by the U.S. Congress, was launched as an experimental mission to further validate Ka-band technology, on-board processing, multibeam antennas, hopping beams, and on-board switching. In 1998, Iridium was the first satellite system designed for personal communications; it was followed a few years later by Globalstar. Both systems utilize LEO constellations. Despite limited commercial penetration, the two systems demonstrated the technical feasibility of implementing a network in the space and they are currently operational.

WHY AND WHEN TO USE SATELLITES

As mentioned in the previous sections, satellites must be considered a component of a global system and as such it is extremely important to carefully identify which kind of requirements can be satisfied by satellites and which market niches can be addressed. To this aim, satellites' main characteristics are listed and briefly discussed.

- *Costs independent of distance (within one satellite coverage):*

The cost of a satellite link is independent of distance, in contrast to terrestrial networks. In fact, because of the broadcast nature of the signal transmitted by the satellite, it can be received in all the coverage area. For this reason, trade-offs may be studied to find the distance threshold above which it would be cheaper to use satellites instead of terrestrial systems.

- *Efficient and cost effective for collecting, broadcasting, and multicasting:*

Satellites are very suitable for efficiently distributing and collecting signals for a very large population. In fact, because of their capability to cover very large areas, one repeater in space is able with just one carrier to reach theoretically infinite users. In the case of terrestrial fixed networks, as many connections as the number of users are required.

- *Unique in areas with scarce or no infrastructures:*

In scenarios involving developing countries or countries with unfriendly environments or low traffic requirements where the installation of terrestrial infrastructures is not economically feasible, the use of satellites, especially if they have already been deployed, is the only possibility.

- *Unique in case of disaster:*

In cases of natural disaster (earthquakes, storms) or war, when terrestrial infrastructures can be seriously damaged or even destroyed, the satellite facilities usually keep working. Even if a gateway earth station were damaged, other stations will continue to provide service.

- *Suitable for large coverage areas and long-range mobility:*

Because of their capability to cover very large areas (up to one third of the world), the satellite is particularly suitable to ensure long-range mobile services, such as in the aeronautical or maritime fields.

- *Relatively short deployment time:*

For large coverage areas, a satellite system can reach its target in a very short time as compared to a terrestrial infrastructure. For standard commercial satellites, even about 18 months can be sufficient to design, build, and launch the system. For more innovative solutions, more time may be needed. Moreover, to set up a network of satellite terminals using existing satellites can even take just a few weeks.

- *Flexible architecture:*

The satellite on-board architecture allows an extremely flexible use of resources. In fact, in cases of multibeam coverage, capacity to the different beams can be allocated unevenly in time according to actual requirements.

- *Bypass very crowded terrestrial networks:*

It is estimated that a typical Internet connection needs to pass through 17–20 routers on average. With satellites, very distant servers can be reached with only one link.

- *With the same terrestrial infrastructure, both fixed and mobile services:*

As with any radio system, the same infrastructure is able to provide both fixed and mobile services.

- *Extremely suitable for localization services worldwide:*

Last, because it is not telecommunication in strict sense, but not least in terms of commercial, strategic and social importance, the satellite solution is largely the most efficient for localization and navigation services. In fact, both the present global positioning system (GPS) and the forthcoming Galileo adopt this kind of architecture based on a limited number of satellites (24 and 30, respectively).

SATELLITE SYSTEM CHARACTERISTICS

Security can be provided to operate at any layer of the protocol stack (link, network, transport, or application).

For this reason, assuming the Internet protocol stack as a reference, a brief description of the main characteristics for each layer will be presented.

Orbits

The satellite, by definition, describes an orbit around the Earth that has equilibrium between the centrifugal and the gravitational forces. The orbits can be classified according to eccentricity (circular or elliptical, where the Earth is located in one of the two focuses) or according to inclination with respect to the equatorial plane (equatorial, polar, or inclined; Maral & Bousquet, 2003; Lutz, Werner, & Jahn, 2000). Furthermore, they can be classified according to altitude: LEO (low Earth orbit), between 500 and 1,700 km; MEO (medium Earth orbit), between 5,000 km and 10,000 km and at more than 20,000 km; GEO (geosynchronous Earth orbit), at 35,800 km. The elliptical orbits can have the apogee between 39,000 km and 54,000 km. The altitudes below 500 km are not used to avoid atmospheric drag, whereas altitudes in-between LEO and MEO are not used to avoid the Van Allen belts.

The main geometrical parameters, as shown in Figure 1, are strictly correlated. In fact, once the altitude is defined, given an average Earth radius, the other parameters are calculated as a consequence. In particular, we highlight the two most important parameters: α_m (minimum elevation angle) and D_M (maximum user to satellite distance). The former assumes importance on the propagation channel, for both tropospheric effects and mobility, and the latter affects performance in terms of both free space losses and propagation delay, which represents the only really unavoidable impairments of satellite communications. Furthermore, the delay implies subjective disturbance in the case of real-time interactive services (e.g., videoconference) and objective disturbance in the case of delay sensitive protocols (e.g., TCP).

The geostationary orbit theoretically allows a satellite to be in a fixed position with respect to the Earth's surface. Actually, the presence of many forces in addition to the gravitational one induces a precession movement that may require a tracking system for the ground terminals.

Figure 1: Geometrical parameter of a satellite link.

Satellite systems positioned in the GEO orbit are characterized by high delay (120–135 ms one-way) and high free space losses. The elevation angle α_m decreases as the latitude increases. On the other hand, the Earth can be covered with the simplest architecture, composed of just three satellites. In this respect, the limitations of the Clarke's conceptions concern the geometrical impossibility to cover the polar regions (above 70° latitude N and below -70° latitude S), the position of the satellites on the arc (not spaced 120° apart, but according to the requirements of the user distribution), and the number of satellites that, for capacity requirements, in some orbital positions can be more than one. If aiming at global coverage, two strategies are applicable: (a) the satellites positioned over the three ocean regions (Atlantic, Pacific, and Indian), which is the largely preferred configuration although it maximizes delay and free space losses (FSL), or (b) the satellites positioned over land masses (Europe/Africa, Asia/Australia, and America), which minimizes delay and FSL but must be interconnected through inter-satellite link (ISL) to achieve full connectivity.

Satellite systems utilizing LEO orbits perform better than those in GEO in terms of free space losses and propagation delay (20–40 ms), but a large number of satellites is necessary to provide full coverage and real time interactive services. The continuous movement of the satellites causes Doppler effects and frequent handovers between spots and between satellites. Moreover, an efficient tracking system is necessary on the ground station. The elevation angle can be very high at any latitude (even high latitude) and in general is time dependent.

Satellite systems utilizing MEO orbits show performance in-between the two previously presented. They are actually not utilized for telecommunication systems (just planned for ICO system) but are used for localization and navigation systems such as GPS (global positioning system) and the forthcoming Galileo.

Satellites in HEO orbits travel over an ellipse, inclined 63.4° with respect to the equatorial plane, in which the Earth is located in one of the two foci. With respect to Kepler's law, satellites on this kind of orbits span equal areas in equal time intervals. As a consequence, they go very slowly around the apogee and appear almost fixed for users located at very high latitudes. Satellite handover, Doppler effect, and zoom effect represent the main drawbacks but these are not so critical. Delay and FSL are comparable to GEO.

The different orbital configurations need not be used alone but can be combined to create a hybrid constellation. For example, a constellation can be composed of one or more satellites in GEO orbit and one or more satellites in LEO orbits. The two components can either be interconnected to reciprocally extend coverage or be alternative points of access to improve availability.

Space Segment

The space segment consists of the spacecraft, which contains a number of pieces of equipment. In particular, it contains a power section (batteries and solar panels), a

stabilization and propulsion section (including propellant), a TT&C (telemetry telecommand and control) section to remotely control the spacecraft's on-board motors, and, finally, a payload section, the communication component. The payload exploits communication between two Earth stations. The payload architecture can be transparent if it acts as a bent pipe (just change the frequency and amplify signals) or it can be regenerative if it implements some on-board processing (OBP) features, which means that it must at least demodulate and remodulate signals and separate the uplink from the downlink. In a transparent configuration, it is in charge of providing radio relay for links between earth stations, which involves capturing the carriers transmitted by the earth stations, amplifying the received carriers, changing carrier frequency, and radiating the carriers back. In a regenerative configuration, it can also regenerate signals, change polarization (if required), interconnect any beam to any beam, route packets, and switch messages. On-board switching can be implemented at either base band or microwave frequencies.

Terrestrial Segment

The Earth segment functionality includes the gateway to interconnect terrestrial networks and the NCC (network control center), which is in charge of configuration management, capacity/bandwidth management, acquisition/synchronization control, performance management, alarm management, security management, billing, and accounting. The NCC links all traffic terminals of the network through the master station (MS), which must reside at the same site as the network control center. Moreover, the network management system (NMS) is the graphical user interface (GUI) for network configuration management. The Earth terminals can be of two types: gateway and user terminals. The gateway, usually a big station, is in charge of connecting the satellite systems and the terrestrial networks. The user terminals represent the physical devices through which the users can access the satellite resources. They can be classified as fixed (very small aperture terminal, VSAT), transportable (VSAT-like, mounted on a vehicle but working in stationary conditions), or mobile (handheld, cellular-like). Each terminal is equipped with a base-band section and a radio frequency (RF) section. VSAT terminals can be connected in full mesh topology or in star topology. The former minimizes the use of the bandwidth and the delay (one hop), whereas the latter requires the presence of a hub to connect the terminals, thus needing a double hop, which increases delay and use of the bandwidth. Terminals suitable to the mesh topology are more complex and expensive than those utilized for star networks. Hybrid configuration is another possibility, which has trade-offs in performance.

Moreover, the TT&C Earth segment exchanges information with the TT&C section on-board.

Physical Layer

Physical layer concerns the capability to establish, to ensure, and to keep physical connectivity, taking into account propagation channel characteristics, and the

capability to produce power on-board. In fact, the propagation channel is characterized by meaningful nonlinearity that strongly affects technical choices.

With regard to modulation, phase modulation schemes are usually adopted. The most used scheme is QPSK (Quadrature Phase Shift Keying), but in particular cases even higher order modulations are utilized. In particular, the recently approved DVB-S2 (digital video broadcasting—satellite 2) standard adopts adaptive modulation ranging from BPSK (Binary Phase Shift Keying) up to 32 APSK (Amplitude Phase Shift Keying).

Channel encoding introduces redundancy to protect signals against errors. In satellite communications, concatenated coding is often adopted to counteract both burst errors and random errors. For example, the present DVB-S (ETSI, 1997) standard adopts Reed Solomon block coding (204,188) to combat burst errors and convolutional coding (adaptive rate from 1/2 up to 7/8) to combat random errors. Also, turbo codes are actually used in recently launched systems (Giancristofaro, Piloni, Novello, Giubilei, & Tousch, 2000).

Interleaving, used to combat channel fluctuations resulting from multipath, aims at randomizing bit errors to change burst errors in random errors. It consists of rearranging the order of a sequence in deterministic way and then rebuilding the original sequence (Luglio, Bellini, Marinelli, Tartara, & Vatalaro, 1997). The bits can be arranged in a rows, of a matrix and transmitted in columns. Either block or convolutional interleaving can be implemented.

The coverage strategy can significantly affect the physical layer. In fact, multibeam coverage improves spatial selectivity (allowing frequency reuse) and gain, which allows less critical user terminal design and uneven power distribution at the price of increasing complexity and costs (Loreti, Luglio, & Palombini, 2000).

Another impairment, mainly resulting from multi-beam coverage, is the intrasystem co-channel interference (Vatalaro, Corazza, Caini, & Ferrarelli, 1995; Caini, Carazza, Falciassecca, Ruggieri, & Vatalaro, 1992; Loreti & Luglio, 2002). It arises from the overlapping of several side lobes of the interfering beams with the main lobe of the interfered beam. In the case where every beam utilizes the same frequency (code division multiple access, CDMA), the overlapping of two main lobes can cause serious interference. In satellite systems, co-channel interference is more critical than in terrestrial cellular networks. In fact, for terrestrial systems morphology and man-made buildings sometimes isolate adjacent cells and zones, allowing a more significant use of frequency reuse.

Finally, OBP capabilities can greatly improve the link design because isolating uplink and downlink avoids direct transfer of noise accumulated on the uplink to the downlink. Furthermore, it achieves better performance in terms of the E_b/N_0 required, the reduced power needed on both links, and the reduced intermodulation.

MAC Layer

The same multiple access techniques developed and implemented on terrestrial systems are adopted. In

particular, the classical orthogonal techniques are utilized: FDMA (frequency division multiple access), TDMA (time division multiple access), and CDMA or hybrid schemes such as MF-TDMA (multifrequency time division multiple access). FDMA can be implemented in different schemes: SCPL (single carrier per link), SCPS (single carrier per station), SCPC (single carrier per channel). Each scheme shows different performance in terms of efficiency and intermodulation products generation. The use of TDMA, more flexible than FDMA, requires a critical synchronization system that takes into account the variance of the propagation delay, which must be carefully considered also in the design of the guard time slots. CDMA (De Gaudenzi & Giannetti, 1998) allows full frequency reuse, satellite soft handover, satellite path diversity exploitation, and application of interference mitigation techniques such as multiuser detection (MUD).

Also, nonorthogonal random access techniques (Aloha or Slotted Aloha) or those based on the PRMA (packet reservation multiple access) concept are applicable. The latter, requiring a framelength longer than RTT (round trip time) to achieve significant efficiency, seems to be more suitable for systems in LEO orbit (Del Re, Fantacci, Giambene, & Walter, 1997).

Network Layer

Network issues for satellite systems are applicable whenever the satellite link is not considered just a branch in the network but routing operations are foreseen. In the latter case, two approaches can be adopted: connection-oriented, where the system performs routing at call setup, as in the “big-LEO” architectures, or a connectionless network, which performs routing hop-by-hop, as is used by the Internet. The latter approach is preferred because IP (Internet protocol) is connectionless, and thus by using IP a homogenous network protocol may be simpler and have lower overhead. Moreover, the use of IP protocol well suits multicast management, and, as in a terrestrial network, connectionless networks offer some degree of fault tolerance for data delivery. Against this approach, satellite networks (such as LEO systems) may be too dynamic for standard IP routing and Internet-style routers may require too much memory (maybe not compatible with the limited space on-board). Among the other problems with using IP, the TTL (time-to-live) and IP packet fragmentation are emphasized because of the huge delay when IP is applied to satellite systems (Partridge & Shepard, 1997).

Present satellite networks that provide multimedia wideband services offer an IP interface, although they use transparent payloads. For this kind of services, it is hoped that the use of regenerative payloads able to perform network-layer functionality in space will be a reality in a short time, offering the opportunity to more efficiently manage satellite networks.

Transport Layer

The transport-layer performance suffers a lot from satellite systems features. In fact, the most widely used

transport-layer protocol, TCP (transmission control protocol), on which most of the Internet applications are based, is strongly delay sensitive and delay is the only impairment we cannot rid of, because it depends only on the speed of light in space. Nonetheless, if satellite systems aim to be perfectly integrated in the global network and to be really part of it, the utilization of the most used network protocol standard must be pursued. In this sense, a huge amount of research has been and is currently being done to try to mitigate the impairments resulting from delay on performance of TCP via satellite links (Allman, Glover, & Sanchez, 1999; Border, Kojo, Griner, Montenegro, & Shelby, 2001; Loreti, Luglio, Kapoor, Stepanek, Gerla, Vatalaro, et al., 2001; Luglio, Yahya Sanadidi, Stepanek, & Gerla, 2001). In particular, some of the proposed solutions are specifically designed for satellites whereas others are for more general environments. Many proposals are based on modification of the flow control (e.g., enlarging the dimension of the initial window, reducing the number of acknowledgments) and of the recovery mechanism (dynamic estimation of the available bandwidth, etc.); others are based on the modification of the architecture (e.g., splitting the path, terminating the connection at each step, and acknowledging packet reception). Among the latter type of solutions, some adopt standard algorithms or modified versions, and there are solutions typically known as accelerators, which are implemented in real systems and based on proprietary standards.

Application Layer

There is not a real limitation to provide any service through a satellite network. Every kind of service and relative application can be implemented by taking into account specific performance. In fact, the propagation delay affects performance of real-time interactive service (e.g., voice, videoconference) but, on the other hand, the suitability to multicast operation makes satellite systems more efficient and cost effective. In particular, both real-time and store and forward services, both fixed and mobile services, both narrow band and wideband services, unicast, multicast, and broadcast services are currently provided.

Standards

One of the most important factors affecting market penetration is the availability of common standards. In fact, it is well known that the availability of open standards has greatly favored the large diffusion of systems such as GSM (Global System Mobile). Actually, in the satellite arena, the DVB (digital video broadcasting) standard was issued in 1997 for broadcasting services (ETSI, 1997). It includes standards for terrestrial, cabled, and satellite systems. The DVB-S (DVB satellite) standard regulates the broadcasting of signals in digital format and how they must be processed before being transmitted. Two basic operations are regulated: base-band processing and satellite channel adaptation.

The base-band processing concerns the adoption of MPEG-2 (Moving Picture Expert Group—2) as the source coding technique on different source signals (video, audio,

and data), the following (not mandatory) packetization of data of a single program into packetized elementary stream (PES), and the final multiplexing of a number of PES into the MPEG-2 transport stream (TS). The different data elements can carry independent timing information. In this way, audio information can be synchronized with video information in the receiver, even if they do not arrive aligned at the receiver, which allows the transmission of conventional television programs.

The satellite channel adaptation concerns the types of modulation and coding schemes to be adopted to meet the target quality of the signal (Bit Error Rate around 10^{-11}). This level of quality, called “quasi error free” (QEF), ensured at the MPEG-2 decoder input, allows the system to correctly rebuild audio and video information.

The processes involved in this adaptation are transport multiplex adaptation and randomization for energy dispersal, outer coding (i.e., Reed-Solomon), convolutional interleaving, inner coding (i.e., punctured convolutional code), base-band shaping, and modulation. The randomization is applied to make the RF spectrum similar white noise process. It is implemented over sequential groups of eight bytes by adding a pseudo-random binary sequence (PRBS) to the transport stream data. The channel coding is applied through three steps: outer code Reed-Solomon (204, 188, $T = 8$), convolutional interleaving with the aim to randomize errors occurring in bursts, and convolutional coding with a variable code rate (1/2, 2/3, 3/4, 5/6, and 7/8). Gray-coded QPSK modulation with absolute mapping (no differential coding) is adopted. Prior to modulation, the base-band signal is square-root-raised-cosine-filtered with a roll-off factor of 0.35.

The DVB approach offers a good degree of flexibility. A 38 Mbit/s data flux could contain eight standard definition television (SDTV) programs, four enhanced definition television programs (EDTV), or one high definition television (HDTV) program, all with associated multichannel audio and ancillary data services. In satellite applications, the maximum data rate for a data stream is typically about 38 Mbit/s. It can be accommodated in a 33-MHz satellite transponder and provides sufficient capacity to deliver, for example, four to eight standard definition television programs, 150 radio channels, 550 ISDN (integrated service digital network) channels, or any combination of these services.

Recently, the DVB-S standard was updated in the DVB-S2 version. In the new scheme, which modifies the satellite channel adaptation block only, adaptive modulation and coding (ACM) have been introduced. In particular, low density parity check codes (LDPC) have been selected with Bose–Chaudhuri–Hochquenghem (BCH) block code length 64,800-bit (or 16,200-bit) periodic structures that facilitate parallel decoding with about 50 decoding iterations. Available coding rates are 1/2, 3/5, 2/3, 3/4, 4/5, 5/6, 8/9, and 9/10. Moreover, five modulation formats, all optimized to operate over nonlinear transponders, have been selected: BPSK (1 bit/s/Hz), QPSK (2 bit/s/Hz), 8PSK (3 bit/s/Hz), 16APSK (4 bit/s/Hz), and 32APSK (5 bit/s/Hz). Then, three roll-off factors are allowed: 0.35, 0.25, and 0.20 (DVB-S: only 0.35). With the new standard, an optimization of spectral resources in

Table 1 Spectrum Allocation for Satellite Services

	Band	Uplink	Downlink
Fixed services	C	5,925–6,425 MHz	3,700–4,200 MHz
		7,900–8,400 MHz	7,250–7,750 MHz
			10.95–11.2 GHz
	Ku	13.75–14.5 GHz	11.45–11.7 GHz
			12.5–12.75 GHz
			17.7–20.2 GHz
Mobile services	UHF	148–150.05 MHz	137–138 MHz
	L	1,626.5–1,660.5 MHz	1,525–1,559 MHz
		1,610–1,626.5 MHz	2,483.5–2,500 MHz
	S	2,170–2,200 MHz	1,980–2,010 MHz
		2,655–2,690 MHz	2,500–2,535 MHz
		7,900–8,025 MHz	7,250–7,375 MHz
	Ka	29.9–30 GHz	20.1–20.2 GHz
30–31 GHz		20.2–21.2 GHz	

the order of 30–40% is estimated. If confirmed, the satellite may compete in terms of costs with terrestrial services such as ADSL (asymmetric digital subscriber line).

The success of the DVB standard because of its capability to transmit a huge quantity of data in a very flexible way, with consequent availability of technology at low cost, extends its field of applicability beyond the transmission of only data information. In addition, the compatibility with IP protocol allows the processing of the IP packet in the DVB stream. As a consequence, first the use of DVB for one-way systems (DVB IP with return channel on terrestrial networks) has been introduced. The data are received through the same equipment (antenna and receiver) utilized for digital TV but the equipment is connected to a PC with a suitable decoder. Then, a two-way standard based on DVB was recently introduced with return channel on satellite (DVB RCS), which allows bidirectional communications up to 2 Mbit/s in the return link and shares the bandwidth on a MF-TDMA discipline. The user terminal is very similar to the receiving equipment but with a RF front-end working at 1–4 W. The great success and market penetration of this technology is leading researchers and standardization bodies to extend the use of DVB RCS for mobile services.

Another standard that has been evaluated by ETSI and that may be implemented in the near future concerns the satellite component of the UMTS (universal mobile telecommunication system; Caire, Corazza, De Gaudenzi, Gallinaro, Luglio, Lyons, et al., 2002). To ensure the maximum degree of compatibility with the W-CDMA (wideband CDMA) of the terrestrial component, the developed standard SW-CDMA (satellite wideband CDMA) is still based on CDMA.

It is very similar to the ETSI UTRA proposal and is suited to the specific satellite environment. To reach this aim, the main features have been identified: wide range of bearer services (from 2.4 kbit/s up to 144 kbit/s), power and spectral efficiency achieved through path diversity exploitation, coherent demodulation on the return link, multi-user detection scheme, overhead reduction using

common pilot/beam approach, and compatibility with adaptive antenna systems. Moreover, user localization capabilities are implemented. Two bit-rate options are supported: 4.096 Mbit/s (frame duration = 10 ms) and 2.048 Mbit/s (frame duration = 20 ms). QPSK and dual-BPSK (for low data rate) modulations are adopted. The use of scrambling code is optional.

Spectrum Allocation

Spectrum allocation is performed by ITU-R and in particular by the World Radiocommunication Conference. Table 1 shows the allocated bandwidth for ITU region 2.

SATELLITE AND SECURITY: REFERENCE SCENARIO

The security scenario drastically changed at the beginning of the new century. On one side, there is the traditional need of protecting transmission from disturbances and communications from interception, but on the other side, there is the new need of protecting the physical integrity of the infrastructures, among which the telecom network is one of the most critical, and the even more important need to add intelligence to the network, which allows the capability of using the available information at the right time and at the right network node. These new system requirements are often synthesized using two acronyms: NCI (national critical infrastructure; White House, 2003) protection and NCC (network-centric communications).

In this new scenario, it is even more evident that there is no privileged telecommunications subsystem to ensure security, but the opportune utilization of each component and the right cooperation among all kinds of communication infrastructures (terrestrial cabled, terrestrial wireless, satellite, and HAPS/UAV) can provide the required level of security at the communication level and, as a consequence, when applicable, at human life protection. In this scenario, the key concepts are

Figure 2: The communications system as the central ring of security architecture.

robustness, vulnerability, threat, attack (passive or active), reliability, availability, survivability, and countermeasure.

Security and Communications in the New Century

The telecommunication network is one of the most important and critical networks, which shall survive to any hostile activity with the highest probability. This concept has always been assumed for defense networks, but its extension to all the civilian uses is not trivial.

Information protection and redundancy are not sufficient to face the new threats of the century and it is not viable to change all the existing network architectures, even if security is nowadays a socially accepted expense. Security is therefore a complex process; potential threats shall be continuously analyzed and protection and security added where it is needed, using flexibility, modularity, and implementation velocity.

A communication system can be seen as the central ring of this complex architecture (Figure 2). The performance of the network shall be guaranteed against voluntary attacks and intrusions.

Telecommunication networks used by civilian entities must satisfy requirements on security, availability, and robustness that are more challenging than a few years ago, and satellites can be the key element without boosting prices and inflating deployment times to deliver performance such as the following:

1) *On the architecture:* High level of configurability: the capability of supporting different network connectivity and topology configurations (full mesh, hierarchical, star, polygonal, etc.). High level of robustness against unwanted failures and deliberated attacks: sensitive site protections, autonomous power supply, local redundancy, and alternate communication routes. High level of redundancy to face major failures: full duplication of the network hubs and control centers. Gracefully degradation of the network performance: no type of attack can cause a total outage of the network.

2) *On the services:* Voice services, IP services, multimedia services, data transfer services.

3) *On the users:* Fixed communications, hand-held terminal communications, mobile vehicular communications, naval communications, airborne communications.

Secure transmission capability: the capability of optimizing the transmission parameters (power, modulation type, number of users, coding rate, etc.).

Secure communication capability: the capability of protecting the information content against intruders using end-to-end encryption devices.

4) *On the evolution:* High level of scalability: the capability of growing with the customer's needs without change of key technologies. High level of modularity: the capability of endorsing additional services and technologies, without major architectural impacts.

5) *On the operations:* Full monitor and control of the network at the remote control center, easy commissioning capability, easy configuration capability, high level of maintainability, easy configuration upgrading, built-in training, redundant database synchronization, network statistics and metrics availability.

Effectiveness of Satellite on Security for Public and Private Users

Satellite networks are a key element to add flexibility, extend the coverage, and increase the resilience and the robustness of terrestrial networks. The satellite networks have the ability to overcome the network hierarchy and to connect a couple of points present in different network layers; in addition they allow to cover the territory without any physical infrastructure apart from the access point to the satellite. As a consequence, zero deployment time at the start-up of the system is needed, which adds security against volunteer attacks and safety against natural disasters.

A unique, well-known characteristic of satellite communications is the multicast capability, which allows distribution of information to all the connected sites in parallel using the same physical satellite channel.

The broadband solutions are typically based on multimedia satellite networks, which are composed of a hub connected with the control center and a large number of micro stations (with a diameter of less than 90 cm), capable of two-way transmission up to a few hundreds kbit/s and a receiving capability up to a few tenths Mbit/s (as in DVB RCS like systems previously introduced). An example of this architecture is shown in Figure 3, operating in the 11–14 GHz frequency band, where a typical bidirectional connectivity is represented: the forward link is a DVB standard flux whereas the return link works on a MF-TDMA discipline.

With respect to a traditional satellite link, the secure link shall manage the security procedure at the various agreed levels. It is very important to optimize the security session with respect to the overall optimization, considering that the satellite link for each security package exchange adds an additional 0.5-s delay. On the other hand, the satellite solution is very flexible and can operate at the user, back haul, and core network levels, which breaks the network hierarchy. Very often, this delay is strongly

Figure 3: Typical fixed satellite service network used for security.

compensated by the hopping of a few routers in the terrestrial network. Indeed, the satellite network can directly connect the remote router with the control center, bypassing all the network layers. In a few cases, the application layer may require multiple hops between the access point and the server at the hub; this can imply some unwished additional latency time.

Satellite networks have an intrinsic security level supplied by the need to synchronize the access (TDMA technique), which is a function managed by the complex hub. In addition to this built-in security level, satellite networks can include cryptography devices for public and private keys. It is important to briefly analyze the effect of encryption on satellite transmissions: cryptography is based on the application of an algorithm to the transmission, which is based on the knowledge of the activation keys. This knowledge is limited to the end nodes of the encryption process. The strength of the encryption algorithm is a function of its complexity and is evaluated on the basis of the number of operations necessary to break it and on the not yet discovered set of rules necessary to break it.

Complexity plays a negative role for real-time encryption of high data rate stream. The encryption key can be private and public. In the former case, the key is distributed between the authorized correspondents. The key information is changed from time to time, and this is a very delicate phase of the overall encryption process. In the latter one, from the generation of two random numbers, a public modulus is generated and a procedure is available to the correspondents so that they have access to the clear information (NIST, n.d.). The network system security should be guaranteed at both information and communication levels. The encryption can be introduced as a service at three different levels:

- Link by link,
- Node by node, and
- End to end.

In the first case, security is managed from the user to the control center, at each level of the network. In the second case, routers and switches are included in the protection level. Secure communications are managed at the routing level. In the third case, the encryption protection is solved out only at the final user destination, which offers the maximum level of protection. In the most general case, satellite communications (in a way similar to other sub-networks) can guarantee node-to-node protection more easily than end-to-end protection. When end-to-end is not viable, the critical network nodes, where encryption algorithms are applied, shall be adequately protected from potential intrusions.

A very special satellite encryption process applies to the point-to-multipoint transmission, very popular for TV broadcasting applications but also usable for videoconference services.

A list of encryption processes for TV satellites includes the following (*European satellite TV frequently asked questions*, n.d.):

- Videocrypt, originally English, works on PAL (**P**hase **A**lternating **L**ine) channels. There are two variants, the original Videocrypt, which should basically be used inside England, and Videocrypt II, which is meant for Europe outside the UK.
- Eurocrypt was developed with MAC (multiplexed analog component), and almost all MAC receivers have an integrated Eurocrypt decoder.
- Nagravision, also known as Syster, is mainly used in France, thus SECAM (**S**ysteme **E**lectronique pour **C**ouleur avec **M**emoire) channels, but is also used with PAL in Germany and Spain, primarily by channels owned by France's Canal+ network.

Another system may be mentioned, Luxcrypt, used by the Dutch RTL4/V network; it does not need a smart card. Some other, less used systems also exist.

It is important to outline that studies and investigations are ongoing to allow the combined use of low orbiting

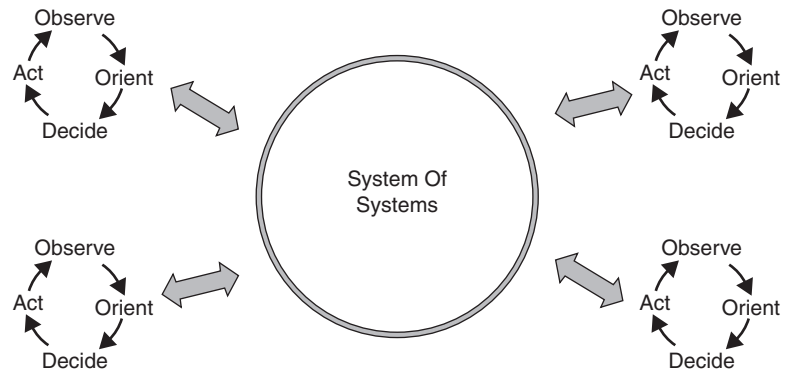

Figure 4: Multilevel OODA loop capability of a system of systems.

satellites (such as Globalstar and Iridium) with GEO stationary satellite, which would create an additional service channel, have virtually no latency time, and improve the overall performance of encrypted satellite channels (Carducci, 2004).

Importance of Satellite Systems in the Process of O²DA

A system capable of fulfilling the main high level objective is very complex, has to be distributed over a wide territory, and is structured (from the operational point of view) in “functional cells” capable of performing on a local basis some specific (though sometimes more elementary) OODA loops (closed-loop observe-orient-decide-act chains of operational functions), which from a conceptual point of view are the “elementary modules” of a modern surveillance-awareness-decision-action system/process.

OODA is used for synthesizing a complex process necessary for supporting security in a very wide sense:

- The first phase (observe) consists in monitoring potential threats, monitoring the critical aspects of the system to be protected (including telecommunications and transmission), and reporting to the competent entities.
- The second one (orient) is probably the most delicate and is dedicated to prepare all the information needed for a correct counter measurement.
- The third one (decide) consists in implementing the strategy to face the threat.
- The last one (act) is dedicated to the countermeasure application.

In addition to this “local OODA loop” capability (which may be rather independent from the presence of a national coordination system), these functional cells must also be capable to operate as part of the nationwide state border integrated management system (SBIMS), which is fully integrated with other (often more complex) decisional loops so as to permit the national coordination authorities:

- to have knowledge of the overall situation (observe and orient),
- to take in a minimum time the right decisions in face of a certain situation (decide), and

- to command specific appropriate counteractions, having then the possibility to be immediately informed of the results of such actions.

The system able to provide this multilevel OODA loop capability is a “system of systems” (see Figure 4). This is a well-consolidated approach for military operations, already in use in several parts of the world and highly appreciated for its ability to transform a large quantity of sparse “information” into a consolidated “knowledge” of the overall situation in a very short time. The idea of reporting to the central authorities a large quantity of information from remote sites and to centralize the decisional power is not new; what is now made possible by the progress in the “information technologies” is to close the OODA loops in real time, while a traditional, noncomputerized approach would take much longer.

The possibility of making different existing networks interoperable and making information available where it is needed at the correct time is based on the concept of network-centric communications, which is basically service independent. Network-centric communications will help to prevent cost explosion by increasing overall performance through the networking of existing systems.

The concept of network-centric communication supports the trend toward smaller and interoperable forces with the capability to dynamically connect and share sensors (regardless of platform), decision makers (regardless of location), and effectors (regardless of kind and location). With the concept of network-centric communications, it will be possible to designate reconnaissance data (targets) to each system, the best countereffect. Individual systems lose importance and a system of systems arises that shows their full performance only in the network. The network-centric communications operational architecture will closely couple the following capabilities:

- sensors,
- decision makers (command and control), and
- security enforcement/engagement unit.

Information superiority and the fast, secure, and appropriate knowledge on all levels are decisive according to the model of observe, orient (understand), decide, and act as fast as possible.

The additional elements of this new architecture are the sensor grid, which consists of the software applications associated with specific sensor peripherals and the software applications that enable multimode sensor tasking and data fusion; the information grid, which consists of a network of networks (communications paths, computational nodes, operating systems, and information management applications) that enables network-centric computing and communications across the security space domains; the engagement grid, which effectively exploits security space domain awareness to enable new operational capabilities for security enforcement/engagement unit employment.

The importance of the satellite systems as the key element for creating the overlay network among the existing networks, thereby minimizing the investment and optimizing the overall performance, is evident. Satellite links can easily interconnect the network nodes, supply the needed band when and where it is needed, complement the existing network coverage in a short time, and create real alternative paths to the existing terrestrial links without any terrestrial infrastructure but the access points.

COMMUNICATION, TRANSMISSION, AND INFORMATION SECURITY

In a typical communication scenario, with particular reference to wireless systems, we identify three levels of security: communication security, which refers to the capability to create a network with restricted access; transmission security, which refers to the capability to transmit and receive signals at physical level; and information security, which refers to information content and traffic flow protection.

Effectiveness of Satellite System Characteristics on Security Provision

Among the several aspects briefly overviewed previously, some are particularly relevant to security provision performance and affect the degree of security that is possible to ensure. In particular, we highlight the role that three characteristics (type and extension of the coverage area, broadcast nature of the signal from satellites, and accurate pointing and propagation delay) assume in the security scenario.

The coverage area is typically quite extended. This characteristic allows the network to serve a large number of users even in remote, isolated, and even impervious locations, where usually terrestrial infrastructures are not deployable (either for economic or feasibility reasons) and where typically some office that requires isolation for confidentiality can be located.

The broadcast peculiarity of the satellite signal, apparently a disadvantage from the security point of view, can be actually considered an advantage if the same key or set of keys must be distributed to a large set of users. Furthermore, the broadcast nature does not imply the capability to receive the signal for everybody. In fact, a highly directional antenna is mostly necessary and as a consequence accurate pointing must be implemented to receive just the electromagnetic signal from just one satellite; that does

not imply the ability to decode the information, as will be stressed in the next section. In case an omnidirectional antenna is foreseen, no pointing is necessary but the latter aspect still applies.

The propagation delay, which is as previously mentioned the only unavoidable impairment, actually limits security implementation performance. In fact, in case frequent key distribution updating is required, as for example in the multicast scenario (Howarth, Iyengar, Sun, & Cruickshank, 2004), the huge delay introduces significant inefficiency.

Intrinsic Security

Despite the broadcast nature of transmission from satellite over a large area, some peculiarities of satellite equipments and their deployment make the system be intrinsically secure.

First of all, facilities and equipment are well localized and not spread over the territory and thus extremely easy to be garrisoned. As a consequence, the unauthorized access to telecommunication resources is practically impossible. On the contrary, it is well known that in the case of terrestrial public networks, based on the deployment over the territory of kilometers of cables, routers, and switches, the accessibility is much easier. In fact, it is sufficient to access one of the switches, which, being large in number and spread over the service area, are not easily monitored and continuously overseen.

Furthermore, the absence of an open, diffused standard, which actually represents a weakness from the market penetration point of view, represents an additional factor of security. In fact, to be able to not only receive the electromagnetic signal but to decode information, it is necessary to be authenticated by the NCC. The authentication process cannot be performed if the utilized standard is not known. The following two subsections will present two study cases that refer to two different access techniques. Of course, in case open SCPC is used, the procedures are simpler and the intrinsic security does not entirely apply.

Last but not least, a further peculiar characteristic ensuring security is represented by the extremely high level of reliability of both the space segment and terrestrial segment equipment. The former is necessary considering the practical impossibility to fix the devices once they are orbiting. It is achieved by utilizing the best performing materials to build circuits and mechanical components, through the implementation of the most accurate tests to check the resistance to mechanical vibrations to sudden and conspicuous thermal variations, and through the redundancy of all the critical devices (in some case, even 1:1). The terrestrial segment, even though not as reliable as the space segment for the obvious reason that it is easier to fix or replace in case of failure, shows a degree of reliability much higher than that of the terrestrial equivalent equipment. Nevertheless, the concept of redundancy is rigorously applied to the gateway stations. Definitively, such a degree of reliability increases the confidence of the satellite user that the service, once set up, will be provided with continuity and without interruption. This feature encourages the use of satellites for secure services that, in

most of the cases dealing with, for example, human safety and disaster relief, need also the highest degree of survivability.

Security Management

As outlined previously, a cryptographic mechanism is one of the strongest ways to provide security services. NBS (now NIST) started in 1977 publishing DES (Data Encryption Standard) a suite of approved algorithms for unclassified but sensitive applications, based on an IBM effort.

New classes of algorithms have been added, such as secure hash algorithms and asymmetric algorithms for digital signatures. The suite of algorithms now provides different levels of cryptographic strength through a variety of key sizes, and the algorithms may be combined in many ways to increase the complexity of the protocols and applications.

When the satellite element is introduced, the network management of the keys shall take this into account operating via simulation, tests, and management procedures. The satellite has an effect on the key management life-cycle, which establishes a framework for the lifecycle of the cryptographic key (use, lifetime, validation, recovery issues) and on general key management, which encompasses the key management policy, the cryptography algorithm, the key size selection, and schemes.

The experience for point-to-point cryptographic connection is that the satellite system works reasonably well in a very wide area of applications, but a specific validation activity should be envisaged.

Communication Security Implementation

Commercial systems implement security mechanisms to allow only a restricted number of authorized users to access information or to establish connection. These mechanisms can be part of the standard or of a proprietary solution.

Conditional Access in DVB-S

Conditional access is based on encrypting signals to allow only a restricted number of users to view certain programs. The first level of restriction allows the view only to subscribers, whereas further levels can restrict the view to particular subsets of users (for example, users who view adult movies, have partial subscriptions, or are in particular geographic areas). Moreover, with conditional access, pay-per-view and video on demand can be implemented.

In DVB, conditional access is performed through three functions: scrambling/descrambling, entitlement checking, and entitlement management. The first aims at modifying the information sequence so that only users who know a secret password can recognize the original information. The second function broadcasts the encrypted secret codes to enable proper descrambling, utilizing a specific message (entitlement checking message). The third function is to manage this process.

The weakness of this technique is due to the broadcast's one-way transmission. In fact, because there is no return channel, it is not possible to realize eventual cloning of smart cards.

Security in DVB RCS Systems

In DVB RCS systems, security provision in the forward link is based on the previously mentioned DVB scrambling/descrambling mechanism. A similar mechanism can be applied to the return link, as well as authentication algorithms implemented at MAC layer (as that described in a previous section). Finally, because the communication is based on the IP interface, a further degree of security is provided through proper IP addressing. Additional IP security mechanisms (such as IPSec) can be applied, taking into account the constraints presented previously.

Security in the MF TDMA Case

Most of satellite networks operating on a MF-TDMA discipline are based on the use of proprietary standards, which represent an intrinsic level of security, with the drawback that they slow down market penetration. In fact, very robust authentication mechanisms are usually adopted. A terminal willing to either receive or transmit data within a certain network must continuously perform acquisition and synchronization procedures, which are impossible without the express authorization and cooperation of the network operator. As an example, the Viasat Linkway network case is described.

The network architecture is based on the presence of an NCC, a master reference terminal (MRT), and many traffic terminals (TT). The MRT acquires and keeps an univocal reference of each TT in its database, so that, before starting a traffic exchange, the MRT can send the reference burst (RB) to every TT to provide timing information and outbound signaling. The TTs send to NCC a signaling burst (SB) for inbound signaling to require bandwidth allocation, using the proper time slot in the frame, sometimes according to Aloha discipline. The TTs send a control burst (CB) to MRT that provides frequency, timing, and delay information, which can be used by the NCC to determine if any correction is needed. In fact, NCC knows the position of each TT, and thus the expected delay, even in case of terminals mounted on mobile vehicles (trucks or ships) when the position is continuously updated. Thus, TTs transmit the acquisition burst (AB) to the MRT. The arrival time is measured and compared with the expected time. If it arrives within a certain interval, the TT is accepted, otherwise not. All the TTs use a single AB timeslot in the frame. After acquisition, synchronization is kept with CBs. In addition, the commissioning of a new terminal requires a number of operations to be performed by the NCC: new site configuration with latitude, longitude, and RF information; new terminal definition; definition of appropriate service interface; definition of IP interface; and creation of a boot file for the new traffic terminal by loading it onto a floppy disk to be installed when commissioning the traffic terminal. (Boot files contain the information required for a terminal to acquire, transmit, and receive synchronization.)

Security in the CDMA Case

CDMA offers an inherent degree of security because discrimination among users is achieved by assigning a different code to each user, which modifies the spectral

pattern of the signal. To decode information from the signal, the proper code must be known. For these reasons, military environments (where it was first developed in the 1970s) have a lot of interest in this kind of technology.

In addition to inherent security, CDMA networks can provide an additional degree of security by implementing a proper authentication mechanism. An example of such CDMA network is represented by the Globalstar system.

The CDMA scheme utilized by Globalstar system is based on Qualcomm CDMA standard, namely IS-41, derived from terrestrial IS-95. Security is provided as an authentication mechanism and as voice/data encryption applicability. The former is exploited by the SIM Card, similar to the terrestrial cellular systems; the latter can be implemented using end-to-end devices such as DCS-1800. In addition, the IS-41 user terminal (UT) utilizes a security module (SM), which stores long-term cryptographic keys as well as stores and executes cryptographic algorithms. The SM is associated to an UT HW identity through a unique electronic serial number (ESN). This association is stored in the HLR (home location register) to hamper the working of any SM into any other UT.

Transmission Security

As introduced previously, interference represents one of the main impairments that can either cause overall capacity limitation or even hamper transmission capability, should the interference level significantly degrade the SINR (signal to interference + noise ratio).

By taking advantage of this vulnerability of transmission capability, signals can be produced in the direction of the satellite antenna just aiming to degrade SINR to a level that hampers proper communication. Moreover, the extension of the coverage area makes it difficult to locate the eventual unwanted source. Such a phenomenon, named jamming, is typical of military operations, and is produced to disturb the other party's communication.

The protection from this kind of "aware" interference, derived from military technology, is typically a task of the on-board antenna capability of creating a variable number of nulls in the direction of the various interferers. The antenna design and manufacturing is based on the possibility of using sophisticated phased arrays, driven by a local intelligence. Because of the price reduction of the phase components and the microprocessing capability up to the highest frequency bands (in the antenna Rx mode), it is well within the next satellite generation to consider this anti-jamming technique for a governmental satellite system for security uses (National Bureau of Standards, 1977; Multimidea.net, n.d.).

Network Security

At present, most satellite networks for wideband services provide such an interface. To ensure security for IP via satellite, a number of service requirements are identified (Noubir & von Allmen, 1999): confidentiality (protection from passive attacks, unauthorized release of message content, and traffic flow analysis), authentication (the message sender is really who he claims to be), integrity (the message content is not modified), nonrepudiation

(sender or receiver does not deny a transmitted message), access control (limit access), and key management and exchange (negotiate security keys between communication entities). Moreover, as concerns protection of the information content at network level, security can be ensured implementing the IPsec mechanism, which is a protocol operating between the IP layer and the TCP layer, as reported in Kent and Atkinson (1998c). In this way security is independent on upper layer protocols, traffic rerouting and network configuration modifications are preserved, and both real-time and non-real-time applications are protected. In particular, two protocols are proposed: authentication header (AH; Kent & Atkinson, 1998a) for integrity without confidentiality, and encapsulating security payload (ESP; Kent & Atkinson, 1998b) for confidentiality with optional integrity and authentication. In addition, two modes of operating are defined: transport mode (to protect upper-layer protocols) and tunnel mode (to protect the whole datagram). The former applies to host-to-host authentication, the latter to gateway-to-gateway and host-to-gateway, which is useful in case the same entity owns two or more private networks connected through the public Internet. As far as IPsec is concerned, the IP datagram is composed of three parts: IP header, TCP header, and user data. In transport mode, an IPsec header (AH or ESP) is inserted between the IP header and the TCP header. In tunnel mode, the whole IP packet is encapsulated in a new IPsec packet (a new IP header followed by an AH or ESP header). In both cases, the IP payload, composed of TCP header and user data, results in one indivisible protected unit. The keys used to encrypt and authenticate must be known only at the two end users. The intermediate nodes (routers) are only allowed to forward packets based on routing tables.

Definitively, all these mechanisms require keeping the end-to-end semantic. Thus, as long as the adopted upper-layer protocol does not introduce a violation of this concept, no particular problem arises in implementing IPsec in satellite networks, excluding the delay in key distribution. Nevertheless, to speed up the TCP process, modification to the standard mechanism must be introduced, as mentioned previously. When such modifications concerning the flow control mechanism, involve only the two end hosts, or involve the intermediate routers but do not require access to TCP data encapsulated in the IP packet, no particular incompatibility arises. In contrast, if splitting or some PEP or network address translator (NAT) options are implemented, as in most of the commercial systems for wideband services, the end-to-end semantic is violated. Thus, compatibility with standard IPsec implementation drops. In fact, relevant information to perform PEP mechanisms is present in the TCP header. In particular, the flow identification number (identifying source and destination port numbers) and the sequence numbers (used to match acknowledgements with the data segments) are necessary to be accessed for PEP operations. Both ESP protocol (encrypting TCP header inside the ESP header) and AH protocol (not allowing modification to ACK stream) are incompatible with PEP implementation.

To overcome these problems, a number of approaches can be adopted (Zhang & Singh, 2000), such as replacing

IPSec with a transport-layer security mechanism, tunneling one security protocol within another, using transport-friendly ESP format, and splitting IPSec into as many segments as the whole path is splinted, but each has its own limitations.

Another approach named multilayer IPSec (ML-IPSec) has been proposed. It is based on partitioning the IP packet into different parts and applying a different kind of protection to each. For example, two zones can be identified: TCP header and TCP data. The former can use a protection scheme with key shared among the source, the destination and a certain number of intermediate nodes, where PEP is implemented. The latter can use classical end-to-end protection with keys shared only between the source and destination hosts. This approach, other than showing full compatibility with standard IPSec, adds not too much complexity and performs very promisingly. Definitely, it looks the right solution to provide security; in fact, we can exploit TCP enhancement mechanisms (for example accelerators), largely utilized in commercial systems, and ensuring security applying standard algorithms, such as IPSec, as well. In addition, when multicast connectivity is exploited, which takes advantage of the already underlined suitability of satellite communications, additional problems arise and must be resolved (Howarth, Iyengar, Sun, & Chuickshank, 2004). As a matter of fact, multicast security is in general more complex than unicast security, and even more costly and performs less well if applied to satellite. In fact, the rekeying procedure must be performed for a number of reasons: regularly (every few seconds or minutes) to avoid cryptanalysis of traffic, on demand if the key may be compromised, when a new user join the group to avoid the possibility that previous traffic may be decrypted, and when a member leaves the group to avoid the possibility that future traffic may be decrypted. Because the key distribution is performed through the satellite, the cost of the operation can be high because the bandwidth is expensive and the delay is meaningful, especially if the multicast group membership updates frequently. To limit costs, efficient algorithm must be implemented.

Transport-Layer Security

It is also possible to provide security at the transport layer. In this case, the IP header (addresses) is not protected and therefore traffic analysis is possible, but key management is simplified. Two solutions are applicable: TLS (transport layer security) and SRTP (secure real-time transport protocol).

TLS is designed to provide privacy and is composed of two layers: TLS record protocol and TLS handshake protocol. The former works on top of TCP (and therefore is not useful for UDP connections, largely used for multicast and real-time traffic), which ensures privacy and reliability. Symmetric cryptography is used (DES or AES). The latter provides connection security at the authentication level before starting transmission of application data.

SRTP is a profile of real-time transport protocol (RTP). It provides confidentiality, message authentication, and replay protection.

Security Provision to Other Networks

To guarantee proper working conditions for several kind of terrestrial telecommunication networks, the ability to get localization information (especially for mobile services and search and rescue applications) and synchronization information is particularly relevant.

Satellites are actually used as a means to provide synchronization signals to terrestrial telecommunication networks (for example, cellular that is based on the IS-95 standard) and to support security by supplying the localization information of the network users. GPS Constellation and the forthcoming Galileo make this information available.

The GPS is a worldwide radio-navigation system utilizing a constellation of 24 satellites and their ground stations (Dana, 1994; European Space Agency, 2004). GPS uses these “man-made stars” as reference points to calculate accurate positions on the order of meters. In fact, with advanced forms of GPS, it is possible to get measurements accurate to a few centimeters.

GPS and, in a short while, Galileo work in five logical steps.

- “Triangulation” from satellites is the basic principle.
- To triangulate, a GPS receiver measures distance (called pseudo-range) using the travel time of radio signals;
- To measure travel time, GPS needs, on one side, a reasonably accurate internal clock and, on the other side, one additional unknown (the satellite time), which it achieves by solving the equation system;
- Along with distance, the satellite positions, which are communicated to the receiver in space, are used;
- Finally, a correction is needed for any delays the signal experiences as it travels through the atmosphere.

The possible use of GPS and Galileo for supporting the authentication procedure of the correspondent, delivering the relative position with a high degree of accuracy to the security authority, has the potential to increase the security level of the overall system.

SECURE SYSTEMS AND APPLICATIONS IMPLEMENTED USING SATELLITES

It is worth briefly presenting and describing some not exhaustive example of commercial secure services provided via satellite.

Euteltracs is the first European commercial mobile satellite service. Based on the Omnitrac project in United States, it provides message service, bidirectional two-way service, and localization. The system architecture is composed of five elements:

- user terminal, which exchanges messages with the service provider’s network management center (SNMC) that is receiving the position;
- the SNMC connected to the hub station;
- the hub station, which consists of two front-end antennas and HTF (hub terminal facilities) to monitor, to process, and to control traffic between SNMC and the mobile terminals;

Table 2 Satellite Use Summary for Military Applications

Satellite Systems	Mission
Defense support program	Missile warning
Global positioning system (GPS) Galileo	Navigation
Nuclear detonation detection system	Nuclear detonation detection
Meteorological satellites	Weather and environmental monitoring
Defense satellite communications system:	Communications:
EHF band	Army fixed and mobile communications (EHF, SHF, UHF)
SHF band	Maritime communications (EHF, SHF, UHF)
UHF band	Air communications (SHF, UHF)

- the space segment; and
- the MCT (mobile communication terminal) mounted on the vehicle.

Euteltracs is at present used to provide secure services to several private police companies by remotely authorizing the opening of doors of vans used to carry money and jewels, thereby preventing and discouraging robberies.

Satellite Security Systems (S3) provides a number of secure services through the use of satellites (Satellite Security Systems, n.d.). More specifically, they combine the use of telecommunication infrastructures (ReFlex by Motorola) and positioning systems (GPS).

In particular, S3 offers these products:

- First Responder Alert and Monitoring System (FRAMSM), which provides an end-to-end solution for monitoring, control, and decision support;
- FleetGuard™, aiming at fleet management and localization;
- GlobalGuard™ for fixed-point monitoring and control;
- GlobalGuard LE Systems™ for law enforcement, which are used in a variety of applications to track and monitor activities of suspect vehicles, cargo trailers, or any other asset that could be utilized in criminal activities; and
- IONIT School Transportation to enable school bus tracking and monitoring (based on GlobalGuard).

ELEMENTS ON MILITARY SATELLITES

Communications is vital to the modern military establishment. In particular, space systems are an integral part of the overall military forces. In fact, military satellites on the geostationary orbit have been launched by many nations (United States; France; United Kingdom; former U.S.S.R., now Russia; and Italy) and international organizations such as NATO (North Atlantic Treaty Organization).

Satellites permit direct communications with units on the battlefield. Lightweight mobile terminals can be erected in a matter of hours, thereby keeping advancing troops in constant contact with higher authorities. Today, the soldier in the field can use satellite links to establish direct and instantaneous communication with the national command authorities.
